Some ectopic pregnancies resolve by resorption or by tubal abortion, obviating the need for medical or surgical therapy (221–225). The proportion of ectopic pregnancies that resolve spontaneously and the reason they do so while others do not are unknown. There are no specific criteria for patient selection that predict successful outcome after spontaneous resolution. A falling hCG level is the most common indicator used, but tubal rupture can occur even with falling hCG levels. Patients with low initial levels of β-hCG are generally the best candidates for expectant management, and there is a reported 88% success rate of spontaneous remission with an initial β-hCG level less than 200 mU/mL (226). These patients should be followed with serial β-hCG levels and active management initiated if these levels plateau or rise or the patient develops abdominal pain or signs of tubal rupture (190).

Persistent Trophoblastic Tissue

Persistent ectopic pregnancy occurs when a patient underwent conservative surgery (e.g., salpingostomy, fimbrial expression) and viable trophoblastic tissue remains. Histologically, there is no identifiable embryo, the implantation usually is medial to the previous tubal incision, and residual chorionic villi are confined to the tubal muscularis. Peritoneal trophoblastic tissue implants may be responsible for persistence (182,183,227–230).

The incidence of persistent ectopic pregnancy increased with the increased use of surgery that conserves the tubes. Persistence is diagnosed when the β-hCG levels plateau after conservative surgery. Risk factors for persistent ectopic pregnancy are based on the type of surgical procedure, the initial β-hCG level, the duration of amenorrhea, and the size of the ectopic pregnancy. Patients treated with laparoscopic salpingostomy have a higher rate of persistent ectopic pregnancies compared to those treated with salpingostomy at the time of a laparotomy, with an incidence of persistence after laparoscopic linear salpingostomy ranging from 4% to 15% (49,177). Other risk factors for persistent ectopic pregnancies include very early gestations (amenorrhea less than 7 weeks' duration), ectopic pregnancies less than 2 cm, and those with high starting β-hCG levels (183,185,229).

Persistent ectopic pregnancy can be treated surgically or medically; surgical therapy consists of either repeat salpingostomy or, more commonly, salpingectomy. Methotrexate offers an alternative to patients who are hemodynamically stable at the time of diagnosis. Methotrexate may be the treatment of choice because the persistent trophoblastic tissue may not be confined to the tube and, therefore, not readily identifiable during repeat surgical exploration (231–233).
Chronic Ectopic Pregnancy

Chronic ectopic pregnancy is a condition in which the pregnancy does not completely resorb during expectant management. The condition arises when there is persistence of the chorionic villi with bleeding into the tubal wall, which is distended slowly and does not rupture. It may arise from chronic bleeding from the fimbriated end of the fallopian tube with subsequent tamponade. In a series of 50 patients with a chronic ectopic pregnancy, pain was present in 86%, vaginal bleeding was present in 68%, and both symptoms were present in 58% (234). Ninety percent of the patients had amenorrhea ranging from 5 to 16 weeks (mean, 9.6 weeks). Most patients develop a pelvic mass that usually is symptomatic. The β-hCG level usually is low but may be absent; ultrasonography may be helpful in the diagnosis; rarely, bowel involvement or ureteral compression or obstruction exists (234,235).

This condition is treated surgically with removal of the affected tube. Often, the ovary must be removed because there is inflammation with subsequent adhesion development. A hematoma may be present secondary to chronic bleeding.

Nontubal Ectopic Pregnancy

Cervical Pregnancy

The incidence of cervical pregnancy in the United States ranges from 1 in 2,400 to 1 in 50,000 pregnancies and accounts for less than 1% of ectopic pregnancies (236,237). The cause of cervical ectopic pregnancies is unknown and the rare occurrence prevents identification of known risk factors. The incidence does appear to be higher with in vitro fertilization procedures, accounting for 3.7% of IVF-related ectopic pregnancies (238).

The clinical criteria for diagnosing a cervical pregnancy include the following findings (239):

- Uterus is smaller than the surrounding distended cervix;
- External os may be open;
- Visible cervical lesion often blue or purple in color;
- Profuse bleeding on manipulation of cervix.

Patients classically present with painless vaginal bleeding, but reports of associated cramping and pain are published (240).

When a cervical pregnancy is suspected, imaging studies are useful in confirming the diagnosis. Ultrasonographic diagnostic criteria are described that are helpful in differentiating a true cervical pregnancy from an ongoing spontaneous abortion (Table 20.5). MRI of the pelvis is used in this situation (241). Other potential diagnoses that must be differentiated from cervical pregnancy include cervical carcinoma, cervical or prolapsed submucousal leiomyomas, trophoblastic tumor, placenta previa, and low-lying placenta.
Table 20.5 Ultrasound Criteria for Cervical Pregnancy

- Gestational sac or placental tissue visualized within the cervix
- Cardiac motion noted below the level of the internal os
- No intrauterine pregnancy
- Hourglass uterine shape with ballooned cervical canal
- No movement of the sac with pressure from transvaginal probe (i.e., no “sliding sign” that is typically seen with incomplete abortions)
- Closed internal os

Management of cervical ectopic pregnancies includes medical treatment with methotrexate and surgical dilation and curettage. The ideal regimen for medical management is unknown and success is reported with both the single- and multidose regimens, as previously described. More advanced gestations, especially with fetal cardiac activity, may require a combination of multidose methotrexate and intra-amniotic/intrafetal injection of PCl. These injections require skill to avoid rupture of membranes during the procedure (240). As with tubal ectopic pregnancies, medical management is appropriate only for those patients who are hemodynamically stable.

If the patient and physician elect to proceed with surgical management, the preoperative preparation should include blood typing and cross-matching, establishment of intravenous access, and detailed informed consent. This consent should include the possibility of hemorrhage that may require transfusion or hysterectomy.

The diagnosis may not be suspected until the patient is undergoing suction curettage for a presumed incomplete abortion and hemorrhage occurs. In some cases, bleeding is light, whereas in others, there is hemorrhage. Various techniques that can be used to control bleeding include uterine packing, lateral cervical suture placement to ligate the lateral cervical vessels, placement of a cerclage, and insertion of an intracervical 30-mL Foley catheter in an attempt to tamponade the bleeding. Alternatively, angiographic artery embolization can be used. If laparotomy is required, an attempt can be made to ligate the uterine or internal iliac arteries (242–244). When none of these methods is successful, hysterectomy is required.

Ovarian Pregnancy

A pregnancy confined to the ovary accounts for up to 3% of all ectopic pregnancies and is the most common type of nontubal ectopic pregnancy (1). The incidence ranges from 1 in 40,000 to 1 in 7,000 deliveries (245,246). The diagnostic
Criteria were described in 1878 by Spiegelberg (Table 20.6) (247). Unlike tubal gestation, ovarian pregnancy is associated with neither PID nor infertility. The risk of ovarian ectopic pregnancies in patients using IUDs is controversial.

**Table 20.6 Criteria for Ovarian Pregnancy Diagnosis**

- The fallopian tube on the affected side must be intact.
- The fetal sac must occupy the position of the ovary.
- The ovary must be connected to the uterus by the ovarian ligament.
- Ovarian tissue must be located in the sac wall.

Patients have symptoms similar to those of ectopic pregnancies in other sites. Misdiagnosis is common because it is confused with a ruptured corpus luteum in up to 75% of cases (245). As with other types of ectopic pregnancy, an ovarian pregnancy was reported after hysterectomy (248). Ultrasonography makes preoperative diagnosis possible in some cases (249).

The treatment of ovarian pregnancy has changed. Whereas oophorectomy was advocated in the past, **ovarian cystectomy and/or wedge resection is now utilized with success** (250–252). Successful treatment with methotrexate is reported (253–255).

**Abdominal Pregnancy**

Abdominal pregnancies are classified as primary and secondary. Listed in Table 20.7 are criteria for classifying a primary abdominal pregnancy. Secondary abdominal pregnancies are the most common and result from tubal abortion or rupture or, less often, from subsequent implantation within the abdomen after uterine rupture. The incidence of abdominal pregnancy varies from 1 in 372 to 1 in 9,714 live births and accounts for 1.4% of ectopic pregnancies (1,256). Risk factors for abdominal pregnancy include PID, multiparity, endometriosis, assisted reproductive techniques, and tubal damage (257,258). **Abdominal pregnancy is associated with high morbidity and mortality, with the risk for death seven to eight times greater than from tubal ectopic pregnancy and 50 times greater than from intrauterine pregnancy** (256). There are scattered reports of term abdominal pregnancies. When this occurs, perinatal morbidity and mortality are high, usually as a result of growth restriction and congenital anomalies such as fetal pulmonary hypoplasia, pressure deformities, and facial and limb asymmetry. The incidence of congenital anomalies ranges from 20% to 40% (259,260).

**Table 20.7 Studdiford’s Criteria for Diagnosis of Primary Abdominal Pregnancy**

- Presence of normal tubes and ovaries with no evidence of recent or past pregnancy
No evidence of uteroplacental fistula

The presence of a pregnancy related exclusively to the peritoneal surface and early enough to eliminate the possibility of secondary implantation after primary tubal nidation.

The presentation of patients with an abdominal pregnancy varies and depends on the gestational age. In the first and early second trimesters, the symptoms may be the same as with tubal ectopic gestation; in advanced abdominal pregnancy, the clinical presentation is more variable. The patient may report painful fetal movement, fetal movements high in the abdomen, or sudden cessation of movements. Physical examination may disclose persistent abnormal fetal positioning, abdominal tenderness, a displaced uterine cervix, easy palpation of fetal parts, and palpation of the uterus separate from the gestation. The diagnosis may be suspected when there are no uterine contractions after oxytocin infusion. Other diagnostic aids include abdominal radiography, abdominal ultrasonography, CT, and MRI (261–263).

Because the pregnancy can continue to term, the potential maternal morbidity and mortality are very high. As a result, **surgical intervention is recommended when an abdominal pregnancy is diagnosed.** At surgery, the placenta can be removed if its vascular supply can be identified and ligated, but hemorrhage can occur, requiring abdominal packing that is left in place and removed after 24 to 48 hours. Angiographic arterial embolization was described (264). If the vascular supply cannot be identified, the cord is ligated near the placental base, and the placenta is left in place. Placental involution can be monitored using serial ultrasonography and assessment of β-hCG levels. Potential complications of leaving the placenta in place include bowel obstruction, fistula formation, and sepsis as the tissue degenerates. There are concerns regarding the use of methotrexate treatment in abdominal pregnancies. Specifically, there is theoretically an increased risk of infection and sepsis resulting from the rapid tissue necrosis that occurs following methotrexate administration (265). There are reports of successful treatment of abdominal pregnancies with methotrexate in patients not considered to be optimal surgical candidates (266).

### Interstitial Pregnancy

**Interstitial pregnancies represent about 2.4% of ectopic pregnancies** (1). This section of the fallopian tube is relatively thick with an increased capacity to expand prior to rupture. This ability may allow these types of ectopic pregnancies to remain asymptomatic for 7 to 16 weeks of gestation (267). Late presentations are rare and these patients typically present between 6 to 8 weeks of gestation, similar to other types of ectopic pregnancies (268,269). The diagnosis of an interstitial ectopic pregnancy can be difficult, because this area has a relatively high level of vascular supply. Interstitial pregnancies represent a disproportionately large percentage of fatalities from ectopic pregnancy with a 2.5% mortality rate (268,270).

Treatment classically was a cornual resection by laparotomy, but early detection allows
for a more conservative management approach in hemodynamically stable patients without evidence of rupture. Medical management with methotrexate is well described, with both the single- and multidose regimens. Approximately 10% to 20% of patients treated medically will ultimately require surgery and close follow-up, as is warranted with all medically managed ectopic pregnancies (271).

Although cornual wedge resection by laparotomy is an acceptable surgical option, minimally invasive techniques were described, including cornual excision, minicornual excision, and cornuostomy. Laparoscopic approaches are more widely used and are dependent on surgical skill. Transcervical suction evacuation under laparoscopic or ultrasound guidance is reported (271). The appropriate surgical technique and approach depends on the individual patient presentation and the surgeon’s expertise.

**Interligamentous Pregnancy**

Interligamentous pregnancy is a rare form of ectopic pregnancy that occurs in about 1 of 300 ectopic pregnancies (272). An interligamentous pregnancy usually results from trophoblastic penetration of a tubal pregnancy through the tubal serosa and into the mesosalpinx, with secondary implantation between the leaves of the broad ligament. It can occur if a uterine fistula develops between the endometrial cavity and the retroperitoneal space. As in abdominal pregnancy, with interligamentous pregnancy the placenta may be adherent to the uterus, bladder, and pelvic side walls. If possible, the placenta should be removed; when this is not possible, it can be left in situ and allowed to resorb. Cases of live birth are reported with this type ectopic gestation (272).

**Heterotropic Pregnancy**

Heterotropic pregnancy occurs when intrauterine and ectopic pregnancies coexist. The reported incidence varies widely from 1 in 100 to 1 in 30,000 pregnancies (273). Patients who underwent assisted reproduction have a much higher incidence of heterotrophic pregnancy than those who have a spontaneous conception (274,275). An intrauterine pregnancy is seen during ultrasonography examination, and an extrauterine pregnancy may be overlooked, delaying diagnosis. Serial β-hCG levels are not helpful because the intrauterine pregnancy causes the β-hCG level to rise appropriately.

The ectopic pregnancy is treated surgically if the intrauterine pregnancy is desired. When the ectopic pregnancy is removed, the intrauterine pregnancy continues in most patients. The rate of spontaneous abortion is higher with approximately one in three ending in miscarriage (276,277). It may be possible to treat the ectopic pregnancy using nonchemotherapeutic medical treatment, such as KCl, by transvaginal or laparoscopically directed injection; however, a reported 55% may require additional surgical treatment (278).

**Multiple Ectopic Pregnancies**
Twin or multiple ectopic gestations occur less frequently than heterotropic gestations and may appear in a variety of locations and combinations. Multiple ectopic pregnancies are thought to be rare, but with the advent of assisted reproductive technologies the incidence appears to be rising. A recent review of bilateral tubal pregnancies reported 242 cases between 1918 and 2007, with 42 cases in the past 10 years alone. Fifty percent of these twin tubal pregnancies were associated with assisted reproductive technologies (279). Another review of 163 cases of tubal ectopic pregnancies had a reported rate of twin tubal pregnancies of 2.4% (280). Although most reports are confined to twin tubal gestations, ovarian, interstitial, and abdominal twin pregnancies were reported. Twin and triplet gestations were reported following partial salpingectomy and IVF (281,282). Management is similar to that of other types of ectopic pregnancy and is somewhat dependent on the location of the pregnancy.

**Pregnancy after Hysterectomy**

The most unusual form of ectopic pregnancy is one that occurs after vaginal or abdominal hysterectomy (283,284). Such a pregnancy may occur after supracervical hysterectomy because the patient has a cervical canal that may provide intraperitoneal access. Pregnancy may occur in the perioperative period with implantation of the already fertilized ovum in the fallopian tube. Pregnancy after total hysterectomy probably occurs secondary to a vaginal mucosal defect that allows sperm into the abdominal cavity.

Early detection of breast cancer is improved by risk assessment, clinical breast examination, screening mammography, and magnetic resonance imaging in selected patients.

Triple-test concordance requires agreement between results of clinical breast examination, breast imaging, and tissue diagnosis. In the absence of concordance, further diagnostic intervention is required.

The most common benign breast problems include fibrocystic changes and mastalgia. These problems are usually best treated by reassurance. Pharamceutic agents are available but have side effects that usually are not well tolerated.

Histologic differences exist between fibroadenomas and phyllodes tumors; phyllodes tumors require excision, whereas small asymptomatic fibroadenomas can be observed if the diagnosis is confirmed by histologic or cytologic assessment and there is no evidence of growth.

Spontaneous, unilateral, bloody discharge requires histologic evaluation to exclude malignancy, but symptoms usually are caused by a benign process such as intraductal papilloma or duct ectasia.

Breast abscesses are managed with fine needle aspiration and antibiotics; the use of incision and drainage is reserved for recurrence.

Benign breast diseases are among the most common diagnoses that the busy obstetrician-gynecologist will see in practice. An ability to accurately and promptly diagnose both benign and malignant breast diseases is within the purview of the practicing gynecologist (1). Benign breast disease is a complex entity with a range of physiologic changes and clinical manifestations that have an impact on a woman’s health independent of breast cancer risk (2).
Detection

History

Evaluation of a new breast symptom begins with assessment of symptoms based on a thorough clinical history (3). The history should include questions regarding current symptoms, duration of the condition, fluctuation of the signs and symptoms, and factors that aggravate or relieve the symptom. **Assessment of breast problems should focus on the following points:**

- **Nipple discharge**
- Characteristics of discharge (spontaneous or nonspontaneous, appearance, unilateral or bilateral, single or multiple duct involvement)
- **Breast mass** (size and change in size, density, or texture)
- **Breast pain** (cyclic versus continuous)
- Association of symptoms with menstrual cycle
- Change in breast shape, size, or texture
- Previous breast biopsies
- History of breast trauma

The patient should be questioned about the following risk factors for breast cancer (see Chapter 40 for more details):

- **Sex**
- Increasing age (approximately 50% of breast cancers occur after age 65)
- Age of menarche less than 12 years
- Nulliparity or first pregnancy at greater than 30 years of age
- Late menopause (older than 55 years of age)
- Family history of breast cancer (especially premenopausal or bilateral disease)
- Number of first-degree relatives with breast cancer and their ages when diagnosed
- Family history of male breast cancer
- Inherited conditions associated with a high risk for breast cancer, including BRCA1 and BRCA2 genes, Li-Fraumeni syndrome, Cowden’s disease, ataxia telangiectasia syndrome, and Peutz-Jeghers syndrome
- Other malignancies (ovary, colon, and prostate)
- Pathology of previous breast biopsy showing atypia or lobular or ductal carcinoma in situ
- Hormone therapy
- Alcohol consumption
- Postmenopausal weight gain
- Personal history of breast cancer

Breast cancer risk can be determined by the **Gail Risk assessment model**, which is
available electronically (4). **The Gail Risk assessment model calculates risk based on patient race, age, age of menarche, age of first live birth, number of first-degree relatives with breast cancer, number of previous breast biopsies, and presence of atypia on the biopsy.**

It is important to obtain a current list of medications used, including hormone therapy and herbal medications such as phytoestrogens. The gestational history should take into consideration the possibility that the patient may be pregnant or has a prior history of miscarriage or abortion. A personal history of exposure to radiation, especially in the treatment of childhood malignancies, is associated with a higher incidence of developing breast cancer (5). The goal of breast evaluation is to determine clearly whether the symptom represents a benign breast condition or may be indicative of a neoplastic process.
Physical Examination

Breast tumors, particularly cancerous ones, usually are asymptomatic and are discovered by the patient or through physical examination or screening mammography. Typically, the breast changes slightly during the menstrual cycle. During the premenstrual phase, most women have increased innocuous nodularity and mild engorgement of the breast. Rarely these characteristics can obscure an underlying lesion and make examination difficult. Findings should be carefully documented in the medical record to serve as a baseline for future reference.

Inspection

Inspection is performed initially while the patient is seated comfortably with her arms relaxed at her sides. The breasts are compared for symmetry, contour, and skin appearance. Edema or erythema is identified easily, and skin dimpling or nipple retraction is shown by having the patient raise her arms above her head and then press her hands on her hips, thereby contracting the pectoralis muscles (Fig. 21.1). Palpable and even nonpalpable tumors that distort Cooper's ligaments may lead to skin dimpling with these maneuvers.

Figure 21.1 Raising the arm reveals retraction of the skin of the lower outer quadrant caused by a small palpable carcinoma. (From Giuliano AE. Breast disease. In: Berek JS, Hacker NF, eds. Practical gynecologic oncology. 4th ed. Baltimore, MD: Lippincott Williams & Wilkins, 2005:628, with permission.)
Palpation

While the patient is seated, each breast should be palpated methodically. Some physicians recommend palpating the breast in long strips, but the exact palpation technique used is probably not as important as the thoroughness of its application over the entire breast. One very effective method is to palpate the breast in enlarging concentric circles until the entire breast is covered. A pendulous breast can be palpated by placing one hand between the breast and the chest wall and gently palpating the breast between both examining hands. The axillary and supraclavicular areas should be palpated for enlarged lymph nodes. The entire axilla, the upper outer quadrant of the breast, and the axillary tail of Spence are palpated for possible masses. While the patient is supine with one arm over her head, the ipsilateral breast is again methodically palpated from the clavicle to the costal margin and from the sternum to the latissimus dorsi laterally. If the breast is large, a pillow or towel may be placed beneath the scapula to elevate the side being examined; otherwise, the breast tends to fall to the side, making palpation of the lateral hemisphere more difficult. The major features to be identified on palpation of the breast are temperature, texture and thickness of skin, generalized or focal tenderness, nodularity, density, asymmetry, dominant masses, and nipple discharge. Most premenopausal patients have normally
nodular breast parenchyma. The nodularity is diffuse but predominantly in the upper outer quadrants, where there is more breast tissue. These benign parenchymal nodules are small, similar in size, and indistinct. By comparison, breast cancer usually occurs in the form of a nontender, firm mass with irregular margins. A cancerous mass feels distinctly different from the surrounding nodularity. A malignant mass may be fixed to the skin or to the underlying fascia. A suspicious mass is usually unilateral. Similar findings in both breasts are unlikely to represent malignant disease (6).
Breast Self-Examination

There is controversy about recommending breast self-examination (BSE). There is no evidence that doing BSE improves survival rates from breast cancer (7). Staunch opponents of BSE argue that it doubles a woman’s risk of undergoing a breast biopsy for benign pathology (8). BSE increases breast health awareness and helps promote early detection of cancer (9–11). Most breast cancers are detected by women themselves (48%), followed by breast imaging (41%), and by physician clinical examination in only 11% (12). Although young women have a low incidence of breast cancer, it is important to teach BSE early so it becomes habitual. Organizations such as the American Cancer Society sponsor courses in BSE. Reassurance, support, and patient education may encourage women to overcome psychological barriers to routine BSE (13). Such instruction is available through electronic resources (14).

The following seven “P”s represent the essential components of breast examination:

- **Positions**
- **Palpation**
- **Pads of fingers for palpation**
- **Pressure**
- **Perimeter**
- **Pattern of search**
- **Patient education**

The woman should inspect her breasts while standing or sitting before a mirror, looking for any asymmetry, skin dimpling, or nipple retraction. Elevating her arms over her head or pressing her hands against her hips to contract the pectoralis muscles will highlight any skin dimpling. Finally, the woman should examine her breasts while bending over and leaning forward. While standing or sitting, she should carefully palpate her breasts with the fingers of the opposite hand. She should lie down and again palpate each quadrant of the breast as well as the axilla using the pads of the three middle fingers with three pressures—light, medium, and deep—covering the entire breast from the clavicle to the inframammary fold, from sternum to latissimus dorsi laterally. The area within the perimeter of the breast should be palpated, preferably using an up-and-down method called vertical stripe, rather than the concentric circular or radial methods, in which the edges of the breast tissue often are omitted. Many women feel anxious about performing breast examination. The examination may be performed while showering; soap and water may increase the sensitivity of palpation, and the privacy of the shower may provide a less anxiety-provoking environment.

It is helpful for all women to examine their breasts at the same time each month to develop a routine. Premenopausal women should examine their breasts monthly 7 to 10 days after the onset of the menstrual cycle. For postmenopausal women, selection of a specific calendar date is a helpful way
to remember to perform a monthly BSE. Women should be instructed to report any abnormalities or changes to their physicians. If the physician cannot confirm the patient’s findings, the examination should be repeated in 1 month or after her next menstrual period.
Mammography

Screen-film mammography was considered the best method for imaging the breast (15). Full-field digital mammography, which records mammographic images on a computer, is a modification of screen-film mammography (16). Some advantages of digital mammography include lower radiation exposure, ability to manipulate a computerized image for optimal viewing, and access to distance consultations through telemammography (17). Studies comparing the sensitivity of full-field digital mammography with screen-film mammography in detecting cancer had mixed results. The Digital Mammographic Imaging Screening Trial (DMIST) consisted of 49,528 asymptomatic women presenting for screening mammography, who underwent both digital and film mammography. Results suggested that while the overall accuracy of digital and film mammography for screening breast cancer is similar, digital mammography may be more accurate in women under the age of 50 years, women with radiographically dense breast, and premenopausal or perimenopausal women (18).

Slow-growing breast cancers can be identified by mammography at least 2 years before the mass reaches a size detectable by palpation. These tumors have a less aggressive biologic behavior than interval breast cancers (19–21). Mammography is the only reproducible method of detecting nonpalpable breast cancer, but its use depends on the availability of state-of-the-art equipment and a dedicated breast radiologist.

Compression of the breast is necessary to obtain good images, and patients should be forewarned that breast compression is uncomfortable. With good technique and well-maintained modern equipment, exposure to radiation can be limited. Full-field digital mammography (FFDM) has a 22% lower mean glandular radiation dose than film-screen mammography per acquired view. FFDM delivers 1.86 mGy average breast radiation dose per view compared to 2.37 mGy for film screen (22).

Indications for Mammography

The indications for mammography are as follows:

To screen, at regular intervals, women who are at high risk for developing breast cancer. About one-third of the abnormalities detected on screening mammography prove malignant when biopsy is performed (23).

To evaluate a questionable or ill-defined breast mass or other suspicious change in the breast that is detected by clinical breast examination.

To establish a baseline breast mammogram and reevaluate patients at yearly intervals to diagnose a potentially curable breast cancer before it has been diagnosed clinically.

To search for occult breast cancer in a patient with metastatic disease in axillary nodes or elsewhere from an unknown primary origin.
To screen for unsuspected cancer before cosmetic operations or biopsy of a mass.
To monitor breast cancer patients who were treated with a breast-conserving surgery and radiation.

**Screening**

Screening programs to evaluate asymptomatic, healthy women combine physical examination with mammographic screening to identify breast abnormalities. During the past 30 years, there was an increase in the use of mammography, mammographic screening, and public awareness of breast health care. The cancer detection rate for screening mammography is 5 per 1,000 screening examinations (24). The cancer detection rate is 11-fold higher, at 55 per 1,000 examinations, when breast imaging is performed for a specific finding (i.e., diagnostic imaging) (24). Of seven randomized mammographic screening trials performed, five demonstrated a reduction in overall mortality from breast cancer screening programs (25–32). A study from the Rhode Island Cancer Registry indicates that the institution of population-based breast cancer screening programs can result in the reduction in the median tumor size at initial detection from 2.0 to 1.5 cm, which is associated with a 25% reduction in mortality (33). A study from the Norwegian breast-cancer screening program was associated with a reduction in the rate of death from breast cancer, but the screening itself accounted for only about a third of total reduction (30). Detecting breast cancer before it spreads to the axillary nodes greatly increases the chance of survival; about 85% of women with such cancer will survive at least 5 years (31,34). Because breast cancer presents first as local disease, screening mammography for breast cancer in asymptomatic women can detect small tumors and offer a better prognosis. These tumors had less opportunity to metastasize regionally or systemically; thus women have more options for treatment with reduced toxicity.

The American Cancer Society published an extensive review of the benefits, limitations, and potential harms of screening mammography (35). It addresses the role of physical examination, discusses screening in older and high-risk women, and reviews the role of newer technologies. A summary of the guidelines recommends that women of average risk for breast cancer begin mammographic screening at age 40. The rationale for beginning mammographic screening at age 40 is a 24% reduction in mortality in screened populations (28). For women in their 20s and 30s, a clinical breast examination is suggested at least every 3 years, and preferably annually, as part of a well-woman examination. For women older than age 40 years, annual clinical breast examination and mammography are recommended. For older women, recommendations for mammographic screening may be individualized based on the presence of any comorbidities. Chronologic age alone should not be considered a contraindication to mammographic screening as long as a woman is in reasonable health and would be a candidate for breast cancer surgery (35). The American Geriatrics Society recommends annual or at least biennial mammography for women up to age
75 years, and after that age, every 2 to 3 years if the woman has a life expectancy of more than 4 years (36). The reasons for liberalization of the screening interval recommendations for older women include improved biology profile, slower growth rate, and lower risk for recurrence (37–41). The natural history of the disease in older women must be balanced against life expectancy as a function of overall health (42). For high-risk women, consideration can be given to earlier initiation of screening (5 to 10 years earlier than the age of the index case) and shorter intervals between screening, and the use of additional imaging modalities such as breast ultrasonography and magnetic resonance imaging (MRI) with dedicated breast coils. No screening test is perfect, and false-negative imaging studies or benign clinical examinations may lead the patient to an erroneous sense of well-being only to be confronted later with a subsequent cancer. Likewise, a false-positive result can lead to significant anxiety and unnecessary biopsy.

Mammographic Abnormalities

A mammographic abnormality includes a mass (solid versus cystic), microcalcifications (benign, indeterminate, suspicious), asymmetric density, architectural distortion, and appearance of a new density. There are eight morphologic categories of mammographic abnormalities (43,44):

- **Calcification distribution**
- **Number of calcifications**
- **Description of calcifications**
- **Mass margin**
- **Shape of mass**
- **Density of mass**
- **Associated findings**
- **Special cases**

Mammographic abnormalities should be visible on two views, usually craniocaudal (CC) and mediolateral oblique (MLO). The lesion should triangulate to the same location on those two views. Calcifications can be macrocalcifications, which are coarse and usually represent benign degenerative breast conditions. Calcifications associated with breast cancer are clustered pleomorphic microcalcifications; typically five to eight or more calcifications are aggregated in one part of the breast (45). These calcifications may be associated with a mammographic mass density. A mass density may appear without evidence of calcifications. It can represent a cyst, benign tumor, or a malignancy. A malignant density usually has irregular or ill-defined borders and may lead to architectural distortion, which may be subtle and difficult to detect in a dense breast. Other mammographic findings suggesting breast cancer are architectural distortion, asymmetric density, skin thickening or retraction, or nipple retraction. Examples of mammographic abnormalities can be found in several electronic sources (46).

Mammographic Reports
The American College of Radiology recommended the **Breast Imaging Reporting and Data System (BI-RADS)** as a standardized scheme for describing mammographic lesions (47). In the BI-RADS system, there are six categories for mammographic findings (other than incomplete) (43,44).

0. Incomplete, needs further imaging
1. Negative
2. Benign finding
3. Probably benign, short-interval follow-up recommended
4. Suspicious finding and biopsy should be considered
5. Highly suggestive of malignancy and appropriate action should be undertaken
6. Known malignancy (a category that is often used for follow-up of a lesion that is undergoing neoadjuvant treatment)

The patient should be referred for tissue diagnosis if the report identifies a lesion as a category 4 or 5 (47). A category 0 indicates incomplete evaluation, and further diagnostic studies are required. Category 3 connotes a finding that is most likely benign; a short-interval follow-up is recommended, and breast examination by an expert should be considered.

**Correlation of Findings**

**Biopsy must be performed on patients with a dominant or suspicious mass despite absence of mammographic findings** (48). Mammography should be performed before biopsy so other suspicious areas can be noted and the contralateral breast can be checked (Fig. 21.2). Mammography is never a substitute for biopsy because it may not reveal clinical cancer, especially when it occurs in the dense breast tissue of young women with fibrocystic changes. The sensitivity of mammography is 75%, with a specificity of 92.3% depending on the patient’s age; breast density; use of hormone therapy; and the size, location, and mammographic appearance of the tumor (49). Mammography is less sensitive in young women with dense breast tissue than in older women, who tend to have fatty breasts, in which mammography can detect at least 90% of malignancies (50). Small tumors, particularly those without calcifications, are more difficult to detect, especially in women with dense breasts.

**Figure 21.2** Bilateral mammography shows the extent of breast carcinoma, illustrating the importance of bilateral mammography in the workup of a clinically apparent mass. (From Giuliano AE. Breast disease. In: Berek JS, Hacker NF, eds. Practical gynecologic oncology. 4th ed. Baltimore, MD: Lippincott Williams & Wilkins, 2005:630, with permission.)
Ultrasonography

Breast ultrasonography is used for focused scanning of a questionable finding or for evaluation of a mammographic finding (51). Reliable, portable, computer-enhanced ultrasonography with high-frequency transducers and improved imaging is available to evaluate and treat problems of the breast (52). It is a sensitive, minimally invasive technique that is used frequently to evaluate some breast symptoms, especially in younger women with dense breast tissue, but is dependent on the availability of a skilled ultrasonographer (53). Some lesions can be detected only with ultrasonography (54). It is the preferred modality to distinguish a solid from a cystic mass (51). Breast ultrasonography is not recommended for routine screening, but is being studied as a means to screen women with dense breast tissue (54). Ultrasonography has a higher false-positive rate than mammography (51,53–55).

Following are indications for breast ultrasonography:

Characterization:
- Palpable abnormality
- Ambiguous mammographic findings
- Silicone leak
- Mass in woman younger than 30 years, lactating, or pregnant

Guidance for interventional procedures

Possible role for additional imaging in high-risk individuals

Ultrasonography is useful in distinguishing benign from malignant lesions identified by mammography (56). Ultrasonography may be especially useful if the patient feels a mass, but the physician cannot detect an abnormality and the mammogram does not disclose one. It may identify cancers in the dense breast tissue of premenopausal women,
but it is usually used to distinguish a benign cyst from a solid tumor. Ultrasonography cannot reliably detect microcalcifications, and it is not as useful as mammography in assessing women with fatty breasts.

**Handheld or real-time ultrasonography is 95% to 100% accurate in differentiating solid masses from cysts** (57). This finding is of limited clinical value because a dominant mass should be evaluated by biopsy, and a cystic mass can be studied by needle aspiration, which is far less expensive than ultrasonography. If a lesion proves to be a simple cyst, no further evaluation is necessary. Rarely ultrasonography may identify a small cancer within a cyst, an intracystic carcinoma. These complex cysts warrant surgical biopsy.

**Magnetic Resonance Imaging**

Magnetic resonance imaging may be of value in assessing breast lesions of an indeterminate nature detected by clinical and mammographic examination or occurring in patients who have implants (58). Both MRI and positron emission tomography (PET) are used to identify occult lesions, and MRI is increasing in popularity as a means of imaging the breast (58–60). It tends to be highly sensitive but not specific, leading to biopsies of benign lesions. Image enhancement with gadolinium discriminates between benign and malignant lesions with varying degrees of accuracy.

Several roles are proposed for breast MRI. The lack of radiation exposure makes MRI theoretically an ideal method for screening of healthy women, but widespread use is not cost-effective. Focal asymmetry is usually benign but can represent a malignancy. MRI may help identify those patients with focal asymmetric areas who should undergo biopsy. A scar can easily be distinguished from recurrent tumor based on the evaluation and diminution of the scar over time. Some scars do not resolve rapidly and are confused with cancer or, more commonly, with recurrent cancer after breast-conserving surgery and whole breast irradiation. Ideally, such cases are evaluated with MRI, sometimes obviating the need for biopsy. MRI is extremely useful in identifying silicone released by ruptured breast implants in patients with augmented breasts (Fig. 21.3). In patients with implants, MRI with gadolinium may be performed to detect breast cancer even if silicone release is not suspected. There may be a role for **MRI in evaluation of specific conditions. It is used for the following indications:**

**Figure 21.3** Mammography shows implant and extracapsular free silicone (arrow).
Stage tumor to rule out multicentric disease
Differentiate postoperative scar from recurrence after breast-conserving surgery
Find a lesion seen in only one view of mammogram
Evaluate positive axillary nodes in the presence of negative mammogram and clinical breast examination results
Rule out silicone implant rupture
Assess focal asymmetry
Detect additional ipsilateral and contralateral cancers
Evaluate the effect of neoadjuvant chemotherapy

The American Cancer Society recommends annual MRI screening for women who are high risk (greater than 20% lifetime risk) and consideration given to women with moderate risk (15% to 20% lifetime risk) (61). A study from the Netherlands in high-risk women reported 71% sensitivity for MRI compared with 17.9% for clinical breast examination and 40% for mammography (62). The International Cooperative Magnetic Resonance Mammography Study will help identify the advantages and limitations of MRI. At present, MRI should be considered only after conventional imaging is performed; it should not be used as a screening tool or a substitute for mammography or biopsy. Centers that perform MRI should have the ability to perform MRI-guided biopsies of lesions detected
with MRI only and that are not visible with mammogram or ultrasound.

**Positron Emission Tomography Scan**

PET scanning is a diagnostic modality that assesses the metabolic activity of tumors. Radioactive fluorodeoxyglucose (FDG) is an analogue of glucose that is metabolized by tissues of high metabolic activity. Although not specifically approved for the initial diagnosis of breast cancer or for staging the axilla, it can be useful in patients with advanced disease \(^{(59,63)}\). This technique is used to identify occult breast lesions with positive axillary lymph nodes \(^{(59)}\).
The safest course is tissue or cytologic biopsy evaluation of all dominant masses found on physical examination and, in the absence of a mass, evaluation of suspicious lesions shown by breast imaging. Over 1 million women have breast biopsies each year in the United States. Between 70% and 80% of these biopsies yield a benign lesion (64). The diagnosis of a benign breast lesion versus breast cancer is often difficult to determine based on clinical examination and requires evaluation of tissue by fine needle aspiration cytology (FNAC), core needle biopsy (CNB), or excisional biopsy (EB). Both FNAC and CNB are reasonable techniques for the evaluation of a palpable or image-identified lesion. CNB evolved as the diagnostic procedure of choice. More than half of all breast biopsies use a core-needle technique. The sensitivity of CNBs performed using either stereotactic or ultrasound guidance is 97% to 99% (65). CNB is used increasingly to diagnose breast cancer and to determine tumor histology, grade, and marker expression; select neoadjuvant therapy; and predict sentinel lymph node status (66). CNB and fine needle aspiration (FNA) are less invasive and achieve better cosmesis than excisional or even incisional biopsy. The main limitations of FNA are high rate of insufficient sampling and inability to distinguish invasive from noninvasive cancers. CNB is a well-accepted alternative to surgical biopsy and can avoid surgical biopsies in most patients (67). Investigators of the Fifth Radiologic Diagnostic Oncology Group demonstrated that image-guided biopsy of breast lesions provides high diagnostic accuracy. The sensitivity, specificity, and accuracy of CNB were 0.91, 1.00, and 0.98, respectively (68).

About 30% of lesions suspected to be cancer prove on biopsy to be benign, and about 15% of lesions believed to be benign prove to be malignant (23). Dominant masses or suspicious nonpalpable breast lesions require histopathological examination. Histologic or cytologic diagnosis should be obtained before the decision is made to monitor a breast mass (69). An exception may be a premenopausal woman with a nonsuspicious mass presumed to be fibrocystic disease. An apparently fibrocystic lesion that does not completely resolve within several menstrual cycles should be sampled for biopsy. Any mass in a postmenopausal woman who is not taking estrogen therapy should be presumed to be malignant. Some clinicians will monitor a mass when results of the clinical diagnosis, breast imaging studies, and cytologic studies are all in agreement, such as with fibroadenoma. Many clinicians will not leave a dominant mass in the breast even when FNAC or CNB results are negative, unless the FNA or CNB shows fibroadenoma. Such cases require periodic follow-up. Some surgeons excise lesions when the sampling technique shows only fibrocystic disease. Figures 21.4 and 21.5 present algorithms for management of breast masses in premenopausal and postmenopausal patients. Simultaneous evaluation of a breast mass using clinical breast examination, radiography, and needle biopsy can lower the risk of missing cancer to only 1%, effectively reducing the rate of diagnostic failure and increasing the quality of patient care (70).
**Figure 21.4** Algorithm for management of breast masses in premenopausal women. (Revised and updated from Giuliano AE. Breast disease. In: Berek JS, Hacker NF, eds. Practical gynecologic oncology. 4th ed. Baltimore, MD: Lippincott Williams & Wilkins, 2005:640, with permission.)

**Figure 21.5** Algorithm for management of breast masses in postmenopausal women. (Revised and updated from Giuliano AE. Breast disease. In: Berek JS, Hacker NF, eds. Practical gynecologic oncology. 4th ed. Baltimore, MD: Lippincott Williams & Wilkins, 2005:641, with permission.)
If the presence of breast cancer is strongly suggested by physical examination, the diagnosis can be confirmed by FNAC or CNB, and the patient may be counseled regarding treatment. Treatment should not be determined based on results of physical examination and mammography alone, in the absence of biopsy results. The most reasonable approach to the diagnosis and treatment of breast cancer is outpatient biopsy (either FNAC, CNB, or EB), followed by definitive surgery at a later date if needed. This two-step approach allows patients to adjust to the diagnosis of cancer, carefully consider alternative forms of therapy, and seek a second opinion. Studies show no adverse effect from the 1- to 2-week delay associated with the two-step procedure (71). Because cancer is found in the minority of patients who require biopsy for diagnosis of a breast mass, definitive treatment should not be undertaken without an unequivocal histologic diagnosis of cancer.

**Fine-Needle Aspiration**

With FNAC, cells from a breast tumor are aspirated with a small (usually 22-gauge) needle and examined by a pathologist. Precise guidelines for this technique are available (72). It can be performed easily, with no morbidity, and is much less expensive than excisional or open biopsy. It requires the availability of a pathologist skilled in the cytologic diagnosis of breast cancer to interpret the results, and it is subject to sampling problems, particularly when lesions are deep. Cytologic diagnoses must be correlated
with clinical and imaging findings to achieve triple-test concordance and to decrease the false-negative rate (73). **The triple-test concordance (i.e., concordance between fine-needle aspiration, physical examination, and mammography) is the foundation of breast evaluation. The triple-test results are more powerful than each modality alone (74).** The incidence of false-positive diagnoses was 0% to 0.3%, and the rate of false-negative diagnoses was 1.4% to 2.3% in several recent studies (74,75).

**Core Needle Biopsy**

A core of tissue can be obtained from palpable lesions using a large cutting needle (76). Image-guided large-core needle biopsy is a reliable diagnostic alternative to surgical excision of suspicious nonpalpable breast lesions (77). As in the case of any needle biopsy, the main drawback is false-negative findings caused by improper positioning of the needle. False-negative findings may be reduced if core biopsy is performed with ultrasonographic guidance. **The interpretation of results from CNB is classified by categories B1 to B5 (78):**

**B1: Normal tissue**
**B2: Benign lesions: fibroadenomas, fibrocystic change, sclerosing adenosis, duct ectasia, fat necrosis, abscess**
**B3: Uncertain malignant potential: atypical epithelial hyperplasia, lobular neoplasia, phyllodes tumor, papillary lesions, radial scar, complex sclerosing lesions**
**B4: Suspicious**
**B5: Malignant**

**Open Excisional Biopsy**

Open biopsy with local anesthesia as a separate procedure before deciding on definitive treatment is the most reliable means of diagnosis. Its utility is reserved for when the results of needle biopsy are nondiagnostic or equivocal.

**Histologic Analysis**

Histologic evaluation with hematoxylin and eosin (H&E) staining confirms benign or malignant disease. Images of benign and malignant breast lesions can be viewed through the Internet Pathology Laboratory for Medical Education (79). **Assessment of prognostic factors, tumor grade; estrogen, progesterone, her-2/neu receptor status; and proliferative indices is performed on paraffin-fixed tissue by immunohistochemistry (78).** Her-2/neu assessment in breast cancer by immunohistochemistry (IHC) is appropriate for patients with tumors that score 3+. **Fluorescence in situ hybridization (FISH) is recommended for 2+ IHC to more accurately assess her-2/neu amplification and provide better prognostic information (80).**
Ductal Lavage Cytology

Ductal lavage using a microcatheter is a modality that was investigated in high-risk women (81). Patients undergo gentle nipple suction to elicit nipple fluid. A duct that yields fluid is cannulated with a microcatheter, and 10 to 20 mL of saline are introduced in 2- to 4-mL increments. The cytologic assessment of a sample obtained by ductal lavage is more sensitive than that of nipple aspiration. Ductal lavage performed to identify abnormal cells is not an effective tool in detecting breast cancer and is rarely performed (81).
Benign Breast Conditions

Benign breast disorders account for most breast problems. These conditions are frequently considered in the context of excluding breast cancer and often are unrecognized for their own associated morbidity (82). To provide appropriate management, it is important to consider benign breast disorders from four aspects: (i) clinical picture, (ii) medical significance, (iii) treatment intervention, and (iv) pathologic etiology (83). A framework for understanding benign breast problems is called Aberrations of Normal Development and Involution (ANDI) (2,82,83). It includes symptoms, histology, endocrine state, and pathogenesis in a progression from a normal to a disease state. Most benign breast conditions arise from normal changes in breast development, hormone cycling, and reproductive evolution (82).

Three life cycles reflect different reproductive phases in a woman’s life and are associated with unique breast manifestations.

During the early reproductive period (15–25 years), lobule and stromal formation occurs. The ANDI conditions associated with this period are fibroadenoma (mass) and juvenile hypertrophy (excessive breast development). In this first stage, the progression from ANDI to a disease state results in the formation of giant fibroadenomas and multiple fibroadenomas.

During the mature reproductive period (25 to 40 years), cyclic hormonal changes affect glandular tissue and stroma. In this second period, the ANDI is an exaggeration of these cyclic effects, such as cyclic mastalgia and generalized nodularity.

The third phase is involution of lobules and ducts or turnover of epithelia, which occurs during ages 35 to 55 years. The ANDI associated with lobular involution are macrocysts (lumps) and sclerosing lesions (mammographic abnormalities). Those associated with ductal involution are duct dilation (nipple discharge) and periductal fibrosis (nipple retraction), and those with epithelial turnover are mild hyperplasia (pathologic description).

Disease conditions with increased epithelial turnover are epithelial hyperplasias with atypia. Breasts are under endocrine control and show a wide range of appearances during reproductive life. ANDI classification allows the clinician to understand the pathogenesis of these conditions and to understand that these disorders are aberrations of a normal process that does not usually require any specific treatment (82).
Fibrocystic Change

Fibrocystic change, the most common lesion of the breast, is an imprecise term that covers a spectrum of clinical signs, symptoms, and histologic changes (76). The term refers to a histologic picture of fibrosis, cyst formation, and epithelial hyperplasia (83). Cysts arise from the breast lobules and are an aberration of normal breast involution (82). Macroscopic cysts occur in approximately 7% of women, and microscopic, nonpalpable cysts occur in about 40% of women (84). It is common in women 35 to 55 years of age, but rare in postmenopausal women not taking hormone therapy. The presence of estrogen seems necessary for the clinical symptoms to occur. This finding is supported by the observation that it is present bilaterally, increased in the perimenopausal age group, and responsive to endocrine therapy (85). In essence, a diagnosis of fibrocystic change can lead to significant patient anxiety but is of little clinical significance as long as malignancy is excluded (86). These lesions are associated with benign changes in the breast epithelium.

Cyst Fluid Analysis

Investigators examined the electrolyte and protein content of cyst fluid, but this is of little significance in the clinical management of fibrocystic disease. The potassium-to-sodium ratio is a marker that may be used to distinguish cyst subtypes (87). Cysts are either lined by apocrine epithelium with a high potassium-to-sodium ratio and a higher hormone or steroid concentration (type I); or by flattened lobule epithelium with a low potassium-to-sodium ratio and a higher concentration of albumin, carcinoembryonic antigen, CA125, and steroid hormone–binding globulin (type II) (87). Apocrine cysts produce and secrete large amounts of prostate-specific antigen (PSA) (88). The role of this serine protease in proliferative breast disease is not fully understood.

Clinical Findings in Fibrocystic Disease

Fibrocystic changes may produce an asymptomatic mass that is smooth, mobile, and potentially compressible. Fibrocystic change is more often accompanied by pain or tenderness and sometimes nipple discharge. In many cases, discomfort coincides with the premenstrual phase of the cycle, when the cysts tend to enlarge. Fluctuations in size and rapid appearance or disappearance of a breast mass are common. Multiple or bilateral masses appear frequently, and many patients have a history of a transient mass in the breast or cyclic breast pain. Cyclic breast pain is the most commonly associated symptom of fibrocystic changes.

Differential Diagnosis

Pain, fluctuation in size, multiplicity of lesions, and bilaterality are the features most helpful to differentiate fibrocystic disease from carcinoma. If a dominant mass is present, the diagnosis of cancer should be suspected until it is disproved by complete aspiration of
a cyst, or histopathologic analysis if a mass is present after aspiration, or by breast imaging. Microscopic findings associated with fibrocystic disease include cysts (gross and microscopic), papillomatosis, adenosis, fibrosis, and ductal epithelial hyperplasia (89).

**Diagnostic Tests**

Patients with cystic disease may have a discrete fibrocystic mass that is frequently indistinguishable from carcinoma, based on clinical findings. Mammography may be helpful, but there are no mammographic signs diagnostic of fibrocystic change. Ultrasonography is useful in differentiating a cystic from a solid mass. **Characteristic findings on ultrasonography that confirm a simple cyst include the following:**

- Mass with thin walls
- Smooth round shape
- Absence of internal echoes
- Posterior acoustic enhancement

If these imaging criteria are not met, a tissue diagnosis of the mass usually requires a FNA, FNAC, or EB. The finding of a simple cyst by ultrasonography rules out carcinoma. **Any lesion that is suspicious by mammography or ultrasonography should be biopsied.**

When the diagnosis of fibrocystic change is established by ultrasonography or is practically certain because the history is classic, aspiration of a discrete mass, suggestive of a cyst, is indicated if the patient is symptomatic, the cyst obscures visualization of breast tissue on mammography and prevents adequate imaging, or if the ultrasonographic criteria are not met. In one study of a screened population, 1% of individuals developed a new cyst that resolved in more than 50% of cases (90). Aspiration may be performed with ultrasonographic guidance, but image guidance is usually not necessary if the cyst is palpable (91). FNA of a cyst is a minimally invasive procedure performed with a 21- or 22-gauge needle without local anesthesia and is not associated with significant risks or complications. There is minimal pain and little risk for infection or bleeding. Benign cyst fluid is straw colored to dark green to brownish and does not need to be submitted for cytologic evaluation (6). Injection of air into the cyst cavity is reported to reduce the likelihood of cyst recurrence but generally is not performed. The patient should be reexamined at a short interval thereafter for cyst recurrence. Cysts will reoccur in 30% of patients, cause anxiety, and require repeated evaluations (84). **Tissue biopsy should be performed in the presence of the following findings:**

- No cyst fluid is obtained
- The fluid is bloody
- The fluid is thick
- The cyst is complex
There is an intracystic mass
A mass persists after aspiration
A persistent mass is noted at any time during follow-up

If a needle biopsy is performed and results are negative for malignancy, a suspicious mass that does not resolve over several months should be excised. Surgery should be conservative, because the primary objective is to exclude cancer. Simple mastectomy or extensive removal of breast tissue is not indicated for fibrocystic disease. Most patients do not require treatment for fibrocystic changes, just reassurance that fibrocystic change is a transient phenomenon of aging that is associated with hormonal effects on the breast glandular tissue that eventually subsides.

Fibrocystic Change and Risk for Breast Cancer

Fibrocystic change is not associated with an increased risk of breast cancer unless there is histologic evidence of epithelial proliferative changes, with or without atypia (92–97). The common coincidence of fibrocystic disease and malignancy in the same breast reflects the fact that both processes are common events. Approximately 80% of biopsies show fibrocystic changes. In an evaluation of the relationship between fibrocystic change and breast cancer in 10,366 women who underwent biopsy between 1950 and 1968 and were followed for a median of 17 years, approximately 70% of the biopsies showed nonproliferative breast disease, whereas 30% showed proliferative breast disease (95). Cytologic atypia were present in 3.6% of cases. Women with nonproliferative disease had no increased risk of breast cancer, whereas women with proliferative breast disease and no atypical hyperplasia had a twofold higher risk of breast cancer. Patients whose biopsy results showed atypical ductal or lobular hyperplasia had an approximately fivefold higher risk than women with nonproliferative disease to develop invasive breast cancer in either breast. Patients with carcinoma in situ have an eight- to tenfold risk of developing breast cancer. This risk is bilateral for lobular lesions and ipsilateral for ductal lesions. A family history of breast cancer added little risk for women with nonproliferative disease, but family history plus atypia increased breast cancer risk 11-fold. The presence of cysts alone did not increase the risk of breast cancer, but cysts combined with a family history of breast cancer increased the risk about threefold (76,92–97). Women with these risk factors (family history of breast cancer and proliferative breast disease) should be followed carefully with physical examination and mammography. For such women, age-specific probability of developing invasive breast carcinoma in the next 10 years is 1 in 2,000 (age 20), 1 in 256 (age 30), 1 in 67 (age 40), 1 in 39 (age 50), and 1 in 29 (age 60) (93). The relative risk for developing breast cancer depends on the type of proliferative lesion diagnosed.

Management of Fibrocystic Change

Fibrocystic change is a normal evolutionary change in breast development and involution and does not require a specific treatment other than a good clinical
breast examination and age-appropriate mammographic screening or imaging studies directed to signs and symptoms. A number of nutritional and dietary supplements were investigated to relieve symptoms. The role of caffeine consumption in the aggravation of fibrocystic change is controversial (98–101). Results of some studies suggest that eliminating caffeine from the diet is associated with improvement of symptoms (100,101). Many patients are aware of these studies and report relief of symptoms after discontinuing intake of coffee, tea, and chocolate. Similarly, many women find vitamin E (150 to 600 IU daily) or B₆ (200 to 800 mg per day) helpful (102,103). Observations about these effects are difficult to confirm and are anecdotal (104–106). A recent review of nutritional interventions for fibrocystic breast conditions that evaluated evening primrose oil, vitamin E, or pyridoxine suggested that there are insufficient data to draw clear conclusions about their effectiveness (107). Exacerbations of pain, tenderness, and cyst formation may occur at any time until menopause, when symptoms usually subside unless patients are taking estrogen. A patient with fibrocystic changes should be advised to examine her own breasts each month just after menstruation and to inform her physician if a mass appears.
Mastalgia

Mastalgia is a recognized organic condition that is studied less thoroughly than other breast problems (108,109). Inflammatory cytokines were implicated in the etiology of breast pain. A study evaluating expression of interleukin-6 and tumor necrosis factor-α in painful and nonpainful breast tissue showed lower levels of these cytokines in painful breast tissue during the luteal phase; however, these levels did not reach statistical significance (110). Elevated estrogen, low progesterone, or an imbalance in the ratio of estrogen and progesterone were suggested as a possible cause for the symptoms (111).

Natural History of Mastalgia

Approximately 70% to 80% of women experience severe breast pain at some time in their lives (112,113). Mastalgia accounts for 30% to 47% of breast clinical evaluations (111,114). In 15% of the patients, the mastalgia is so severe that it alters lifestyle and requires repeated investigations and treatment (112). Mastalgia interferes with sexual (48%), physical (37%), social (12%), and work or school activities (8%) (115).

Types of Mastalgia

Breast pain is a distressing constellation of symptoms that is classified as cyclic, noncyclic, or extramammary (116). Cyclic mastalgia is related to exaggerated premenstrual symptoms beginning in the luteal phase of the menstrual cycle, associated with breast engorgement, pain, ache, heaviness, and tenderness that is bilateral and can last for more than 7 days in 11% of women (116–118). Cyclical mastalgia is more prevalent in women in their third and fourth decades of life and accounts for two-thirds of all breast pain symptoms (119). Noncyclic mastalgia is independent of menstrual cycles and is described as achy, burning soreness. It may be intermittent or constant, is usually unilateral, occurs in the fourth and fifth decades, and is more difficult to treat than cyclic mastalgia (116). Extramammary pain is perceived to be located in the breast but is related to an extramammary site. Chest wall muscular pain, costal cartilage symptoms, herpes zoster, radiculopathies, and rib fractures are among some of the more common causes of extramammary pain. Costochondritis (Tietze syndrome) is a manifestation of chest wall pain that is frequently interpreted as breast pain.

Management of Mastalgia

Breast pain is an unlikely symptom of malignancy, and when malignancy is excluded by a clinical breast examination and age-appropriate breast imaging for focal breast pain, the most important treatment is reassurance. Treatments include medications, such as anesthetics, diuretics, bromocriptine, and tamoxifen; vitamins and supplements, such as evening primrose oil; mechanical support with a well-fitting bra; local excision; and decreased fat intake and reduction in methylxanthines from caffeine, tea, and chocolate (108,116). Discontinuation of hormone therapy may be
effective in some women. Maintenance of a pain score diary is important to understand the relationship of pain to factors such as the menstrual cycle, activities of daily living, and stress. External support may be effective for breast pain associated with generalized fibrocystic changes and is best treated by avoiding trauma and by wearing (night and day) a brassiere that gives good support and protection (120). One study evaluated resolution of symptoms in 200 women randomized either to a regimen of danazol (200 mg per day) or to mechanical support with a sports brassiere worn for regular activities for 12 weeks. The group using mechanical support had 85% relief of symptoms compared with 58% improvement in the danazol group. Symptoms recurred after discontinuance of treatment with danazol (113). The danazol group experienced drug-related side effects in 42%, which led to discontinuance of the medication in 15%. The breast has minimal structural support and is at significant risk for motion-related displacement resulting in mastalgia. The use of external support to minimize breast motion appears to be effective in reducing breast pain. The application of heat packs or cold packs and light breast massage may reduce symptoms in some individuals (116).

Hormone-modulating drugs, including danazol, bromocriptine, tamoxifen, and Depo-Provera, are recognized drug treatments for mastalgia, although tamoxifen is not approved for this use in the United States (116,121–124). These drugs are associated with significant side effects that limit their general use (116). Withdrawal of birth control pills or hormone therapy may be all that is required to alleviate symptoms (116).

Danazol is a synthetic androgen that suppresses release of pituitary gonadotropin, prevents luteinizing hormone surge, and inhibits ovarian steroid formation. It is the only medication approved by the U.S. Food and Drug Administration for mastalgia (116). The androgenic effects—acne, edema, change in voice, weight gain, headaches, depression, and hirsutism—often are intolerable, and many patients stop taking danazol even when symptoms are improved (122). It can be initiated at doses of 100 to 200 mg twice daily orally for patients with severe pain and then tapered to a lower dose of 100 mg per day (122). A survey of surgeons in Great Britain revealed that 75% prescribed danazol as first-line therapy (108). A study conducted to evaluate the response to administration of danazol revealed a 79% amelioration of symptoms (125). This approach reduced the premenstrual mastalgia and resulted in virtually no side effects.

The use of oral progesterone agents reduces cyclical breast pain (111). Further studies may be warranted to see whether medroxyprogesterone acetate suppresses cyclic mastalgia in reproductive-age women.

Breast pain is increased in some individuals who have elevated prolactin (PRL) levels induced by thyrotropin-releasing hormone (TRH) (116). Bromocriptine is a dopamine antagonist that inhibits the release of PRL. Bromocriptine (2.5 mg twice daily) given for 3 to 6 months is effective in reducing mastalgia in women who have TRH-induced elevation of PRL (123). Patients who have normal TRH levels, are resistant to bromocriptine, or do
not tolerate the side effects of nausea, vomiting, and headache respond favorably to progesterone and systemic nonsteroidal anti-inflammatory drugs (NSAIDs).

Prolactin induces active transport of iodine in breast tissue \((126,127)\). Iodine deficiency in rats causes hyperplasia and atypia \((128)\). Iodine replacement is associated with improvement in subjective pain \((129)\). A randomized, double-blind study with supraphysiologic levels of iodine in women with documented cyclic mastalgia demonstrated dose-dependent reduction in physician-assessed and self-reported pain at 3 and 6 months of treatment \((130)\).

Goserelin is a potent synthetic analogue of luteinizing hormone-releasing hormone (LHRH) that causes reversible reduction in serum estrogen level and decrease in breast pain \((131)\). Side effects of goserelin include vaginal dryness, hot flushes, decreased libido, oily skin and hair, and decreased breast size. A recent clinical trial randomized 147 women into goserelin versus placebo groups. The study had a 49% drop-out rate. The mean breast pain score decreased by 67% in the goserelin arm and 35% in the placebo arm. The authors concluded that goserelin is an effective treatment for mastalgia with significant side effects and should be kept as second-line therapy. Hormonal blockade of the estrogen receptor is another approach to minimizing the effects of circulating estrogen on breast pain. Treatment with the selective estrogen receptor modulator tamoxifen demonstrated reduction in breast pain at 10 and 20 mg per day, with equivalent effects compared with danazol and bromocriptine in most studies \((124,132–134)\). Topical nonsteroidal therapy is another option for women with mastalgia \((135)\). Gel forms of NSAIDs often are used for relief of pain. Patients were stratified by cyclic versus noncyclic pain and then randomized to treatment with NSAIDs versus placebo. There was a significant reduction in cyclic and noncyclic pain in all groups, but the magnitude of change was greater in the treatment arms and similar for cyclic and noncyclic pain. Use of NSAIDs appears to be a less toxic treatment and may be considered as an option for both cyclic and noncyclic breast pain.

Nonhormonal therapies such as dietary restrictions, vitamins and supplements, and restriction of methylxantines were investigated as possible treatments for mastalgia because they are less likely to be associated with adverse drug-related side effects \((116)\). Because mastalgia is one of the symptoms associated with fibrocystic disease, the treatments described for fibrocystic disease are relevant to mastalgia. A low-fat diet was effective in one randomized trial \((136)\). Ninety percent of patients taking in 15% dietary fat experienced resolution of pain symptoms after 6 months compared with only 22% of those on a diet containing 36% fat \((p = .0023)\). Evening primrose oil containing essential fatty acids \((\gamma\text{-linolenic acid [GLA]})\) was studied because of its affect on prostaglandin synthesis \((137)\). It was used as first-line therapy, reserving danazol and bromocriptine for treatment of more severe symptoms \((112)\). In a small prospective mastalgia trial, women were given eight capsules of evening primrose oil daily for 4 months \((320 \text{ mg GLA})\) \((138)\). Those who responded had a lower level of essential fatty acids at the time of initiation when compared with poor responders, suggesting that evening primrose oil increases essential fatty acids and that this increase may be associated with the improvement in
symptoms in the responders. Two other trials failed to demonstrate efficacy of evening primrose oil capsules over placebo (139,140). In a Dutch trial, 124 women with cyclic or noncyclic pain lasting on average 7 or more days (minimum 5 days) were randomized to receive the following regimens: (i) fish oil and control oil, (ii) evening primrose oil and control oil, (iii) fish and evening primrose oil, or (iv) both control oils for 6 months (139). There was a statistically significant reduction in the number of days per month with pain but not in the pain score in the entire study population. There was a greater reduction in cyclic than noncyclic pain symptoms, and this finding was true for both the test oils and for the control oils. The authors concluded that neither fish oil nor evening primrose oil had a better effect than the less expensive wheat germ and corn oils. A second large double-blind randomized prospective trial was conducted in 555 women with cyclic mastalgia of moderate to severe degree present for at least 7 days of a menstrual cycle (140). The four groups were (i) GLA and placebo antioxidants, (ii) placebo fatty acids and antioxidants, (iii) GLA and placebo antioxidants, and (iv) placebo fatty acids and placebo antioxidants. The treatments were given in a blinded fashion for 4 months. All groups had a similar 35% reduction in symptoms. This treatment was followed by open treatment with GLA in all groups and blinded treatment with antioxidants. There was continued improvement of symptoms in all groups with a reduction in mastalgia by 50% over the next 12 months. This is the largest and best-controlled study to date evaluating GLA for relief of mastalgia, and GLA was not found to be superior to placebo. The results of this study were not consistent with those from previous smaller studies. The authors cannot exclude a significant psychologic impact that may confound the effect of GLA. GLA use was found to be safe, without any significant side effects, and was prescribed as therapy for mastalgia because of its lack of side effects. The randomized trials, however, bring into serious question the efficacy of these options.
Fibroepithelial Lesions

Fibroadenoma

**Fibroadenomas are the most common benign tumors of the breast.** In one series, they accounted for 50% of all breast biopsies (141). They usually occur in young women (age 20 to 35 years) and may occur in teenagers (142). In women younger than 25 years, fibroadenomas are more common than cysts. They rarely occur after menopause, although occasionally they are found, often calcified, in postmenopausal women. For this reason, it is postulated that fibroadenomas are responsive to estrogen stimulation. A study reports the de novo occurrence of fibroadenoma in 51 women older than age 35 years who had no evidence of a palpable or mammographic visualized lesion in well-documented prior visits (143). Fibroadenomas may appear as single masses or as multiple lesions.

Clinically, a young woman usually notices a mass while showering or dressing. Most masses are 2 to 3 cm in diameter when detected, but they can become extremely large (i.e., the giant fibroadenoma). On physical examination, they are firm, smooth, and rubbery. They do not elicit an inflammatory reaction, are freely mobile, and cause no dimpling of the skin or nipple retraction. They are often bilobed, and a groove can be palpated on examination. On mammographic and ultrasonographic imaging, the typical features are of a well-defined, smooth, solid mass with clearly defined margins and dimensions that are longer than wide and craniocaudal dimensions that are less than the length.

**Fibroadenoma is not associated with an increased risk for breast cancer** (144). The natural history of fibroadenoma can be regression, growth, or no change in size. Most fibroadenomas are static or cease growth at approximately 2 to 3 cm, about 15% of tumors regress spontaneously, and only 5% to 10% progress (145). Because transformation of a fibroadenoma into cancer is rare and regression is frequent, current management recommendations are conservative unless there is evidence of growth (141). A suspected fibroadenoma should be confirmed by FNAC or CNB and observed for increase in size or excised based on patient preference. Rarely will the fibroadenoma increase to more than 2 to 3 cm in size. Large or growing fibroadenomas must be excised. Complete excision of a fibroadenoma with local anesthesia can be performed to treat the lesion and confirm the absence of malignancy. Less invasive local treatment of a fibroadenoma is advocated by some and can be performed with either ultrasonographically guided percutaneous vacuum-assisted biopsy devices or percutaneous cryoablation (146,147). A young woman with a clinical fibroadenoma can undergo needle cytology and observation of the mass (148). Acceptance of observation varies, and many women choose to have the fibroadenoma excised (149).

On gross examination of an excised mass, the fibroadenoma appears encapsulated and sharply delineated from the surrounding breast parenchyma. Microscopically, there is proliferation of both the epithelial and stromal component. In longstanding lesions and in
postmenopausal patients, calcifications may be observed within the stroma.

**Multiple Fibroadenomas**

Multiple fibroadenomas occur in some women and were reported to occur more frequently in premenopausal women undergoing immunosuppression for transplant (150–152). Excision of all lesions through separate incisions could leave significant scarring and deformity. Excision of these mobile lesions through a single periareolar incision was suggested, but this approach can lead to significant ductal disruption (153). Another approach is through an incision in the inframammary crease. Alternatively, these lesions can be treated with observation based on triple-test concordance of results of a classic clinical examination with histologic corroboration with FNAC and ultrasonographic diagnostic criteria consistent with a fibroadenoma (151).

**Phyllodes Tumor**

Phyllodes tumors are rare fibroepithelial tumors that display a spectrum of clinical and pathologic behaviors that are benign, borderline, and malignant (154,155). The distribution of phyllodes tumors demonstrates that most tumors are benign (70%) compared with malignant (23%) and borderline lesions (7%) (156). This distribution is similar to a larger, older study that reported an incidence of 64% benign, 21% malignant, and 14% borderline phyllodes tumors (157). The incidence in some studies should be viewed with caution because of variation in histologic interpretation (156). Phyllodes tumors may occur at any age but tend to be more common in women who are in their late 30s, 40s, and 50s (156,158–162). These lesions are rarely bilateral and usually appear as isolated masses that are difficult to distinguish clinically from a fibroadenoma. Patients often relate a long history of a previously stable nodule that suddenly increases in size. Reported sizes range from 1.0 to 50 cm (154,163,164). Size is not a dependable diagnostic criterion, although phyllodes tumors tend to be larger than fibroadenomas, probably because of their rapid growth. There are no good clinical criteria by which to distinguish a phyllodes tumor from a fibroadenoma. Whereas observation of a fibroadenoma is acceptable, excision of a phyllodes tumor is necessary for local control and for determination of benign or malignant features. To avoid unnecessary excision of benign fibroadenomas that are indistinguishable from phyllodes tumors on clinical examination, imaging criteria were sought to aid in identifying patients who require EB for complete histopathologic evaluation and local control. Mammography may show a halo around a phyllodes tumor mass but cannot reliably distinguish a fibroadenoma from a phyllodes tumor (165–167). Ultrasonography evaluation has limitations even when color and pulse Doppler ultrasonography are used in conjunction with it (163).

**Microscopic evaluation of a lesion is important to determine the diagnosis.** The histologic distinction between fibroadenoma, benign, borderline, and malignant phyllodes tumor can be very difficult on minimal tissue sampling with FNAC or CNB (168,169). It may be easier to distinguish benign phyllodes from
malignant phyllodes tumors than benign phyllodes tumors from fibroadenomas (170). Histologic features that stratify lesions include number of mitoses per high power field, stromal cellularity, pushing or infiltrating tumor margin, cellular atypia, tumor necrosis, and stromal overgrowth (171).

If a lesion cannot be clearly characterized as a fibroadenoma, excision may be necessary. Factors that are considered in recommending excision include older age, new mass in a well-screened individual, rapid growth, size greater than 2.5 to 3 cm, suspicious FNAC or CB, and mammographic or ultrasonographic features that demonstrate lobulation and intramural cysts. If observation is elected, repeat clinical examination and imaging in a short interval is essential to evaluate change in size.

Treatment of biopsy-proven phyllodes tumor is wide local excision, attempting to obtain a 1- to 2-cm margin (156–161). Massive tumors, or large tumors in relatively small breasts, may require mastectomy; otherwise, mastectomy should be avoided, and axillary lymph node dissection is not indicated. Often, however, a patient will undergo excisional biopsy of a mass believed to be fibroadenoma, and final histologic examination reveals a phyllodes tumor. Reexcision with normal breast margins is recommended for borderline and malignant phyllodes tumors (159). An expectant approach is an option for unanticipated diagnosis of benign phyllodes tumors (157).

The prognosis of benign and malignant phyllodes tumors is variable (154,155,157,162,172). Tumors judged to be benign phyllodes tumors can recur locally in up to 10% of patients (159–161). Recurrence is associated with margin involvement, whereas mortality correlates with size and grade (173). In a series reviewing only high-grade malignant phyllodes tumors, size and excision margins were associated with local recurrence and metastatic spread, and mastectomy may be required to achieve complete surgical excision (174). Malignant phyllodes tumors tend to recur locally and occasionally may metastasize to the lung, although brain, pelvic, and bone metastases also may occur (160–162). The stromal component of the tumor is malignant and metastasizes, behaving like a sarcoma. Axillary involvement is extremely unusual. Often, the appearance of metastasis is the first sign that a phyllodes tumor is malignant. Chemotherapy for metastatic phyllodes tumors should be based on regimens for sarcoma, not adenocarcinoma (159). Radiation therapy generally is not used in the treatment of phyllodes tumors. In the presence of a bulky tumor, positive margins, recurrence, or malignant histology, radiation therapy may be of some benefit (175).
Breast Conditions Requiring Evaluation

Nipple Discharge

Nipple discharge is a presenting breast symptom in 4.5% of patients seeking evaluation of a breast symptom, with 48% spontaneous and 52% provoked (176). Nipple discharge that does not occur spontaneously has no pathologic significance. Provoked or self-induced nipple discharge should be managed by reassurance and instruction to discontinue manipulation. Spontaneous nipple discharge is more likely to be associated with an underlying pathologic problem than provoked discharge. **Although it is a distressing finding, spontaneous nipple discharge is infrequently found to be associated with carcinoma, ranging from 4% to 10% (176–178).** Nipple discharge can be caused by neoplastic or nonneoplastic processes (179). Nonneoplastic processes include galactorrhea, physiologic changes resulting from mechanical manipulation, parous condition, periductal mastitis, subareolar abscess, fibrocystic change, and mammary duct ectasia. Neoplastic causes of nipple discharge in nonlactating women are solitary intraductal papilloma, carcinoma, papillomatosis, squamous metaplasia, and adenosis (176,179,180). Extramammary causes are related to hormones and drugs (179).

**Following are the important characteristics of the discharge and other factors to be evaluated by history and physical examination (180):**

- **Nature of discharge (serous, bloody, or milky)**
- **Association with a mass**
- **Unilateral or bilateral**
- **Single or multiple ducts**
- **Discharge that is spontaneous (persistent or intermittent) or expressed by pressure at a single site or on entire breast**
- **Relation to menses**
- **Premenopausal or postmenopausal**
- **Hormonal medication (contraceptive pills or estrogen)**

Unilateral, spontaneous, bloody, or serosanguinous discharge from a single duct is usually caused by an intraductal papilloma or, rarely, by an intraductal cancer. In either case, a mass may not be palpable. The involved duct may be identified by pressure at different sites around the nipple and at the margin of the areola. Bloody discharge is more suggestive of cancer but usually is caused by a benign papilloma in the duct. In premenopausal women, spontaneous multiple-duct discharge, unilateral or bilateral, is most marked just before menstruation. It often is caused by fibrocystic change. Discharge may be green or brownish. Papillomatosis and ductal ectasia are usually seen on biopsy. If a mass is present, it should be removed. Milky discharge from multiple ducts in nonlactating women presumably reflects increased secretion of pituitary prolactin; serum prolactin and thyroid-stimulating hormone levels should be evaluated to detect a pituitary tumor or hypothyroidism. Hypothyroidism may cause galactorrhea. Alternatively, phenothiazines may cause milky discharge that disappears when the
medication is discontinued. Oral contraceptive agents may cause clear, serous, or milky discharge from multiple ducts or, less often, from a single duct. The discharge is more evident just before menstruation and disappears when the medication is stopped.

**Chronic unilateral nipple discharge, especially if it is bloody, is an indication for resection of the involved ducts.** Mammography and ultrasonography are performed to rule out an associated mass. On occasion, ductography may be performed to identify a filling defect before excision of the duct system, but usually this technique is of little value (178). Ductography is not a substitute for excision because it misses multiple lesions and cannot visualize the periphery (181).

Fiberoptic ductoscopy is a technology used to evaluate patients with nipple discharge (182). In 259 patients with nipple discharge, fiberoptic ductoscopy successfully detected intraductal papillary lesions in 92 patients (36%). Office-based, minimally invasive breast ductoscopy with intraductal biopsy is available in some centers (183,184). It was performed for diagnosis in 83 patients with nipple discharge (183). A diagnosis of severe or malignant atypia was established in 21% of patients.

Cytologic examination of nipple discharge or cyst fluid rarely is performed. **Cytologic examination usually is of no value but may identify malignant cells** (178). Negative findings do not rule out cancer, which is more likely in women older than 50 years of age. In any case, the involved duct—and a mass, if present—should be excised (177,178,180,185). Complete histopathologic evaluation of the involved ductal system is the preferred method of diagnosis, and cytologic assessment should not be relied on for diagnosis.

The usual approach for nipple discharge is surgical excision through a periareolar incision adjacent to the trigger point, the pressure point that elicits nipple discharge (179). A microdochotomy of a single duct or a central duct excision of the major subareolar ducts can be performed under local or general anesthesia. The putative duct can be cannulated, methylene blue can be injected, or a lacrimal probe can be inserted into the duct for localization. A resection of breast tissue for 3 to 5 cm, or until no bloody fluid can be identified in the ductal system, is performed. The patient must be warned of possible skin and nipple loss as a result of compromised vascularity, change in nipple sensation, deformity, inability to breastfeed, and recurrence if only a single duct if removed.

When there is a history of unilateral nipple discharge, localization is not possible, and no mass is palpable, the patient should be reexamined every week for 1 month. When unilateral discharge persists, even without definite localization or tumor, surgical exploration should be considered. The alternative is careful follow-up at intervals of 1 to 3 months. Mammography should be performed. Purulent discharge may originate in a subareolar abscess and requires excision of the related lactiferous sinus (186).
Erosive Adenomatosis of the Nipple

Erosive adenomatosis is a rare benign condition of the nipple that mimics Paget’s disease (187). Patients seek treatment for pruritus, burning, and pain. On clinical examination, the nipple can appear ulcerated, crusting, scaling, indurated, and erythematous. The nipple can be enlarged and more prominent during menstrual cycles (188). The differential diagnosis includes squamous cell carcinoma, psoriasis, contact dermatitis, seborrheic keratosis, adenocarcinoma metastatic to the skin, and unusual primary tumors of the nipple (187). Biopsy should be performed to diagnose the lesion. Local excision is curative (187).
Fat Necrosis

Fat necrosis of the breast is rare but clinically important because it produces a mass, often accompanied by skin or nipple retraction, which is indistinguishable from carcinoma. Fat necrosis often presents as a confusing clinical finding. Trauma is presumed to be the cause, although only about one-half of patients have a history of injury to the breast. Ecchymosis is occasionally seen near the tumor. Tenderness may or may not be present. If untreated, the mass associated with fat necrosis gradually disappears. Diagnostic imaging studies are usually insufficient (189). As a rule, the safest course is needle-core or excisional biopsy of the entire mass to rule out carcinoma (189). Fat necrosis is common after segmental resection and radiation therapy or transverse rectus abdominis musculocutaneous (TRAM) flap (190).
Breast Abscess

Lactational Abscesses

Infection in the breast is rare unless the patient is lactating. Lactational mastitis must be distinguished from lactational abscess (191). During lactation, an area of redness, tenderness, and induration frequently develops in the breast. **Lactational mastitis is caused by transmission of bacteria during nursing and poor hygiene.** The organism most commonly found in lactational mastitis and abscesses is *Staphylococcus aureus* (192). If mastitis is diagnosed, manual pressure, antibiotics, and continued breastfeeding are recommended. In its early stages, the infection often can be treated while breastfeeding is continued by administering an antibiotic such as dicloxacillin 250 mg four times daily, or oxacillin 500 mg four times daily, for 7 to 10 days. **If the lesion progresses to a localized mass with local and systemic signs of infection, an abscess is present. It should be drained, and breastfeeding should be discontinued.**

Nonlactational Abscess

Rarely, infections or abscesses may develop in young or middle-aged women who are not lactating (193). The approach to nonlactational abscess is conservative (194,195). A suspected abscess should be evaluated with preliminary ultrasonography to detect the presence of an inflammatory mass, frank pus, solitary cavity, or a multiloculated abscess (196). Aspiration of pus, if present, and antibiotic therapy is instituted with reaspiration, if necessary (196). When the fluid collection is greater than 3 mL, percutaneous drain placement is an option (194). A single aspiration is sufficient in about one-half of patients (194). Recurrent abscess formation is low (10%) (194). Bacteriologic analysis of 190 abscesses in nonlactating and lactating women showed a preponderance of gram-positive cocci. *S. aureus* was the most common organism isolated (51.3%). Of these, 8.6% were methicillin-resistant *S. aureus*. Other common organisms included mixed anaerobes (13.7%) and anaerobic cocci (6.3%) (196). **If these infections recur after multiple aspirations, incision and drainage followed by excision of the involved lactiferous duct or ducts at the base of the nipple may be necessary during a quiescent interval.** In virtually all cases, mammillary sinus (lactiferous duct fistula) can be confirmed as the cause of reinfection or persistent infection (197). Inflammatory carcinoma is a consideration when erythema of the breast is present. Patients should not undergo prolonged treatment for an apparent infection unless biopsy eliminated the possibility of inflammatory carcinoma.

Subareolar Abscess and Lactiferous Duct Fistula

Subareolar abscess and fistula of the lactiferous ducts secondary to squamous metaplasia can occur (198). The distal duct can be occluded with inspissated debris. Two large reviews report a high association of lactiferous duct fistulae in women who smoke (199,200). The definitive treatment for lactiferous duct sinus is excision of the lactiferous...
duct and drainage of the abscess cavity. In both studies, **the recurrence rate was greater when only incision and drainage were performed.** The most common organism occurring in primary subareolar abscess was S. aureus, but anaerobic organisms occurred more frequently in chronic recurring abscesses (200).
Disorders of Breast Augmentation

Estimates indicate that nearly 4 million women in the United States have undergone augmentation mammoplasty. Breast implants are usually placed under the pectoralis muscle or, less desirably, in the subcutaneous tissue of the breast. Most implants are made of an outer silicone shell filled with a silicone gel or saline.

The complications of breast implantation are significant. Rates of contracture vary in the literature from less than 10% to over 60%. Capsular contraction or scarring around the implant, leading to firmness and distortion of the breast, can be painful and sometimes requires removal of the implant and capsule. Implant rupture may occur in as many as 5% to 10% of women, and bleeding of gel through the capsule is even more common (201). In 2006, the U.S. Food and Drug Administration approved silicone gel filled implants for use in women 22 years or older for cosmetic purposes and for reconstruction after breast surgery or in women with traumatic or congenital breast defects (202). The agency recommends MRI scanning 3 years after the first implant surgery and then every 2 years for the detection of implant rupture.

The agency advised symptomatic women with ruptured implants to discuss the need for surgical removal with their physicians. When there is no evidence of associated symptoms or rupture, implant removal is generally not indicated because the risks of removal are probably greater than the risk of retention. If screening ultrasonography shows no rupture, the probability of rupture is 2.2% (203). If ultrasonography shows rupture, true rupture is present in 37.8%. In this setting, a large number of women would have normal implants removed. When MRI is used in addition to ultrasonography, the probability of rupture increases to 86%.

The suggested association between silicone gel and autoimmune disease is poorly documented (204,205). Among the multiple meta-analyses conducted thus far, none have identified a significant association between breast implants and connective-tissue disease (206). Subsequent studies demonstrated no clinical data proving an increased incidence of connective tissue disorders in patients with silicone gel breast implants (207–209). The data continue to reaffirm previous observations that there is no evidence of an association between breast implants and connective tissue diseases (210). In a study of Danish women undergoing reduction mammoplasty compared with silicone implant augmentation, there was no increased incidence of antinuclear antibodies or other autoantibodies between the groups (211). The augmentation group experienced capsular contraction and more pain than the group undergoing reduction mammoplasty. Any association between implants and an increased incidence of breast cancer is unlikely (212). Breast cancer may develop in any patient with a silicone gel prosthesis.

SECTION V OPERATIVE GYNECOLOGY
The preoperative evaluation should be complete and thorough, taking into account the essential aspects of the patient’s general medical condition and prior surgical history. The risks, benefits, and potential complications of the surgical procedure should be discussed with the patient, including the most frequent complications of the particular surgical procedure. Alternative management, if any, should be presented.

A calculated body mass index (BMI) can be used as a surrogate marker for nutritional status.

Careful and meticulous fluid and electrolyte management is essential for all patients undergoing major surgical procedures.

Although satisfactory analgesia is easily achievable with available methods, patients continue to suffer unnecessarily from postoperative pain.

Prophylactic antibiotics should be employed judiciously. Prompt identification of perioperative infections and their specific treatments are critical to minimize the impact of this common morbidity.

Early in the clinical course, a postoperative small bowel obstruction may exhibit signs and symptoms identical to those of ileus. Initial conservative management as outlined for the treatment of ileus is appropriate.

Because pulmonary embolism is the leading cause of death following gynecologic surgical procedures, the use of prophylactic venous thromboembolism regimens is an essential part of management. In patients at moderate risk, intermittent pneumatic compression (IPC) during and after gynecologic surgery reduces the incidence of deep venous thrombosis on a level similar to that of low-dose or low molecular weight heparin. A combination of mechanical (IPC) and pharmacologic prophylaxis is recommended for high-risk patients.
Patients who are predisposed to cardiovascular, respiratory, and endocrine illnesses must be thoroughly evaluated preoperatively. Coronary artery disease and chronic obstructive pulmonary disease (COPD) are major risk factors for patients undergoing abdominal surgery. Patients with hypertension should receive medication to control their blood pressure before surgery. Perioperative management of medical complications must be prompt and meticulous.

The successful outcome of gynecologic surgery is based on thorough evaluation, careful preoperative preparation, and attentive postoperative care. This chapter discusses approaches to the general perioperative management of patients undergoing major gynecologic surgery with specific medical problems that could complicate the surgical outcome.
Medical History and Physical Examination

Gynecologic surgery should be undertaken only after gaining a thorough understanding of a patient’s medical history and performing a complete physical examination.

The medical history should include detailed questions to identify any medical illnesses that might be aggravated by surgery or anesthesia. Coronary artery disease, pulmonary diseases, and obesity are the most common causes of postoperative complications.

Medications currently being taken (including nonprescription drugs) and those discontinued within the month before surgery should be recorded. Information about the use of “alternative therapies,” herbs, and vitamins should be elicited (1,2). Specific instructions must be given to the patient regarding the need to discontinue any medications before surgery (e.g., aspirin, antiplatelet agents, diuretics, hormone replacement, or oral contraceptives), and those medications that should be continued (e.g., beta-blockers, α-2 agonists, statins, H₂ blockers, and proton pump inhibitors). Collaboration with the anesthesiologist in making decisions about continuing preoperative medications is essential. In the case of herbal medications, there is no evidence that herbal medications improve surgical outcomes and many may increase complications (Table 22.1). It is recommended that all herbal medications be discontinued at least a week before surgery.

Table 22.1 Potential Effects of Common Herbal and Dietary Supplements

Valerian
Excessive sedation and delayed emergence from general anesthesia; benzodiazepine-like acute withdrawal

Yerba mate
May cause hypertension or hypotension and excess sympathetic nervous system stimulation

The patient should be questioned regarding known allergies to medications (e.g., sulfa and penicillin), foods, or environmental agents. A history of sensitivity to shellfish may be the only clue of iodine sensitivity, which could be fatal if intravenous contrast is administered without corticosteroid preparation.

Previous surgical procedures, and the patient’s course following those surgical procedures, should be reviewed to identify and protect against potential complications. The patient should be asked about specific complications, such as excessive bleeding, wound infection, venous thromboembolism, peritonitis, or bowel obstruction. Prior pelvic surgery should alert the gynecologist to the possibility of distorted surgical anatomy such as adhesions or ureteral stricture from previous periureteral scarring. In such cases, it may be prudent to identify any preexisting abnormality by performing computed tomography (CT) or other imaging. Many patients may not be entirely clear about the extent of the previous surgical procedure or the details of intraoperative findings. Therefore, operative notes from previous procedures should be obtained and reviewed.

Family history may identify familial traits that might complicate planned surgery. A family history of excessive intraoperative or postoperative bleeding, venous thromboembolism, malignant hyperthermia, and other potentially inherited conditions should be sought.

The review of systems should be detailed to identify any coexisting medical or surgical conditions. Inquiry about gastrointestinal and urologic function is particularly important before undertaking pelvic surgery because many gynecologic diseases involve adjacent nongynecologic viscera. The patient may have less serious symptoms, which could be corrected along with performing the primary surgery (e.g., stress urinary incontinence, fecal soiling, symptomatic cystocele).

Although many women undergoing gynecologic surgical procedures are otherwise healthy, with pathology identified only on pelvic examination, other major organ systems should not be neglected in the physical examination. Identification of abnormalities, such as a heart murmur, pulmonary compromise, hernia, or osteoarthritis of hips or knees should lead the surgeon to obtain additional testing and consultation to minimize intraoperative and postoperative complications.
Laboratory Evaluation

“Routine” preoperative laboratory testing of healthy women is to be discouraged as abnormal results are infrequent and are rarely of consequence in the surgical or anesthetic management of the patient (3). Despite well-established guidelines, approximately 90% of patients undergo unnecessary testing in a major university medical center (4). The selection of appropriate preoperative laboratory studies should depend on the type of the anticipated surgical procedure and the patient’s medical status.

**Chest x-ray:**
- Over age 60 years undergoing major surgery
- American Society of Anesthesiologists (ASA) 3 or greater
- Cardiovascular disease

**Electrocardiogram (5):**
- Over age 60 years undergoing major surgery
- Any cardiovascular disease or diabetes

**Complete blood count:**
- Major surgery
- ASA 3 or greater

**Renal function:**
- Recognized renal or cardiovascular disease

**Coagulation studies (activated partial thromboplastin time [APTT], prothrombin time [PT], platelet count):**
- Not recommended unless patient has history of bleeding or liver disease (6)

**Urinalysis:**
- Not recommended; may be considered given symptoms or history

Imaging of adjacent organ systems should be undertaken in individual cases as follows:

- CT urography is helpful to delineate ureteral patency and course, especially in the presence of a pelvic mass, gynecologic cancer, or congenital müllerian anomaly. A CT urogram is not of value in the evaluation of most patients undergoing pelvic surgery (7).
- Upper endoscopy, colonoscopy, barium enema, or upper gastrointestinal studies with small bowel assessment may be of value in evaluating some patients before undergoing pelvic surgery. Because of the proximity of the female genital tract to the lower gastrointestinal tract, the rectum and sigmoid colon may be involved with benign (endometriosis or pelvic inflammatory disease) or malignant gynecologic conditions. Conversely, a pelvic mass could have a gastrointestinal origin such as a diverticular abscess or a mass of inflamed small intestines (Crohn disease) or, rarely, a gastric or pancreatic carcinoma. Any patient with gastrointestinal symptoms should be further evaluated.
- Other imaging studies, including ultrasonography, CT scanning, or magnetic resonance imaging (MRI), may be useful in selected patients such as in the evaluation of a pelvic mass.
Preoperative Discussion and Informed Consent

The preoperative discussion should include a description of the surgical procedure, its expected outcome and risks and is the basis for obtaining signed informed consent (8,9). Informed consent is an educational process for the patient and her family and fulfills the physician's need to convey information in understandable terms. The items listed in Table 22.2 should be discussed, and, after each item, the patient and family should be invited to ask questions. Documentation of the discussion is an important component of the patient’s record that the physician should always include with the preprinted consent form.

Table 22.2 Outline of Key Points of the Preoperative Informed Consent Discussion

- The nature and extent of the disease process
- The extent of the actual operation proposed and the potential modifications of the operation, depending on intraoperative findings
- The anticipated benefits of the operation, with a conservative estimate of successful outcome
- The risks and potential complications of the surgery
- Alternative methods of therapy and the risks and results of those alternative methods of therapy
- The results likely if the patient is not treated

Following are components of the informed consent process:

A discussion of the nature and the extent of the disease process should include an explanation in lay terms of the significance of the disease or condition. Printed materials, computer-based learning programs, and videotapes may assist in this process. The patient’s competency to understand the discussion and written consent should be assessed. If the patient speaks a different language, a qualified interpreter should be present and the presence of the interpreter documented.

The goals of surgery should be discussed in detail. Some gynecologic surgical procedures are performed purely for diagnostic purposes (e.g., dilation and curettage, cold knife conization, diagnostic laparoscopy), whereas most are aimed at correcting a specific problem. The extent of the surgery should be outlined, including which organs will be removed. Most patients like to be informed regarding the type of surgical incision and the estimated duration of anesthesia.

The expected outcome of the surgical procedure should be explained. If the procedure is being performed for diagnostic purposes, the outcome will depend on surgical or pathologic findings that are not known before surgery. When treating an anatomic deformity or disease, the expected success of the operation should be discussed, and the potential for failure of the operation (e.g., failure of tubal sterilization
or the possibility that stress urinary incontinence may not be alleviated). When treating cancer, the possibility of finding more advanced disease and the potential need for adjunctive therapy (e.g., postoperative radiation therapy or chemotherapy) should be mentioned. Other issues of importance to the patient include discussion of loss of fertility or loss of ovarian function. These issues should be raised by the physician to ensure that the patient adequately understands the pathophysiology that may result from the surgery and to allow her to express her feelings regarding these emotionally charged issues. Unanticipated findings at the time of surgery should be mentioned. For example, if the ovaries are unexpectedly found to be diseased, the best surgical judgment may be that they should be removed.

The risks and potential complications of the surgical procedure should be discussed, including the most frequent complications of the particular surgical procedure. For most major gynecologic surgery, the risks include intraoperative and postoperative hemorrhage, postoperative infection, venous thromboembolism, injury to adjacent viscera, and wound complications. The patient should understand that minimally invasive surgery may have many of the same risks of injury or complications as does “open” surgery. Given the potential for transfusion of blood products, it should be clarified whether the patient would object to receiving a transfusion. Preexisting medical problems (e.g., diabetes, obesity, chronic obstructive pulmonary disease [COPD], coronary artery disease) result in additional risks and should be reviewed with the patient. Measures that will be taken to reduce the risk of complications should be described (e.g., prophylactic antibiotics, bowel preparation, venous thromboembolism prophylaxis).

The usual postoperative course should be discussed in enough detail to allow the patient to understand what to expect in the days following surgery. Information regarding the need for a suprapubic catheter, prolonged central venous monitoring, or an intensive care stay helps the patient accept her postoperative course and avoids surprises to the patient and her family that may be disconcerting. The expected duration of the recovery period, both in and out of the hospital, should be outlined.

Alternative methods of therapy should be discussed, including medical management or other surgical approaches. The patient should have an understanding of the outcome of the disease if nothing is done.
General Considerations

Nutrition

Young patients undergoing elective gynecologic surgery have adequate nutritional stores and, for the most part, do not require nutritional support. All patients should have a nutritional assessment, especially elderly patients and those undergoing gynecologic cancer surgery or other major gynecologic procedures in which a prolonged postoperative recovery is expected. Nutritional status should be reassessed at regular intervals postoperatively until the patient successfully returns to a regular diet.

A nutritional assessment includes a careful history and physical examination, which are the most useful, reliable, and cost-effective methods of determining a patient’s nutritional status. In particular, information about recent weight loss, dietary history, fad diets, extreme exercise, or anorexia or bulimia should be elucidated. Physical evidence of malnutrition includes temporal wasting, muscle wasting, ascites, and edema. Accurate height and weight measurements should be obtained and an ideal body weight, percentage ideal body weight, and percentage usual body weight may be calculated. Many Internet-based body weight calculators are available. A variety of techniques were developed to determine a patient’s nutritional state; however, many methods lack clinical utility outside of a research setting. Anthropometric measurements of skin-fold thickness and arm-muscle circumference provide an estimate of total body fat and lean muscle mass.

The calculated body mass index (BMI) can be used as a surrogate marker for nutritional status. The BMI is calculated as body weight in kilograms divided by the height in square centimeters. A BMI less than 22 increases the risk of malnutrition, and a BMI less than 19 gives clear evidence of malnutrition (10).

Patients who have lost less than 6% of their ideal body weight do not need preoperative nutritional intervention. However, patients who have lost more than 10% of their ideal body weight in 6 months meet the definition of severely malnourished and should be considered for preoperative intervention (11). Patients who have lost between 6% and 10% should undergo further studies to determine if preoperative intervention is needed. Laboratory assessments of albumin, transferrin, and prealbumin may be obtained in addition to the routine preoperative tests. The degree of malnutrition can in part be determined by serum concentrations of albumin, transferrin, and prealbumin. The levels of these serum proteins are greatly influenced by the patient’s level of hydration. Prealbumin has the shortest half-life, at 2 to 3 days, and levels of this protein are depressed very early in comparison with serum transferrin and albumin, which have half-lives of 8 and 20 days, respectively (12). Serum albumin is a substitute for the Prognostic Nutritional Index, which is a time-consuming calculation, in assessing malnutrition in women with gynecologic malignancies (13). A serum albumin level of 3.5 to 5.0 is in the normal range, 2.8 to 3.4 is considered to indicate mild
malnutrition, 2.1 to 2.7 moderate malnutrition, and less than 2.1 severe malnutrition (14). Hypoalbuminemia is correlated with morbidity, mortality, and increased postoperative complication rates in data from the National Surgical Quality Improvement Program (15). Decisions regarding the need for nutritional support should be based on several individualized factors. These factors include the patient’s prior nutritional state, the anticipated length of time in which the patient will not be able to eat, the severity of surgery, and the likelihood of complications. The nutritional assessment should determine whether the cause of the malnutrition is increased enteral loss (malabsorption, intestinal fistula), decreased oral intake, increased nutritional requirements as a result of hypermetabolism (sepsis, malignancy), or a combination of these factors. Severe malnutrition, if not corrected, can further complicate the postoperative problem by causing altered immune function, chronic anemia, impaired wound healing, and eventually multiple organ system failure and death.

The patient’s nutritional requirements are increased by surgery for several reasons. First, there is a period following surgery during which oral intake is not allowed or is very limited. In addition, the operation itself causes increased protein catabolism, increased energy requirements, and a negative nitrogen balance. If the surgery is uncomplicated and the patient is without food for less than 7 days, this response is limited and patients usually recover without the need for nutritional support. An adequate diet is defined as providing 75% of estimated caloric and protein needs. Therefore, if an adequate oral diet is not expected for 7 to 10 days, perioperative nutritional support may be required to avoid progressive malnutrition and associated complications (14). Perioperative nutritional support reduces operative morbidity and decreases the length of hospitalization when commenced early in the postoperative course. Patients with either normal nutritional indices or mild or moderate malnutrition, who will be undergoing surgical procedures likely to require a prolonged catabolic period of more than 7 to 10 days, should have enteral or parenteral nutrition instituted in the early postoperative period as soon as the patient is hemodynamically stable. This type of management should be strongly considered in patients undergoing pelvic exenterations, urinary diversions, or multiple enterectomies (16). Preoperative nutritional support is indicated for patients who have significant preexisting malnutrition or require major elective surgery. According to the American Society for Parenteral and Enteral Nutrition (ASPEN) guidelines, evidence-based medicine supports the use of preoperative nutritional support for 7 to 14 days in moderately to severely malnourished patients undergoing major nonemergent gastrointestinal surgery (12). A Veterans Affairs Total Parenteral Nutrition Cooperative Study found that severely malnourished patients preconditioned with total parenteral nutrition (TPN) had fewer complications than did control patients, excluding infectious complications (17). In a meta-analysis review of 22 studies of preoperative TPN use, a 10% decrease in postoperative complications occurred in TPN-supported patients (18). In a prospective trial including 108 women with ovarian cancer who underwent surgical cytoreduction, 88 patients had prealbumin levels less than 18 mg/dL and 24 had prealbumin levels less than 10 mg/dL (19). All postoperative mortality (23%) and 61.5% of all complications
occurred in women with prealbumin less than 10 mg/dL. Women who received preoperative TPN and had prealbumin levels that increased to greater than 10 mg/dL did not have significantly increased complications. These findings lend support to consideration of preoperative TPN or neoadjuvant chemotherapy with interval cytoreduction when the nutritional status improves. These findings are encouraging but not supported by all studies or meta-analyses (20). If preoperative TPN is prescribed, it should be tapered and stopped at midnight before surgery, restarted 24 to 72 hours after the procedure, and continued until the patient is able to meet nutritional requirements.

ASPEN guidelines do not support the routine use of nutritional support in the immediate postoperative period for patients undergoing major gastrointestinal surgery; however, the guidelines do indicate a role for nutritional support postoperatively in patients in whom oral intake will be inadequate for 7 to 10 days (12). Clinical trials demonstrate that TPN can improve nutritional status as measured by biochemical assays, immune function, and nitrogen balance. The effect of TPN on clinical outcome is less well established. Despite what seems reasonable, based on common sense and preoperative nutritional parameters, the data do not support TPN for mild to moderately malnourished patients. With severe malnutrition, preoperative TPN seems to be beneficial and should be instituted.

Route of Administration

After the decision is made that nutritional support is required, the appropriate route of administration must be determined. Enteral nutrition should be considered primarily because it is easy to deliver, associated with the fewest complications, linked to enhanced wound healing, and relatively inexpensive (21). Contraindications to this route of delivery include intestinal obstruction, gastrointestinal bleeding, and diarrhea. Many types of preparations are commercially available and can be chosen based on their caloric content, fat content, protein content, osmolality, viscosity, and price. Depending on the patient’s problem, the route of delivery may be through a Dobhoff feeding tube, a gastrostomy tube, or a feeding jejunostomy tube (22). If the gastrointestinal tract is unusable for more than 7 days postoperatively, TPN should be implemented.

Total parenteral nutrition must be delivered through a central vein and has wide acceptance as a means of providing nutritional support for surgically ill patients. It must be delivered through a subclavian or internal jugular vein, and the catheter must be placed using meticulous sterile surgical technique. Only intravenous access lines in the right atrium, superior vena cava, or inferior vena cava can be truly deemed central lines (23). Proper daily care is required to avoid infectious complications. When managed by an experienced team, the most frequent complication, infection, can be minimized (24).

Composition of Total Parenteral Nutrition Solutions

Calories. The daily caloric requirements can be met by providing 1,000
calories more than the patient’s basal energy expenditure. Caloric requirements can be calculated based on Long’s modification of the Harrison-Benedict formula for actual energy expenditure (AEE) (25). This is the most accurate available method to calculate an individual’s AEE:

\[
AEE \text{ (women)} = [655.10 + 9.56 \text{ Weight (kg)} + 1.85 \text{ Height (cm)} - 4.68 \text{ Age (yrs)}] \times \text{ (activity factor)} \times \text{ (injury factor)}
\]

**Activity factor:** confined to bed (1.2), out of bed (1.3).

**Injury factor:** minor surgery (1.2), skeletal trauma (1.3), major sepsis (1.6), severe burn (2.1).

Alternatively, daily caloric requirements can be met by giving the patient 35 kcal/kg/day for maintenance and 45 kcal/kg/day for anabolic states.

**Protein. Daily nitrogen requirements may be met by providing 1 g of nitrogen (6.25 g of protein) for every 130 to 150 calories.** Protein is provided by synthetic amino acids. The amino acids provide 15% to 20% of total calories (24).

**Carbohydrates.** The carbohydrate base of TPN is dextrose (glucose) in approximately 25% solution. Adults need approximately 100 g of dextrose per day at baseline. The maximal rate of glucose oxygenation in adults is approximately 7 g/kg/day, and glucose administration in excess of the caloric requirements can lead to fatty infiltration of the liver and other metabolic complications. When given by TPN infusion, the dextrose tolerance in critically ill patients is 5 mg/kg/min (24). Insulin should be used to maintain serum glucose concentration between 150 and 250 mg/dL, and it may be added directly to the TPN solution.

**Fats.** Lipids in a 10% to 20% emulsion can be given as further caloric supplement and supply the essential fatty acids, linoleic acid, and α-linoleic acids. More calories can be given in the form of free fatty acids, which are the major source of energy for most peripheral tissues. When lipids are used as a major source of calories, a minimum of 50 to 150 g per day of glucose should also be given to provide a substrate for the central nervous system. Most patients can tolerate up to 2 g of fat per kilogram of weight per day, and daily dosages should not exceed 4 g of fat per kilogram of weight per day. In critically ill patients, the lipid content should not exceed 1 g/kg/day. These lipid emulsions are isotonic and can be delivered simultaneously with the protein and carbohydrate mixture in a 3-L bag over a 24-hour infusion. In general, 30% to 50% of nonprotein calories should be supplied in lipid form. Serum triglyceride levels should be monitored to ensure that the patient can metabolize the fat.

**Electrolytes, vitamins, and minerals.** In addition to calories and protein, nutritional support should be maintained in terms of electrolytes, vitamins, and trace elements. Daily maintenance requirements for electrolytes are as follows: sodium, 40 to 50 mEq; potassium, 30 to 40 mEq; magnesium, 8 to 10 mEq; calcium, 2 to 5 mEq; and phosphate, 13 to 25 mmol (24). A number of vitamins and trace elements must also be supplied to ensure that the patient is eumetabolic.
Fluid and Electrolytes

Water constitutes approximately 50% to 55% of the body weight of the average woman. Two-thirds of this water is contained in the intracellular compartment. One-third is contained in the extracellular compartment, of which one-fourth is contained in plasma, and the remaining three-fourths is in the interstitium.

Osmolarity, or tonicity, is a property derived from the number of particles in a solution. Sodium and chloride are the primary electrolytes contributing to the osmolarity of the extracellular compartment. Potassium and, to a lesser extent, magnesium and phosphate are the major intracellular electrolytes. Water flows freely between the intracellular and the extracellular spaces to maintain osmotic neutrality throughout the body. Any shifts in osmolarity in any fluid spaces within the body are accompanied by corresponding shifts in free water from spaces of lower to higher osmolarity, thus maintaining equilibrium.

The average adult daily fluid maintenance requirement is approximately 30 mL/kg/day, or 2,000 to 3,000 mL per day (26). This level is offset partially by insensible losses of 1,200 mL per day, which include losses from the lungs (600 mL), skin (400 mL), and gastrointestinal tract (200 mL). Urinary output from the kidney accounts for the remainder of the fluid loss, and this output will vary depending on total body intake of water and sodium. Approximately 600 to 800 mOsm of solute are excreted by the kidneys daily. Healthy kidneys can concentrate urine up to approximately 1,200 mOsm and, therefore, the minimum output can range between 500 and 700 mL per day. The maximal urine output of the kidney can be as high as 20 L per day, as seen in patients with diabetes insipidus. In healthy individuals, the kidney adjusts output commensurate with daily fluid intake.

The major extracellular buffer used in the acid-base balance is the bicarbonate-carbonic acid system: \[ \text{CO}_2 + \text{H}_2\text{O} \leftrightarrow \text{H}_2\text{CO}_3 \leftrightarrow \text{H}^+ + \text{HCO}_3^- \] (27). Typically, the body will maintain a bicarbonate-to-carbonic acid ratio of 20:1 to maintain an extracellular pH of 7.4. Both the lung and the kidney play integral roles in the maintenance of normal extracellular pH via retention or excretion of carbon dioxide and bicarbonate. Under conditions of alkalosis, minute ventilation decreases and renal excretion of bicarbonate increases to restore the normal ratio of bicarbonate to carbonic acid; the opposite occurs with acidosis.

Ultimately, the kidney plays the most important role in fluid and electrolyte balance through excretion and retention of water and solute. Circulating antidiuretic hormone and aldosterone help modulate the process. Serum osmolarity affects hypothalamic release of antidiuretic hormone and aldosterone secretion in response to renal perfusion. Under states of dehydration or hypovolemia, serum antidiuretic hormone levels increase, leading to increased resorption of water in the distal tubule of the kidney. Increased aldosterone release promotes increased sodium and water retention. The opposite occurs in states of fluid excess. Individuals with normal renal function and circulating antidiuretic hormone and aldosterone levels maintain normal serum osmolarity and electrolyte
Various disease states can alter the normal fluid and electrolyte homeostatic mechanisms, making perioperative fluid and electrolyte management more difficult. Patients with intrinsic renal disease are unable to excrete solute and to maintain acid-base balance. In patients undergoing the stress of chronic starvation or severe illness, there may be an inappropriately high level of circulating antidiuretic hormone and aldosterone, resulting in fluid and sodium retention. With severe cardiac disease, secondary renal hypoperfusion can lead to increased aldosterone synthesis and increased sodium and water retention by the kidney. Patients with severe diabetes can have significant osmotic diuresis as well as acid-base dysfunction secondary to circulating keto acids. Treatment of renal, cardiac, or endocrine disorders preoperatively is imperative and often will rectify fluid and electrolyte abnormalities.

**Special attention is warranted in the elderly patient undergoing surgery. Normal physiological changes associated with aging can increase the likelihood of fluid and electrolyte disorders.** These changes include decreased glomerular filtration rate, decreased urinary concentrating ability, and narrowed limits for excretion of water and electrolytes (28). Fluid and electrolyte management in the perioperative period requires knowledge of the daily fluid and electrolyte requirements for maintenance, replacement of ongoing fluid and electrolyte losses, as well as correction of any existing abnormalities.

### Fluid and Electrolyte Maintenance Requirements

The body adjusts to higher and lower volumes of intake by changes in plasma tonicity. Alterations in plasma tonicity induce adjustments in circulating antidiuretic hormone levels, which ultimately regulate the amount of water retained in the distal tubule of the kidney. In the preoperative and the early postoperative periods, it is usually necessary to replace only sodium and potassium. Chloride is automatically replaced, concomitant with sodium and potassium, because chloride is the usual anion used to balance sodium and potassium in electrolyte solutions. There are various commercially available solutions containing 40 mmol of sodium chloride, with smaller amounts of potassium, calcium, and magnesium, designed to meet the requirements of a patient who is receiving 3 L of intravenous fluids per day. **The daily requirement can be met by any combination of intravenous fluids.** For example, 2 L of D5 (5% dextrose)/0.45 normal saline (7 mEq sodium chloride each), supplemented with 20 mEq of potassium chloride, followed by 1 L of D5W (5% dextrose in water) with 20 mEq of potassium chloride, would suffice.

### Fluid and Electrolyte Replacement

Fluid and electrolyte losses beyond the daily average must be replaced by appropriate solutions. The choice of solutions for replacement depends on the composition of the fluids lost. Often, it is difficult to measure free water loss, particularly in patients who
have high losses from the lungs, skin, or the gastrointestinal tract. Weighing these patients daily can be very useful. Up to 300 g of weight loss daily can be attributable to weight loss from catabolism of protein and fat in the patient who is taking nothing by mouth (26). Any loss beyond this level represents fluid loss, which should be replaced accordingly.

**Patients with a high fever can have increased pulmonary and skin loss of free water, sometimes in excess of 2 to 3 L per day.** These losses should be replaced with free water in the form of D5W. Perspiration typically has one-third the osmolarity of plasma and can be replaced with D5W or, if the loss is excessive, with D5/0.25 normal saline.

**Patients with acute blood loss need replacement with appropriate isotonic fluid or blood or both.** There is a wide range of plasma volume expanders, including albumin, dextran, and hetastarch solutions, that contain large molecular weight particles (<50 kDa molecular weight). These particles are slow to exit the intravascular space, and about one-half of the particles remain after 24 hours. Controversy exists over the ideal strategy for intravascular volume replacement (29). A systematic review of 25 randomized clinical trials demonstrated preserved renal function and reduced intestinal edema in surgical patients receiving hyperoncotic albumin solutions, as compared with control fluids (30). Meta-analyses on the use of human albumin and crystalloids versus colloids in fluid resuscitation did not show a benefit in mortality rates (31,32). Caution is required in interpreting results from these pooled controlled trials because mortality outcome was not the end point of most of the studies, and publication bias is a limitation. Possible side effects with synthetic colloid solutions include adverse affects on hemostasis, severe anaphylactic reactions, and impairment of renal function (29). These solutions are expensive and for most cases, simple replacement with 0.9 normal saline or lactated Ringer’s solution will suffice. One-third of the volume of lactated Ringer’s solution or normal saline typically will remain in the intravascular space and the remainder goes to the interstitium.

**Appropriate replacement of gastrointestinal fluid loss depends on the source of fluid loss in the gastrointestinal tract.** Gastrointestinal secretions beyond the stomach and up to the colon are typically isotonic with plasma, with similar amounts of sodium, slightly lower amounts of chloride, slightly alkaline pH, and more potassium (in the range of 10 to 20 mEq/L). Under normal conditions, stool is hypotonic. However, under conditions of increased flow (i.e., severe diarrhea), stool contents are isotonic with a composition similar to that of the small bowel contents. Gastric contents are typically hypotonic, with one-third the sodium of plasma, increased amounts of hydrogen ion, and low pH.

**In patients who have gastric outlet obstruction, nausea, and vomiting, or who undergo nasogastric suction, appropriate replacement of gastric secretions can be provided with a solution such as D5/0.45 normal saline with 20 mEq/L of potassium.** Potassium supplementation is particularly important to prevent hypokalemia.
In these patients, whose kidneys attempt to conserve hydrogen ions in the distal tubule of the kidney in exchange for potassium ions.

In patients with bowel obstruction, 1 to 3 L of fluid can be sequestered daily in the gastrointestinal tract. This fluid should be replaced with isotonic saline or lactated Ringer’s solution. Similarly, patients with enterocutaneous fistulas or new ileostomies should receive replacement with isotonic fluids.

**Correction of Existing Fluid and Electrolyte Abnormalities**

Patients who have fluid or electrolyte abnormalities preoperatively can pose a diagnostic challenge. The correct diagnosis and therapy is contingent on a correct assessment of total body fluid and electrolyte status. The management of hyponatremia, for example, may be either fluid restriction or fluid replacement. The choice of treatment depends on whether there is overall extracellular fluid excess and normal body sodium stores or decreased overall total body sodium stores and extracellular fluid. A detailed history is necessary to disclose any underlying medical illness and to assess the amount and duration of any abnormal fluid losses or intake. Initial evaluation should include an assessment of hemodynamic, clinical, and urinary parameters to determine the overall level of hydration as well as the fluid status of the extracellular fluid compartment. The patient who has good skin turgor, moist mucosa, stable vital signs, and good urinary output is well hydrated. Nonpitting edema is indicative of extracellular fluid excess, whereas patients with orthostasis, sunken eyes, parched mouth, and decreased skin turgor have extracellular volume contraction. A patient’s overall extracellular fluid status does not always reflect the hydration status of the intravascular compartment. A patient can have increased interstitial fluid and yet be intravascularly dry, requiring replacement with isotonic fluid.

The laboratory workup for patients who may have preexisting fluid problems should include assessment of blood hematocrit, serum chemistry, glucose, blood urea nitrogen (BUN) and creatinine, urine osmolarity, and urine electrolyte levels. Serum osmolarity is mainly a function of the concentration of sodium and is given by the following equation:

\[2[Na^+] + \frac{\text{glucose (mg/dL)}}{18} + \frac{\text{BUN (mg/dL)}}{2.8}\]

Normal serum osmolarity is typically 290 to 300 mOsm. Blood hematocrit will rise or fall inversely at a rate of 1% per 500-mL alteration of extracellular fluid volume. The BUN:creatinine ratio is typically 10:1 but will rise to a ratio of greater than 20:1 under conditions of extracellular fluid contraction. Under conditions of extracellular fluid deficit, urine osmolarity will typically be high (>400 mOsm), whereas urine sodium concentration is low (<15 mEq/L), indicative of an attempt by the kidney to conserve sodium. Under conditions of extracellular fluid excess or in cases of renal disease in which the kidney has impaired ability to retain sodium and water, urine osmolarity will be low and
urine sodium will be high (>30 mEq/L). Changes in sodium can give insight into the degree of extracellular fluid excess or deficit. In the average person, the serum sodium rises by 3 mmol/L for every liter of water deficit and falls by 3 mmol/L for each liter of water excess. One must be careful in making these estimates because patients with prolonged water and electrolyte loss can have low serum sodium levels and marked water deficits.

Specific Electrolyte Disorders

Hyponatremia

Because sodium is the major extracellular cation, shifts in serum sodium levels are usually inversely correlated with the hydration state of the extracellular fluid compartment. The pathophysiology of hyponatremia is usually expansion of body fluids leading to excess total body water (27,33). Symptomatic hyponatremia usually does not occur until the serum sodium is below 120 to 125 mEq/L. The severity of the symptoms (nausea, vomiting, lethargy, seizures) is related more to the rate of change of serum sodium than to the actual serum sodium level.

Hyponatremia in the form of extracellular fluid excess can be seen in patients with renal or cardiac failure and in conditions such as nephrotic syndrome, in which total body salt and water are increased, with a relatively greater increase in the latter. Administration of hypertonic saline to correct the hyponatremia would be inappropriate in this setting. The treatment should include, in addition to correcting the underlying disease process, water restriction with diuretic therapy. Inappropriate secretion of antidiuretic hormone (ADH) can occur with head trauma, pulmonary or cerebral tumors, and states of stress. The abnormally elevated ADH results in excess water retention. Treatment includes water restriction and, if possible, correction of the underlying cause. Demeclocycline, a tetracycline antibiotic, is effective in this disorder via its action in the kidney. The introduction of vasopressin receptor antagonists, such as tolvaptan, may replace demeclocycline as the drug of choice for the syndrome of inappropriate ADH secretion (34).

Inappropriate replacement of body salt losses with water alone will result in hyponatremia. This situation will typically occur in patients who lose large amounts of electrolytes secondary to vomiting, nasogastric suction, diarrhea, or gastrointestinal fistulas, and who received replacement with hypotonic solutions. Simple replacement with isotonic fluids and potassium will usually correct the abnormality. Rarely, rapid correction of the hyponatremia is necessary, in which case hypertonic saline (3%) can be administered. Hypertonic saline should be administered very cautiously to avoid a rapid shift in serum sodium, which will induce central nervous system dysfunction.

Hypernatremia

Hypernatremia is an uncommon condition that can be life-threatening if severe (serum sodium greater than 160 mEq/L). The pathophysiology is extracellular fluid
deficit. The resultant hyperosmolar state leads to decreased water volume in cells in the central nervous system, which, if severe, can cause disorientation, seizures, intracranial bleeding, and death. The causes include excessive extrarenal water loss, which can occur in patients who have a high fever, have undergone tracheostomy in a dry environment, or have extensive thermal injuries; who have diabetes insipidus, either central or nephrogenic; and who have iatrogenic salt loading. The treatment involves correction of the underlying cause (correction of fever, humidification of the tracheostomy, administration of desmopressin for control of central diabetes insipidus) and replacement with free water either by the oral route or intravenously with D5W. As with severe hyponatremia, marked hypernatremia should be corrected slowly, no faster than 10 mEq per day, unless the patient is symptomatic from severe acute hypernatremia (35).

**Hypokalemia**

Hypokalemia may be encountered preoperatively in patients with significant gastrointestinal fluid loss (prolonged emesis, diarrhea, nasogastric suction, intestinal fistulas) and marked urinary potassium loss secondary to renal tubular disorders (renal tubular acidosis, acute tubular necrosis, hyperaldosteronism, prolonged diuretic use). It can arise from prolonged administration of potassium-free parenteral fluids in patients who are restricted from ingesting anything by mouth. The symptoms associated with hypokalemia include neuromuscular disturbances, ranging from muscle weakness to flaccid paralysis, and cardiovascular abnormalities, including hypotension, bradycardia, arrhythmias, and enhancement of digitalis toxicity. These symptoms rarely occur unless the serum potassium level is less than 3 mEq/L. The treatment is potassium replacement. Oral therapy is preferable in patients who are on an oral diet. If necessary, potassium replacement can be given intravenously in doses that should not exceed 10 mEq per hour.

**Hyperkalemia**

Hyperkalemia is encountered infrequently in preoperative patients. It is usually associated with renal impairment but can be seen in patients who have adrenal insufficiency, are taking potassium-sparing diuretics, and have marked tissue breakdown such as that occurring with crush injuries, massive gastrointestinal bleeding, or hemolysis. The clinical manifestations are mainly cardiovascular. Marked hyperkalemia (potassium >7 mEq/L) can result in bradycardia, ventricular fibrillation, and cardiac arrest. The treatment chosen depends on the severity of the hyperkalemia and whether there are associated cardiac abnormalities detected with electrocardiography. Calcium gluconate (10 mL of a 10% solution), given intravenously, can offset the toxic effects of hyperkalemia on the heart. One ampule each of sodium bicarbonate and D5W, with or without insulin, will cause a rapid shift of potassium into cells. Over the longer term, cation exchange resins such as sodium polystyrene sulfate (Kayexalate), taken orally or by enema, will bind and decrease total body potassium. Hemodialysis is reserved for emergent conditions in which other
measures are not sufficient or have failed (35).

**Postoperative Fluid and Electrolyte Management**

Several hormonal and physiologic alterations in the postoperative period may complicate fluid and electrolyte management. The stress of surgery induces an inappropriately high level of circulating ADH. Circulating aldosterone levels are increased, especially if sustained episodes of hypotension occurred either intraoperatively or postoperatively. The elevated levels of circulating ADH and aldosterone make postoperative patients prone to sodium and water retention.

**Total body fluid postoperative volume may be altered significantly.** First, 1 mL of free water is released for each gram of fat or tissue that is catabolized and, in the postoperative period, several hundred milliliters of free water are released daily from tissue breakdown, particularly in the patient who has undergone extensive intra-abdominal dissection and who is restricted from ingesting food and fluids by mouth. This free water is often retained in response to the altered levels of ADH and aldosterone. Second, fluid retention is further enhanced by third spacing, or sequestration of fluid in the surgical field. The development of an ileus may result in an additional 1 to 3 L of fluid per day being sequestered in the bowel lumen, bowel wall, and peritoneal cavity.

In contrast to renal sodium homeostasis, the kidney lacks the capacity for retention of potassium. In the postoperative period, the kidneys continue to excrete a minimum of 30 to 60 mEq/L of potassium daily, irrespective of the serum potassium level and total body potassium stores (27). If this potassium is not replaced, hypokalemia may develop. Tissue damage and catabolism during the first postoperative day usually result in the release of sufficient intracellular potassium to meet the daily requirements. Beyond the first postoperative day, potassium supplementation is necessary.

**Correct maintenance of fluid and electrolyte balance in the postoperative period starts with the preoperative assessment, with emphasis on establishing normal fluid and electrolyte parameters before surgery.** Postoperatively, close monitoring of daily weight, urine output, serum hematocrit, serum electrolytes, and hemodynamic parameters will yield the necessary information to make correct adjustments in crystalloid replacement. The normal daily fluid and electrolyte requirements must be met and any unusual fluid and electrolyte losses, including those from the gastrointestinal tract, lungs, or skin, must be compensated. After the first few postoperative days, third-space fluid begins to return to the intravascular space, and ADH and aldosterone levels revert to normal. The excess fluid retained perioperatively is mobilized and excreted through the kidneys, and exogenous fluid requirements decrease. Patients with inadequate cardiovascular or renal reserve are prone to fluid overload during this time of third-space reabsorption, especially if intravenous fluids are not appropriately reduced.
The most common fluid and electrolyte disorder in the postoperative period is fluid overload. Fluid excess can occur concomitantly with normal or decreased serum sodium. Large amounts of isotonic fluids are usually infused intraoperatively and postoperatively to maintain blood pressure and urine output. Because the infused fluid is often isotonic with plasma, it will remain in the extracellular space. Under such conditions, serum sodium will remain within normal levels. Fluid excess with hypotonicity (decreased serum sodium) can occur if large amounts of isotonic fluid losses (e.g., blood and gastrointestinal tract) are inappropriately replaced with hypotonic fluids. The predisposition toward retention of free water in the immediate postoperative period compounds the problem. An increase in body weight occurs concomitantly with the fluid expansion. In the patient who is not allowed anything by mouth, catabolism should induce a daily weight loss as great as 300 g per day. The patient who is gaining weight in excess of 150 g per day is in a state of fluid expansion. Simple fluid restriction will correct the abnormality. When necessary, diuretics can be used to increase urinary excretion.

States of fluid dehydration are uncommon but will occur in patients who have large daily losses of fluid that are not replaced. Gastrointestinal losses should be replaced with the appropriate fluids. Patients with high fevers should be given appropriate free water replacement, because up to 2 L per day of free water can be lost through perspiration and hyperventilation. Although these increased losses are difficult to monitor, a reliable estimate can be obtained by monitoring body weight.

Postoperative Acid-Base Disorders

A variety of metabolic, respiratory, and electrolyte abnormalities in the postoperative period can result in an imbalance in normal acid-base homeostasis, leading to alkalosis or acidosis. Changes in the respiratory rate directly affect the amount of carbon dioxide that is exhaled. Respiratory acidosis will result from carbon dioxide retention in patients who have hypoventilation from central nervous system depression. This condition can result from oversedation with narcotics, particularly in the presence of concurrent severe chronic obstructive pulmonary disease. Respiratory alkalosis can result from hyperventilation caused by excitation of the central nervous system by drugs, pain, or excess ventilator support. Numerous metabolic derangements can result in metabolic alkalosis or acidosis. Proper fluid and electrolyte replacement as well as maintenance of adequate tissue perfusion will help prevent most acid-base disorders that occur during the postoperative period.

Alkalosis

The most common acid-base disorder encountered in the postoperative period is alkalosis (27). Alkalosis is usually of no clinical significance and resolves spontaneously. Several etiologic factors may include hyperventilation associated with pain; posttraumatic transient hyperaldosteronism, which results in decreased renal bicarbonate excretion; nasogastric suction, which removes hydrogen ions; infusion of bicarbonate during blood transfusions in the form of citrate, which is converted to
bicarbonates; administration of exogenous alkali; and use of diuretics. Alkalosis can be corrected with removal of the inciting cause and the correction of extracellular fluid and potassium deficits (Table 22.3). Full correction usually can be safely achieved over 1 to 2 days.

Marked alkalosis, with serum pH higher than 7.55, can result in serious cardiac arrhythmias or central nervous system seizures. Myocardial excitability is particularly pronounced with concurrent hypokalemia. Under such conditions, fluid and electrolyte replacement may not be sufficient to correct the alkalosis rapidly. Acetazolamide (250 to 500 mg) can be given orally or intravenously two to four times daily to induce renal bicarbonate diuresis. Treatment with an acidifying agent rarely is necessary and should be reserved for acutely symptomatic patients (i.e., those with cardiac or central nervous system dysfunction) or for patients with advanced renal disease. Under such conditions, hydrogen chloride (5 to 10 mEq per hour of a 100-mmol solution) can be given via a central intravenous line. Ammonium chloride can be given orally or intravenously but should not be given to patients with hepatic disease.

**Acidosis**

Metabolic acidosis is less common than alkalosis during the postoperative period, but acidosis can be serious because of its effect on the cardiovascular system. Under conditions of acidosis, there are decreased myocardial contractility, a propensity for vasodilation of the peripheral vasculature leading to hypotension, and refractoriness of the fibrillating heart to defibrillation (27). These effects promote decompensation of the cardiovascular system and can hinder attempts at resuscitation.

Metabolic acidosis results from a decrease in serum bicarbonate levels caused by the
consumption and replacement of bicarbonate by circulating acids or the replacement by other anions such as chloride. The proper workup includes a measurement of the anion gap:

\[
\text{Anion gap} = (\text{Na}^+ + \text{K}^+) - (\text{Cl}^- + HCO_3^-) = 10 \text{ to } 14 \text{ mEq/L (normal)}
\]

The anion gap is composed of circulating protein, sulfate, phosphate, citrate, and lactate (36).

**With metabolic acidosis, the anion gap can be increased or normal.** An increase in circulating acids will consume and replace bicarbonate ion, increasing the anion gap. The causes include an increase in circulating lactic acid secondary to anaerobic glycolysis, such as that seen under conditions of poor tissue perfusion; increased ketoacids, as with cases of severe diabetes or starvation; exogenous toxins; and renal dysfunction, which leads to increased circulating sulfates and phosphates (37). The diagnosis can be established via a thorough history and measurement of serum lactate (normal <2 mmol/L), serum glucose, and renal function parameters. Metabolic acidosis in the face of a normal anion gap is usually the result of an imbalance of the ions chloride and bicarbonate, which occurs under conditions leading to excess chloride and decreased bicarbonate. Hyperchloremic acidosis can be seen in patients who underwent saline loading. Bicarbonate loss will be seen in patients with small bowel fistulas, new ileostomies, severe diarrhea, or renal tubular acidosis. In patients with marked extracellular volume expansion, which often occurs postoperatively, the relative decrease in serum sodium and bicarbonate will result in a mild acidosis. A summary of the various causes of metabolic acidosis is shown in **Table 22.4**.

</table>

The treatment of metabolic acidosis depends on the cause. In patients with lactic acidosis, restoration of tissue perfusion is imperative. This state can be accomplished through cardiovascular and pulmonary support as needed, oxygen therapy, and aggressive treatment of systemic infection wherever appropriate. Ketosis from diabetes can be corrected gradually with insulin therapy. Ketosis resulting from chronic starvation or from lack of caloric support postoperatively can be corrected with nutrition. In patients with normal anion gap acidosis, bicarbonate lost from the gastrointestinal tract should be replaced, excess chloride administration can be curtailed, and, where necessary, a loop diuretic can be used to induce renal clearance of chloride. Dilutional acidosis can be corrected with mild fluid restriction.

**Bicarbonates should not be given unless serum pH is lower than 7.2 or severe cardiac complications secondary to acidosis are present.** Close monitoring of serum potassium levels is mandatory. Under states of acidosis, potassium will exit the cell and enter the circulation. The patient with a normal potassium concentration and metabolic acidosis is actually depleted of intracellular potassium. Treatment of the acidosis without potassium replacement will result in severe hypokalemia with its associated risks. A summary of the various acid-base abnormalities and associated therapies is shown in Table 22.5.

NaHCl, sodium hydrochloride.
Perioperative Pain Management

Although satisfactory analgesia is easily achievable with available methods, patients continue to suffer unnecessarily from postoperative pain. Studies consistently show that 25% to 50% of patients suffer moderate to severe pain in the postoperative period \((38,39)\). There are several reasons for the existing inadequacies in pain management. First, patient expectations of pain relief are low and they are not aware of the extent of analgesia that they should expect. In a study of the perception of pain relief after surgery, 86% of patients had moderate to severe pain after surgery, but 70% felt that the pain was as severe as they expected \((40)\). Second, there is a lack of formal physician training in pain management. This lack is epitomized by the commonly written order prescribing a range of narcotic to be given intramuscularly every 3 to 4 hours as needed, leaving pain management decisions to the nursing staff, with no attempt made to titrate the dose of the prescribed narcotic commensurate with individual patient requirements. Third, attitudes continue to be influenced by the common misconception that the use of narcotics in the postoperative period results in opioid dependence. In one review, 20% of nurses responding to a staff questionnaire expressed concern that the use of opioid analgesics during the postoperative period could cause addiction \((40)\). Studies confirm that nurses administer less than one-fourth of the total dose of narcotic that is prescribed on an as-needed basis. To facilitate acute pain management and reduce the number of adverse outcomes, the American Society of Anesthesiologists established practice guidelines for acute pain management in the perioperative setting \((41)\).

The minimal effective analgesic concentration (MEAC) refers to the serum concentration of a drug below which very little analgesia is achieved. At the MEAC, receptor and plasma concentrations of a drug are in equilibrium. Steady-state drug concentrations above the MEAC are difficult to achieve with intramuscular depot injection \((42)\). In one study, patients receiving intramuscular injections with meperidine hydrochloride (Demerol) every 4 hours experienced marked intrapatient and interpatient variations in narcotic drug peak concentrations and in the time required to reach these peaks. As a result, serum concentrations of drug were above the MEAC an average of only 35% of each 4-hour dosing interval \((43)\). Variable pain control following intermittent intramuscular injections is the result of inadequate, highly variable, and unpredictable blood concentrations \((44)\). Adequate analgesia can be achieved through intramuscular or subcutaneous modes of administration, but unpredictable absorption can make titration difficult. Small intravenous boluses can be more easily titrated but may be shorter acting, requiring more frequent injections and thus intensive nursing care, whereas larger intravenous boluses may be associated with a higher incidence of central nervous system and respiratory depression. The patient-controlled analgesia (PCA) technique, which allows patients to self-administer small doses of narcotic on demand, allows titration of measured boluses of narcotic as needed to relieve pain. This technique can provide a more thorough analgesia with maintenance of steady-state drug concentrations above the MEAC.
Irrespective of the route of administration, analgesics must be front loaded to provide prompt analgesia from the start. Without front loading, attainment of the MEAC will not occur for at least three elimination half-lives of the narcotic agent that is used. After front loading, additional small boluses of narcotic can be administered until analgesia is achieved. From the total dose of drug required to achieve analgesia, maintenance drug dosages can then be determined and administered either as a continuous infusion or on a scheduled basis, so that the dose of drug administered offsets the amount that is cleared. Thereafter, prescribed doses of narcotic can be adjusted as needed.

**Patient-Controlled Analgesia**

Devices for administering PCA are electronically controlled infusion pumps that deliver a preset dose of narcotic into a patient’s indwelling intravenous catheter upon patient request. The devices all contain delay intervals or lockout times during which patient demands for more narcotic are not met. **These devices eliminate the delay between the onset of pain and the administration of analgesic agents, a common problem inherent with on-demand analgesic orders in busy hospital wards.** Patient-controlled analgesia has excellent patient acceptance. Compared with conventional intramuscular injections, serum narcotic levels have significantly lower variability in patients using PCA (42). Patients using PCA have improved analgesia, a lower incidence of postoperative pulmonary complications, and less confusion than those given intramuscular narcotics (45). The total dose of narcotic used is lower with PCA than with conventional intramuscular depot injection.

The use of PCA does not eliminate the adverse side effects of narcotics. Potentially life-threatening respiratory depression is seen in as many as 0.5% of patients using PCA. The use of a continuous narcotic infusion in addition to demand dosing is associated with a fourfold increase in respiratory depression. Elderly patients and those with preexisting respiratory compromise are at risk for respiratory depression (42).

Carefully supervised regimens using continuous infusions, on-demand intramuscular therapy, or fixed dosage schedules (every 4-hour dosing) with on-demand supplementation can have analgesic efficacy comparable with PCA. The type of close supervision required to achieve adequate on-demand analgesia without PCA is difficult to maintain. **Use of PCA shortens the time between the onset of pain and the administration of pain medication, provides more continuous access to analgesics, and allows for an overall steadier state of pain control.**

**Epidural and Spinal Analgesia**

Anesthetics and narcotics administered either in the epidural space or intrathecally are among the most potent analgesic agents available; the efficacy of these agents is greater than that provided by intravenous PCA techniques. These drugs can be administered in several ways, including a single-shot dose given by epidural or intrathecal injection, intermittent injection given either on schedule or on demand, and continuous infusion.
Because of the risk of central nervous system infections and headaches, intrathecal administration is usually limited to a single dose of narcotic, local anesthetic, or both. In comparison with epidural administration, duration of action for a single dose is increased via the intrathecal route as a result of the high concentrations of drug attained in the cerebrospinal fluid. The risk of central nervous system and respiratory depression, and systemic hypotension, is increased. The low doses of opioids required for intrathecal analgesia are sufficient to be associated with an increased risk of respiratory depression (46). Some investigators warn against the use of intrathecal spinal analgesia outside the intensive care setting.

**Epidural administration is the preferred approach and provides extended (>24 hours) pain control during the postoperative period.** Relative contraindications are the presence of coagulopathy, sepsis, and hypotension. Both anesthetic and narcotic agents are used with excellent efficacy. Among the anesthetic agents, bupivacaine is the most popular, providing excellent analgesia with minimal toxicity. Epidural analgesia is most suited for pain control in the lower abdomen and extremities. Potential adverse effects of epidural anesthetic agents include urinary retention, motor weakness, hypotension, and central nervous system and cardiac depression. In contrast to anesthetic agents, opioids offer excellent analgesia without accompanying sympathetic blockade. Epidural opioids tend to have a much longer duration of action, and hypotension is a rare complication. Compared with epidural anesthetics, there is a higher incidence of nausea and vomiting, respiratory depression, and pruritus (47).

Compared with analgesics administered intramuscularly or intravenously, epidural analgesia is associated with improved pulmonary function postoperatively, a lower incidence of pulmonary complications, a decrease in postoperative venous thromboembolic complications (most likely secondary to earlier ambulation), fewer gastrointestinal side effects, a lower incidence of central nervous system depression, and shorter convalescence (47). **A systematic review concluded that continuous epidural anesthesia is more effective than intravenous opioid PCA in reducing postoperative pain for up to 72 hours after abdominal surgery** (48). Severe respiratory depression, which occurs in less than 1% of patients, is the most serious potential complication. A lower incidence of respiratory depression occurs with the more lipophilic drugs such as fentanyl, which is quickly absorbed within the spinal cord and is less likely to diffuse to the central nervous system respiratory control centers. Pruritus, nausea, and urinary retention are common but can be managed easily and usually are of little clinical significance. Cost is perhaps the main and most limiting drawback of epidural analgesia.

**Close monitoring by nursing staff is required for safe administration of epidural analgesia.** An intensive care setting is not necessary. Epidural analgesics can be administered safely in a hospital ward setting under close nursing supervision, using respiratory monitoring with hourly ventilatory checks during the first 8 hours of epidural analgesia.
Nonsteroidal Anti-inflammatory Drugs

Current therapeutic strategies for perioperative pain control are largely dependent on multimodal therapy with opioid analgesics and nonsteroidal anti-inflammatory drugs (NSAIDs). The nonselective NSAID ketorolac is a potent drug that can be given orally or parenterally. **Ketorolac has a slightly slower onset of activity than fentanyl but has an analgesic potency comparable to morphine.** The theoretical advantages of NSAIDs over opioids include absence of respiratory depression, lack of abuse potential, decreased sedative effects, decreased nausea, early return of bowel function, and faster recovery. In clinical studies, ketorolac is found to have analgesic effects similar to those of morphine in postoperative orthopedic patients and, when used in conjunction with PCA, significantly reduced opioid requirements (49,50). Depending on the type of surgery, ketorolac has an opioid dose-sparing effect of a mean of 36% and improves analgesic control of moderate to severe pain 24 hours postoperatively (51). In the obstetric population, intravenous ketorolac is effective in reducing postoperative narcotic use after cesarean delivery (52). Although the U.S. Food and Drug Administration has not approved ketorolac for use during lactation, it was quantified in breast milk and has lower levels than ibuprofen (53).

Potential adverse effects associated with the use of NSAIDs include an increased risk of renal compromise (particularly in patients suffering from acute hypovolemia), gastrointestinal side effects, hypersensitivity reactions, and bleeding. The effects of ketorolac on bleeding are inconsistent. Studies of ketorolac on healthy volunteers showed transient increases in bleeding time and decreases in platelet aggregation, but these changes were not clinically significant (54). A retrospective cohort study showed increased risk of gastrointestinal and operative site bleeding in elderly patients receiving high doses of ketorolac, between 105 and 120 mg per day. Increased risk for all gastrointestinal bleeding was associated with use of ketorolac for more than 5 days (55). Controlled prospective studies did not show a significant increase in blood loss in patients who receive NSAIDs perioperatively. Ketorolac may be associated with elevated rates of acute renal failure when therapy exceeds 5 days (56). A meta-analyses of the use of postoperative NSAIDs in patients with normal preoperative renal function showed a clinically insignificant reduction in renal function (57). These agents should be used with extreme care, if at all, in patients with asthma, because 5% to 10% of adult patients with asthma are sensitive to aspirin and other NSAID preparations.

With the advantages of less gastrointestinal toxicity and a lack of antiplatelet effects, selective cyclooxygenase-2 (COX-2) inhibitors are a valuable option in perioperative pain management (58). Although evidence exists showing an increased risk of serious cardiovascular events associated with COX-2 inhibitors, short-term use of these agents in the perioperative setting can be considered in low-risk patients without existing cardiovascular disease (59–64).

In addition to NSAIDs, other adjuvant analgesics are being explored to minimize opioid use and the accompanying side effects, which can delay recovery. Capsaicin is a
nonnarcotic that promotes release of substance P, a neurotransmitter for pain and heat, which initially results in a burning sensation, but eventually leads to substance P depletion and a reduction in pain. It is available in both topical and injectable preparations. Ketamine blocks centrally located N-methyl-d-aspartate pain receptors, and at low subanesthetic doses can reduce central sensitization caused by surgery and prevent opioid-induced hyperalgesia. At higher doses, ketamine is associated with hallucinations, dizziness, nausea, and vomiting. Gabapentin and pregabalin are nonnarcotics that prevent the release of excitatory neurotransmitters that relay pain signals. They reduce opioid requirements and are effective antihyperalgesic agents (64).
Antimicrobial Prophylaxis in Gynecologic Surgery

Gynecologic procedures often involve breaching the reproductive and gastrointestinal tracts, which harbor endogenous bacteria capable of causing polymicrobial infections in the postoperative period (Table 22.6). Despite great advances in aseptic technique and drug development, bacterial contamination of the operative site and postoperative infections are an inevitable part of the practice of gynecologic surgery. Prevention of these surgical complications includes using proper aseptic technique, minimizing tissue trauma, minimizing the amount foreign material in the surgical site, controlling diabetes, avoiding immunologic suppression, maximizing tissue oxygenation, draining blood and serum from the surgical site, and using prophylactic antibiotics. Antibiotic prophylaxis is given with the belief that antibiotics enhance the immune mechanisms in host tissues that resist infections by killing the bacteria that inoculate the surgical site during surgery (65).

Infections in the skin or pelvis that result from gynecologic surgery (e.g., parametritis, cuff cellulitis, pelvic abscess) typically are polymicrobial in nature. These infections are complex and often involve gram-negative rods, gram-positive cocci, and anaerobes. Antibiotic prophylaxis should be sufficiently broad to cover these potential pathogens (66) (Table 22.7).

<sup>a</sup>Alternatives include cefotetan, cefoxitin, cefuroxime, or ampicillin-sulbactam.

<sup>b</sup>A 2-g dose is recommended in women with a body mass index greater than 35 or weight greater than 100 kg or 220 lb.

<sup>c</sup>Antimicrobial agents of choice in women with a history of immediate hypersensitivity to penicillin.

<sup>d</sup>Ciprofloxacin or levofloxacin or moxifloxacin.

<sup>e</sup>If patient has a history of pelvic inflammatory disease or procedure demonstrates dilated fallopian tubes. No prophylaxis is indicated for a study without dilated tubes.

The timing of antimicrobial prophylaxis is important. There is a relatively narrow window of opportunity for affecting outcomes (67). In the United States, it is customary to give antimicrobial prophylaxis shortly before or during the induction of anesthesia. **Data revealed that a delay of 3 hours or more between the time of bacterial inoculation (i.e., skin incision) and administration of antibiotics may result in ineffective prophylaxis. Evidence indicates that for prophylaxis, one dose of antibiotic is appropriate. When the surgical procedure proceeds longer than 1 to 2 times the half-life of the drug or blood loss is greater than 1.5 L, additional intraoperative doses of antibiotics should be administered to maintain adequate levels of medication in serum and tissues (68,69).** There are no data to support the continuation of prophylactic antimicrobial agents into the postoperative period for routine gynecologic procedures. For cases involving colorectal resection, a reduction in surgical site infections (SSI) was seen when antibiotics were
continued for up to 24 hours. Other measures to reduce SSI incidence were taken, including tight glycemic control, maintenance of intraoperative normothermia, and placement of subcutaneous drains in obese patients (70).

**Cephalosporins emerged as the most important class of antimicrobial agents for prophylaxis.** These drugs have a broad spectrum and relatively low incidence of adverse reactions. Cefazolin (1 g) appears to be widely used in the United States by gynecologic surgeons because of its relatively low cost and long half-life (1.8 hours). Other cephalosporins such as cefoxitin, cefotaxime, and cefotetan commonly are used for prophylaxis. These agents appear to have a broader spectrum of activity against anaerobic bacteria and are appropriate selections when colorectal resections are possible, such as during a debulking surgery for ovarian cancer. For the majority of gynecologic procedures, there is little evidence that a clinically relevant distinction exists between cefazolin and the other agents. Morbidly obese patients, defined as having a BMI greater than 35 or weight greater than 100 kg, should receive 2 g of cefazolin to achieve appropriate blood and tissue antibiotic concentrations (71).

**Antimicrobial prophylaxis, although usually beneficial, is not without risk.** Anaphylaxis is the most life-threatening complication from antibiotic use. Anaphylactic reactions to penicillins are reported in 0.2% courses of treatment. The fatality rate is 0.0001%. Data indicate that it is safe to administer cephalosporins to women who report a history of adverse reactions to penicillins. The incidence of adverse reactions (e.g., skin flushing, itching) in women with a history of penicillin allergy who are given cephalosporins is 1% to 10%. The incidence of anaphylaxis in this setting is less than 0.02% (72).

**A single dose of broad-spectrum antibiotics can result in pseudomembranous colitis, caused by Clostridium difficile.** Diarrhea may develop in as many as 15% of hospitalized patients treated with beta-lactam antibiotics (73). In patients receiving clindamycin, the rate of diarrhea is nearly 10% to 25% (74). These gastrointestinal complications from antibiotics may cause serious morbidity in the surgical patient, and the surgeon should be able to recognize and manage these problems.

**Not all gynecologic surgery patients need to receive prophylactic antibiotics.** The surgeon should choose agents to cover procedures based on available data, thereby avoiding the potential for adverse reactions and minimizing the unnecessary use of antibiotics, which may contribute to increased rates of antimicrobial resistance. In patients with cephalosporin allergies or anaphylaxis to penicillin, other drugs or combinations should be chosen to provide adequate prophylactic coverage. Antimicrobial prophylaxis options for common gynecologic procedures are presented in Table 22.6. Antibiotic prophylaxis is not indicated for diagnostic or operative laparoscopy, exploratory laparotomy, or diagnostic or operative hysteroscopy, including endometrial ablation, intrauterine device insertions, endometrial biopsy, or urodynamics (75).

**Subacute Bacterial Endocarditis Prophylaxis**
It was thought that women who had severe valvular disease or other cardiac conditions required antibiotic prophylaxis prior to genitourinary (GU) or gastrointestinal (GI) procedures in order to prevent bacterial endocarditis as a result of the transient bacteremia provoked by the surgery. After reviewing the pertinent evidence-based literature, the American Heart Association issued revised guidelines in 2007 stating that antibiotic prophylaxis was not necessary solely to prevent endocarditis in patients undergoing GI or GU procedures, including hysterectomy (Table 22.8) (76).

Postoperative Infections

Infections are a major source of morbidity in the postoperative period. Risk factors for infectious morbidity include the absence of perioperative antibiotic prophylaxis, contamination of the surgical field from infected tissues or from spillage of large bowel contents, an immunocompromised host, poor nutrition, chronic and debilitating severe illness, poor surgical technique, and preexisting focal or systemic infection. Sources of postoperative infection can include the lung, urinary tract, surgical site, pelvic sidewall, vaginal cuff, abdominal wound, and sites of indwelling intravenous catheters. Early identification and treatment of infection will result in the best outcome for these potentially serious complications.

Although infectious morbidity is an inevitable complication of surgery, the incidence of infections can be decreased by the appropriate use of simple preventive measures. In cases that involve transection of the large bowel, spillage of fecal contents inevitably occurs. A thorough preoperative mechanical and antibiotic bowel preparation in combination with systemic antibiotic prophylaxis will help decrease the incidence of postoperative pelvic and abdominal infections in these patients. The surgeon can further decrease the risk of postoperative infections by using meticulous surgical technique. Blood and necrotic tissue are excellent media for the growth of aerobic and anaerobic organisms. In cases in which there is higher-than-usual potential for serum and blood to collect in spaces that were contaminated by bacterial spill, closed-suction drainage may reduce the risk of infection. Antibiotic therapy, rather than prophylaxis, should be initiated during surgery in patients who have frank intra-abdominal infection or pus. Elective surgical procedures should be postponed in patients who have preoperative infections. In an epidemiologic study conducted by the Centers for Disease Control and Prevention (CDC), the incidence of nosocomial surgical infections ranged from 4.3% in community hospitals to 7% in municipal hospitals (77). Data confirmed this, with an incidence of 2% to 5% (78). Urinary tract infections accounted for approximately 40% of these nosocomial infections. Infections of the skin and wound accounted for approximately one-third of the infections, and respiratory tract infections accounted for approximately 16%. In patients who had any type of infection before surgery, the risk of infection at the surgical wound site increased fourfold. Rates of infection were higher in older patients, in patients with increased length of surgery, and in those with increased length of hospital stay before surgery. The relative risk was three times higher in patients with a community-acquired infection before surgery. These community-acquired infections included infections of the urinary and respiratory tracts.

Historically, the standard definition of febrile morbidity for surgical patients was the presence of a temperature higher than or equal to 100.4°F (38°C) on two occasions at least 4 hours apart during the postoperative period, excluding the first 24 hours. Other sources defined fever as two consecutive temperature elevations greater than 101.0°F (38.3°C) (79,80). Febrile morbidity is estimated to occur in as many as one-half of patients; it is often self-limited, resolves without therapy, and is usually noninfectious in origin (81). Overzealous evaluations of postoperative
fever, especially during the early postoperative period, are time consuming, expensive, and sometimes uncomfortable for the patient (81). The value of 101.0°F is more useful than 100.4°F to distinguish an infectious cause from an inconsequential postoperative fever.

The assessment of a febrile surgical patient should include a review of the patient’s history with regard to risk factors. Both the history and the physical examination should focus on the potential sites of infection (Table 22.9). The examination should include inspection of the pharynx, a thorough pulmonary examination, percussion of the kidneys to assess for costovertebral angle tenderness, inspection and palpation of the abdominal incision, examination of sites of intravenous catheters, and an examination of the extremities for evidence of deep venous thrombosis or thrombophlebitis. In gynecologic patients, an appropriate workup may include inspection and palpation of the vaginal cuff for signs of induration, tenderness, or purulent drainage. A pelvic examination should be performed to identify a mass consistent with a pelvic hematoma or abscess and to look for signs of pelvic cellulitis.

Patients with fever in the early postoperative period should have an aggressive pulmonary toilet, including incentive spirometry (80). If the fever persists beyond 72 hours postoperatively, additional laboratory and radiologic data may be obtained. The evaluation may include complete and differential white blood cell counts and a urinalysis. In one study, results from fever workups included positive blood cultures in 9.7% of patients, a positive urine culture in 18.8%, and a positive chest x-ray in 14%. These data support the need for a tailored workup based on the patient’s clinical picture (82). Blood
cultures can be obtained but will most likely be of little yield unless the patient has a high fever (102°F). In patients with costovertebral angle tenderness, intravenous pyelogram may be indicated to rule out the presence of ureteral damage or obstruction from surgery, particularly in the absence of laboratory evidence of urinary tract infection. Patients who have persistent fevers without a clear localizing source should undergo CT scanning of the abdomen and pelvis to rule out the presence of an intra-abdominal abscess. If fever persists in patients who had gastrointestinal surgery, a barium enema or upper gastrointestinal studies with small bowel assessment may be indicated late in the course of the first postoperative week to rule out an anastomotic leak or fistula.

**Urinary Tract Infections**

Historically, the urinary tract was the most common site of infection in surgical patients (83). The incidence reported in the gynecologic literature is less than 4% (84,85). This decrease in urinary tract infections is most likely the result of increased perioperative use of prophylactic antibiotics. The incidence of postoperative urinary tract infection in gynecologic surgical patients not receiving prophylactic antibiotics is confirmed to be as high as 40%, and **even a single dose of perioperative prophylactic antibiotic decreases the incidence of postoperative urinary tract infection to as low as 4% (86,87).**

Symptoms of a urinary tract infection may include urinary frequency, urgency, and dysuria. In patients with pyelonephritis, other symptoms include headache, malaise, nausea, and vomiting. A urinary tract infection is diagnosed on the basis of microbiology and is defined as the growth of \(10^5\) organisms per milliliter of urine cultured. Most infections are caused by coliform bacteria, with *Escherichia coli* being the most frequent pathogen. Other pathogens include *Klebsiella*, *Proteus*, and *Enterobacter* species. *Staphylococcus* organisms are the causative bacteria in fewer than 10% of cases.

Despite the high incidence of urinary tract infections in the postoperative period, few of these infections are serious. Most are confined to the lower urinary tract, and pyelonephritis is a rare complication (88). Catheterization of the urinary tract, either intermittently or continuously with the use of an indwelling catheter, is implicated as a main cause of urinary tract contamination (89). More than 1 million catheter-associated urinary tract infections occur yearly in the United States, and **catheter-associated bacteria remains the most common etiology of gram-negative bacteremia in hospitalized patients.** Bacteria adhere to the surface of urinary catheters and grow within bile films, which appear to protect embedded bacteria from antibiotics, making treatment less effective. The use of urinary tract catheters should be minimized. An indwelling catheter should be removed or replaced in a patient undergoing treatment for catheter-related infections.

**The treatment of urinary tract infection includes hydration and antibiotic therapy.** Commonly prescribed and effective antibiotics include penicillin, sulfonamides, cephalosporins, fluoroquinolones, and nitrofurantoin. The choice of antibiotic should be
based on knowledge of the susceptibility of organisms cultured at a particular institution. In some institutions, for example, more than 40% of E. coli strains are resistant to ampicillin. For uncomplicated urinary tract infections, an antibiotic that has good activity against E. coli should be given in the interim while awaiting results of the urine culture and sensitivity data.

Patients who have a history of recurrent urinary tract infections, those with chronic indwelling catheters (Foley catheters or ureteral stents), and those who have urinary conduits should be treated with antibiotics that will be effective against the less common urinary pathogens such as Klebsiella and Pseudomonas. Chronic use of fluoroquinolones for prophylaxis is not advised because these agents are notorious for inducing antibiotic-resistant strains of bacteria.

**Pulmonary Infections**

The respiratory tract is an uncommon site for infectious complications in gynecologic surgical patients. In one study only six cases of pneumonia occurred in more than 4,000 women who underwent elective hysterectomy (85). This low incidence is probably a reflection of the young age and good health status of gynecologic patients in general. In acute care facilities, pneumonia is a frequent hospital-acquired infection, particularly in elderly patients (90). Risk factors include extensive or prolonged atelectasis, preexistent COPD, severe or debilitating illness, central neurologic disease causing an inability to clear oropharyngeal secretions effectively, nasogastric suction, and a prior history of pneumonia (90,91). In surgical patients, early ambulation and aggressive management of atelectasis are the most important preventive measures. The role of prophylactic antibiotics remains unclear.

A significant percentage (40% to 50%) of cases of hospital-acquired pneumonia is caused by gram-negative organisms (83). These organisms gain access to the respiratory tract from the oral pharynx. Gram-negative colonization of the oral pharynx is increased in patients in acute care facilities and is associated with the presence of nasogastric tubes, preexisting respiratory disease, mechanical ventilation, and tracheal intubation (92). The use of antimicrobial drugs seems to significantly increase the frequency of colonization of the oral pharynx with gram-negative bacteria.

A thorough lung examination should be included in the assessment of all febrile surgical patients. In the absence of significant lung findings, chest radiography is probably of little benefit in patients at low risk for postoperative pulmonary complications. In patients with pulmonary findings or with risk factors for pulmonary complications, chest radiography should be performed. A sputum sample should be obtained for Gram stain and culture. The treatment should include postural drainage, aggressive pulmonary toilet, and antibiotics. The antibiotic chosen should be effective against both gram-positive and gram-negative organisms. In patients who are receiving assisted ventilation, the antibiotic spectrum should include drugs that are active against Pseudomonas organisms.
Phlebitis

Historically, intravenous catheter–related infections were common; the reported incidence is 25% to 35% in the 1980s (93). Because the incidence of catheter-related phlebitis increases significantly after 72 hours, intravenous catheters should be changed at least every 3 days according to the CDC (94). The institution of intravenous therapy teams decreased the incidence of phlebitis by as much as 50% in one study (95). In combination, these measures led to a dramatic decrease in peripheral catheter site infection.

The intravenous site should be inspected daily, and the catheter should be removed if there is any associated pain, redness, or induration. Phlebitis can occur even with close surveillance of the intravenous site. In one study, more than 50% of the cases of phlebitis became evident more than 12 hours after discontinuation of intravenous catheters (96). Less than one-third of patients had symptoms related to the intravenous catheter site 24 hours before the diagnosis of phlebitis.

Phlebitis can be diagnosed based on the presence of fever, pain, redness, induration, or a palpable venous cord. Occasionally, suppuration will be present. Phlebitis is usually self-limited and resolves within 3 to 4 days. The treatment includes application of warm, moist compresses and prompt removal of any catheters from the infected vein. Antibiotic therapy with antistaphylococcal agents should be instituted for catheter-related sepsis. Excision or drainage of an infected vein rarely is necessary.

Wound Infections

The results of a prospective study of more than 62,000 wounds were revealing in regard to the epidemiology of wound infections (97). The wound infection rate varied markedly, depending on the extent of contamination of the surgical field. The wound infection rate for clean surgical cases (infection not present in the surgical field, no break in aseptic technique, no viscus entered) was lower than 2%, whereas the incidence of wound infections with dirty, infected cases was 40% or higher. Preoperative showers with hexachlorophene slightly lowered the infection rate for clean wounds, whereas preoperative shaving of the wound site with a razor increased the infection rate. A 5-minute wound preparation immediately before surgery was as effective as preparation for 10 minutes. The wound infection rate increased with the duration of preoperative hospital stay and with the duration of surgery. Incidental appendectomy increased the risk of wound infection in patients undergoing clean surgical procedures. The study concluded that the incidence of wound infections could be decreased by short preoperative hospital stays, hexachlorophene showers before surgery, minimizing shaving of the wound site, use of meticulous surgical technique, decreasing operative time as much as possible, bringing drains out through sites other than the wound, and dissemination of information to surgeons regarding their wound infection rates. A program instituting these conclusions led to a decrease in the clean wound infection rate from 2.5% to 0.6% over an 8-year period.
The wound infection rate in most gynecologic services is lower than 5%, reflective of the clean nature of most gynecologic operations.

The symptoms of wound infection often occur late in the postoperative period, usually after the fourth postoperative day, and may include fever, erythema, tenderness, induration, and purulent drainage. Wound infections that occur on postoperative days 1 through 3 are generally caused by streptococcal and Clostridia infections. The management of wound infections is mostly mechanical and involves opening the infected portion of the wound above the fascia, with cleansing and debridement of the wound edges as necessary. Wound care, consisting of debridement and dressing changes two to three times daily with mesh gauze, will promote growth of granulation tissue, with gradual filling in of the wound defect by secondary intention. Clean, granulating wounds can often be secondarily closed with good success, shortening the time required for complete wound healing.

The technique of delayed primary wound closure can be used in contaminated surgical cases to lower the incidence of wound infection. This technique involves leaving the wound open above the fascia at the time of the initial surgical procedure. Vertical interrupted mattress sutures through the skin and subcutaneous layers are placed 3 cm apart but are not tied. Wound care is instituted immediately after surgery and continued until the wound is noted to be granulating well. Sutures may then be tied and the skin edges further approximated using sutures or staples. Using this technique of delayed primary wound closure, the overall wound infection rate is decreased from 23% to 2.1% in high-risk patients (98).

Pelvic Cellulitis
Vaginal cuff cellulitis is present in most patients who underwent hysterectomy. It is characterized by erythema, induration, and tenderness at the vaginal cuff. A purulent discharge from the apex of the vagina may be present. The cellulitis is often self-limited and does not require any treatment. Fever, leukocytosis, and pain localized to the pelvis may accompany severe cuff cellulitis and most often signifies extension of the cellulitis to adjacent pelvic tissues. In such cases, broad-spectrum antibiotic therapy should be instituted with coverage for gram-negative, gram-positive, and anaerobic organisms. If purulence at the vaginal cuff is excessive or if there is a fluctuant mass noted at the vaginal cuff, the vaginal cuff should be gently probed and opened with a blunt instrument. The cuff can be left open for dependent drainage or, alternatively, a drain can be placed into the lower pelvis through the cuff and removed when drainage, fever, and symptoms in the lower pelvic region have resolved.

Intra-abdominal and Pelvic Abscess
The development of an abscess in the surgical field or elsewhere in the abdominal cavity is an uncommon complication after a gynecologic surgery. It is likely to occur in contaminated cases in which the surgical site is not adequately drained or as a secondary
The causative pathogens in patients who have intra-abdominal abscesses are usually polymicrobial in nature. The aerobes most commonly identified include E. coli, Klebsiella, Streptococcus, Proteus, and Enterobacter. Anaerobic isolates are common, usually from the Bacteroides group. These pathogens arise mainly from the vaginal tract but can be derived from the gastrointestinal tract, particularly when the colon was entered at the time of surgery.

Intra-abdominal abscess is sometimes difficult to diagnose. The evolving clinical picture is often one of persistent febrile episodes with a rising white blood cell count. Findings on abdominal examination may be equivocal. If an abscess is located deep in the pelvis, it may be palpable by pelvic or rectal examination. For abscesses above the pelvis, the diagnosis will depend on radiologic confirmation.

Ultrasonography can occasionally delineate fluid collections in the upper abdomen and in the pelvis. Bowel gas interference makes visualization of fluid collections or abscesses in the midabdomen difficult to distinguish. Computed tomography scanning is more sensitive and specific for diagnosing intra-abdominal abscesses and often is the radiologic procedure of choice. Occasionally, if conventional radiologic methods fail to identify an abscess and the index of suspicion for an abscess remains high, labeled leukocyte scanning may be useful for locating the infected focus.

Standard therapy for intra-abdominal abscess is evacuation and drainage combined with appropriate parenteral administration of antibiotics. Abscesses located low in the pelvis, particularly in the area of the vaginal cuff, can be reached through a vaginal approach. In many patients, the ability to drain an abscess by placement of a drain percutaneously under CT guidance obviated the need for surgical exploration. With CT guidance, a pigtail catheter is placed into an abscess cavity via transperineal, transrectal, or transvaginal approaches. The catheter is left in place until drainage decreases. Transperineal and transrectal drainage of deep pelvic abscesses is successful in 90% to 93% of patients, obviating the need for surgical management (99,100). For those patients in whom radiologic drainage is not successful, surgical exploration and evacuation are indicated. The standard approach to initial antibiotic therapy is the combination of ampicillin, gentamicin, and clindamycin. Adequate treatment can be achieved with available broad-spectrum single agents (including the broad-spectrum penicillin), second- and third-generation cephalosporins, levofloxacin and metronidazole, and the sulbactam-clavulanic acid–containing preparations (101).

Necrotizing Fasciitis

Necrotizing fasciitis is an uncommon infectious disorder, affecting roughly 1,000 patients per year (102). This disease process is characterized by a rapidly progressive bacterial infection that involves the subcutaneous tissues and fascia while characteristically sparing underlying muscle. Systemic toxicity is a frequent feature of this disease, as manifested by the presence of dehydration, septic shock, disseminated intravascular coagulation, and multiple organ system failure.
The pathogenesis of necrotizing fasciitis involves a polymicrobial infection of the dermis and subcutaneous tissue. Hemolytic streptococcus was initially believed to be the primary pathogen responsible for the infection in necrotizing fasciitis (103). Other organisms are often cultured in addition to streptococcus, including other gram-positive organisms, coliforms, and anaerobes (104). Bacterial enzymes such as hyaluronidase and lipase released in the subcutaneous space destroy the fascia and adipose tissue and induce a liquefactive necrosis. Noninflammatory intravascular coagulation or thrombosis subsequently occurs. Intravascular coagulation results in ischemia and necrosis of the subcutaneous tissues and skin. Subcutaneous spread of up to 1 inch per hour can be seen, often with little effect on the overlying skin (104). Late in the course of the infection, destruction of the superficial nerves produces anesthesia in the involved skin. The release of bacteria and bacterial toxins into the systemic circulation can cause septic shock, acid-base disturbances, and multiple organ impairment.

The diagnosis is often difficult to make early in the disease course. Most patients with necrotizing fasciitis develop erythema, edema, and pain, which in the early stages of the disease is disproportionately greater than that expected from the degree of cellulitis present and characteristically extends beyond the border of erythema (105). Late in the course of the infection, the involved skin may be anesthetized secondary to necrosis of superficial nerves. Temperature abnormalities, both hyperthermia and hypothermia, are concomitant with the release of bacterial toxins and with bacterial sepsis (104). The involved skin is initially tender, erythematous, and warm. Edema develops, and the erythema spreads diffusely, fading into normal skin, characteristically without distinct margins or induration. Subcutaneous microvascular thrombosis induces ischemia in the skin, which becomes cyanotic and blistered. As necrosis develops, the skin becomes gangrenous and may slough spontaneously (104). Most patients will have leukocytosis and acid-base abnormalities. Subcutaneous gas may develop, which can be identified by palpation and by radiography. The finding of subcutaneous gas by radiography is often indicative of clostridial infection, although it is not a specific finding and may be caused by other organisms. These organisms include Enterobacter, Pseudomonas, anaerobic streptococci, and Bacteroides, which, unlike clostridial infections, spare the muscles underlying the affected area. A tissue biopsy specimen for Gram stain and aerobic and anaerobic culture should be obtained from the necrotic center of the lesion to identify the etiologic organisms (105). Although necrotizing fasciitis often is diagnosed during surgery, a high index of suspicion and liberal use of frozen-section biopsy can provide an early life-saving diagnosis and minimize morbidity (104).

Predisposing risk factors for necrotizing fasciitis include diabetes mellitus, alcoholism, an immunocompromised state, hypertension, peripheral vascular disease, intravenous drug abuse, and obesity (104). The most frequent site of infection is in the extremities, but the infection can occur anywhere in the subcutaneous tissues, including the head and neck, trunk, and perineum. Necrotizing fasciitis occurs
after trauma, surgery, burns, and lacerations; as a secondary complication in perirectal infections or Bartholin duct abscesses; and de novo (103,106–109). Increased age, delay in diagnosis, inadequate debridement during initial surgery, extensive disease at the time of diagnosis, and the presence of diabetes mellitus are all factors that are associated with an increased likelihood of mortality from necrotizing fasciitis (104–106). Early diagnosis and aggressive management of this lethal disease contribute to improved survival.

Successful management of necrotizing fasciitis involves early recognition, immediate initiation of resuscitative measures (including correction of fluid, acid-base, electrolyte, and hematologic abnormalities), aggressive surgical debridement and redebridement as necessary, and broad-spectrum intravenous antibiotic therapy (104). During surgery, the incision should be made through the infected tissue down to the fascia. An ability to undermine the skin and subcutaneous tissues with digital palpation often will confirm the diagnosis. Multiple incisions can be made sequentially toward the periphery of the affected tissue until well-vascularized, healthy, resistant tissue is reached at all margins. The remaining affected tissue must be excised. The wound can be packed and sequentially debrided on a daily basis as necessary until healthy tissue is displayed at all margins. Hyperbaric oxygen therapy may be of some benefit, particularly in patients for whom culture results are positive for anaerobic organisms (110). Retrospective nonrandomized studies demonstrated that the addition of hyperbaric oxygen therapy to surgical debridement and antimicrobial therapy appears to significantly decrease both wound morbidity and overall mortality in patients with necrotizing fasciitis (110). The benefit of hyperbaric therapy demonstrated in one study was remarkable, given that patients receiving hyperbaric oxygen were sicker and had a higher incidence of diabetes mellitus, leukocytosis, and shock (106).

After the initial resuscitative efforts and surgical debridement, the primary concern is the management of the open wound. Allograft and xenograft skin can be used to cover open wounds, thus decreasing heat and evaporative water loss. Temporary biologic closure of open wounds seems to decrease bacterial growth (111). Amniotic membranes were effective wound covering in patients with necrotizing fasciitis (112).

A new technology demonstrated to significantly improve wound healing in laboratory and clinical studies is a vacuum-assisted closure (VAC) method that uses a subatmospheric pressure technique (113–115). In situations in which spontaneous closure is not likely, the VAC device may allow for the development of a suitable granulation bed and prepare the tissue for graft placement, thereby increasing the probability of graft survival. Skin flaps can be mobilized to help cover open wounds when the infections resolve and granulation begins.
Gastrointestinal Preparation

Traditionally, mechanical bowel preparation was advised before abdominal surgery, especially if colonic surgery was anticipated. Despite the infrequent need for colonic surgery (or injury) when performing gynecologic surgery, bowel preparation is part of the standard practice for many gynecologists. Advantages of mechanical bowel preparation include reduction of gastrointestinal contents, which facilitates the surgical procedure by allowing more room in the abdomen and pelvis. If a rectosigmoid colon enterotomy occurs, the mechanical bowel preparation eliminates formed stool and reduces the risk of bacterial contamination, thus reducing infectious complications.

Randomized clinical trials questioned the need for mechanical bowel preparation in colonic surgery (116). Although somewhat controversial, a meta-analyses including almost 5,000 patients showed no statistical difference between the groups for anastomotic leakage ($p = 0.46$), pelvic or abdominal abscess ($p = 0.75$), and wound sepsis ($p = 0.11$). The use of different mechanical regimes did not influence primary and secondary outcomes. The authors concluded that this analysis demonstrates that any kind of mechanical bowel preparation should be omitted before colonic surgery. The main limitation concerned rectal surgery for which the limited data preclude any interpretation.

A randomized trial of mechanical bowel preparation versus no bowel preparation with rectal surgery found that the overall and site-specific infectious morbidity rates were significantly higher in no preparation versus the mechanical preparation group. Regarding anastomotic leakage, length of hospital stay, major morbidity and mortality rates, there was no significant difference between the no preparation and mechanical bowel preparation groups. This was the first randomized trial to demonstrate that rectal cancer surgery without mechanical preparation is associated with higher risk of overall and infectious morbidity rates without any significant increase of anastomotic leakage rate. It suggests continuing to perform mechanical preparation before elective rectal resection for cancer (117).

Despite evidence of the infectious complications associated with mechanical preparation or no preparation, many gynecologic surgeons prefer a mechanical preparation to aid with exposure in the pelvic operative field. This may be particularly relevant to the surgeon performing minimally invasive surgery.

Mechanical bowel preparation may be accomplished as presented in (Table 22.10) The traditional use of laxatives and enemas requires at least 12 to 24 hours and causes moderate abdominal distention and crampy pain. Randomized trials comparing traditional mechanical bowel preparation (magnesium citrate and enemas) with oral gut lavage (PEG electrolyte solution, GoLYTELY) found that the use of approximately 4 L of GoLYTELY (administered until the rectal effluent is clear) provides more complete, faster, and more comfortable bowel preparation (118). However, the ingestion of 4 L of fluid is problematic for many patients, so magnesium citrate may be preferable when mechanical preparation is to be used.
Table 22.10 Mechanical Bowel Preparation

**Preoperative Day 1** Clear liquid diet

**Mechanical Prep**

4 L of GoLYTELY

OR

Fleet Phospho-Soda Saline laxative (3 oz. bottle)\(^a\)

(one bottle of laxative 1 p.m. and another at 7 p.m.)

Fleet enemas until no solid stool in p.m. (optional)

**Antibiotic Prep (Optional)**

Neomycin (oral), 1 g every 4 h for three doses (4, 8, 12 p.m.)

Erythromycin (oral), 1 g every 4 h for three doses or metronidazole 500 mgm every 4 h for three doses

\(^a\)Be aware of acute phosphate nephropathy. Avoid use of phospho-soda in patients with inadequate hydration, increased age, a history of hypertension, current use of an angiotensin receptor blocker, or angiotensin-conversing enzyme (ACE) inhibitors; renal disease or chronic heart failure and those taking nonsteroidal anti-inflammatory drugs (NSAIDs) or diuretics.

An alternative mechanical preparation method is the use of oral sodium phosphate (Phospho-Soda). When evaluated in a randomized trial comparing the 4 L of GoLYTELY with oral sodium phosphate, colonoscopic examination disclosed that both methods were equally effective in colonic cleansing, and more patients preferred the sodium phosphate method (119). Some patients are at higher risk to develop acute phosphate nephropathy, leading to acute renal failure or worsening of chronic renal disease after the use of sodium phosphate. Although the pathophysiology is not fully understood, it may be secondary to substantial fluid shifts and electrolyte changes. It is speculated that potential etiologic factors included inadequate hydration, increased patient age, a history of hypertension, and current use of an **angiotensin receptor blocker** or angiotensin-converting enzyme (ACE) inhibitors. Patients with chronic renal disease or chronic heart failure and those taking NSAIDs or diuretics appear to be at higher risk of acute phosphate nephropathy (120). For these patients, the guidelines recommend an alternative bowel preparation agent, polyethylene glycol, which is not associated with volume shifts and electrolyte abnormalities (121,122).

Oral antibiotic prophylaxis was advised over the past three decades to reduce the infectious complications following colonic surgery. The usual regimen was a combination of oral erythromycin and neomycin taken the day before surgery. Many surgeons would substitute oral metronidazole for erythromycin because patients tolerate it better. **With the use of perioperative parental antibiotics, the benefit of oral antibiotics is questioned and most surgeons abandoned the use of oral antibiotics in favor of perioperative parenteral antibiotics.**
Postoperative Gastrointestinal Complications

Ileus

Following open abdominal or pelvic surgery, most patients experience some degree of intestinal ileus. The exact mechanism by which this arrest and disorganization of gastrointestinal motility occurs is unknown, but it appears to be associated with the opening of the peritoneal cavity and is aggravated by manipulation of the intestinal tract and prolonged surgical procedures. Infection, peritonitis, and electrolyte disturbances may result in ileus. For most patients undergoing common gynecologic operations, the degree of ileus is minimal, and gastrointestinal function returns relatively rapidly, allowing the resumption of oral intake within a few days of surgery. Patients who have persistently diminished bowel sounds, abdominal distention, and nausea and vomiting require further evaluation and more aggressive management. Patients with symptoms of ileus or small bowel obstruction who underwent minimally invasive surgery are a different matter. Minimally invasive surgery should result in a daily improvement in GI function. An “ileus” in the case of minimally invasive surgery more likely represents GI injury, which should be evaluated immediately with a CT scan using GI contrast.

Ileus is usually manifested by abdominal distention and should be evaluated by physical examination. Pertinent points of the abdominal examination include assessment of the quality of bowel sounds and palpation in search of distension, masses, tenderness, or rebound. The possibility that the patient’s signs and symptoms may be associated with a more serious intestinal obstruction or intestinal complication (such as a perforation) must be considered. Pelvic examination should be performed to evaluate the possibility of a pelvic abscess or hematoma that may contribute to the ileus. Abdominal radiography to evaluate the abdomen in the flat (supine) position and in the upright position will aid in the diagnosis of an ileus. The most common radiographic findings include dilated loops of small and large bowel and air-fluid levels while the patient is in the upright position. Sometimes, massive dilation of the colon or stomach may be noted. The remote possibility of distal colonic obstruction suggested by a dilated cecum should be excluded by rectal examination, proctosigmoidoscopy, colonoscopy, or barium enema. In the postoperative gynecology patient, especially in the upright position, the abdominal x-ray may show free air. This common finding following surgery lasts 7 to 10 days in some instances and is not indicative of a perforated viscus in most patients.

The initial management of a postoperative ileus is aimed at gastrointestinal tract decompression and maintenance of appropriate intravenous replacement fluids and electrolytes.

The patient should be made NPO status (nothing by mouth) with intravenous (IV) fluids and electrolytes. If nausea and vomiting persist, a nasogastric tube should be used to evacuate the stomach of its fluid and gaseous contents.
Continued nasogastric suction removes swallowed air, which is the most common source of gas in the small bowel.

**Fluid and electrolyte replacement must be adequate to keep the patient well hydrated and in metabolic balance.** Significant amounts of third-space fluid loss occur in the bowel wall, the bowel lumen, and the peritoneal cavity during the acute episode. Gastrointestinal fluid losses from the stomach may lead to metabolic alkalosis and depletion of other electrolytes as well. Careful monitoring of serum chemistry levels and appropriate replacement are necessary.

**Most cases of severe ileus begin to improve over a period of several days.** This improvement is recognizable by a reduction in the abdominal distention, return of normal bowel sounds, and passage of flatus or stool. Repeat abdominal radiographs should be obtained as necessary for further monitoring.

**When the gastrointestinal tract function appears to have returned to normal, the nasogastric tube may be removed and a liquid diet instituted.**

If a patient shows no evidence of improvement during the first 48 to 72 hours of medical management, other causes of ileus should be sought. Such cases may include ureteral injury, peritonitis from pelvic infection, unrecognized gastrointestinal tract injury with peritoneal spill, or fluid and electrolyte abnormalities such as hypokalemia. With persistent ileus, the use of water-soluble upper gastrointestinal contrast studies (CT scan with oral contrast) may assist in the resolution, but prospective randomized data regarding this maneuver are lacking.

**Small Bowel Obstruction**

Obstruction of the small bowel following major gynecologic surgery occurs in approximately 1% to 2% of patients (123). The most common cause of small bowel obstruction is adhesions to the operative site. If the small bowel becomes adherent in a twisted position, partial or complete obstruction may result from distention, ileus, or bowel wall edema. Less common causes of postoperative small bowel obstruction include entrapment of the small bowel into an incisional hernia and an unrecognized defect in the small bowel or large bowel mesentery. Early in its clinical course, a postoperative small bowel obstruction may exhibit signs and symptoms identical to those of ileus. Initial conservative management as outlined for the treatment of ileus is appropriate. Because of the potential for mesenteric vascular occlusion and resulting ischemia or perforation, worsening symptoms of abdominal pain, progressive distention, fever, leukocytosis, or acidosis should be evaluated carefully because immediate surgery may be required.

In most cases of small bowel obstruction following gynecologic surgery, the obstruction is only partial and the symptoms usually resolve with conservative management.

**Further evaluation after several days of conservative management may be necessary.** Evaluation of the gastrointestinal tract with barium enema, an upper gastrointestinal study, or a CT scan with small bowel assessment is appropriate. In most
cases, complete obstruction is not documented, although a narrowing ("transition point") or tethering of the segment of small bowel may indicate the site of the problem.

**Further conservative management with nasogastric decompression and intravenous fluid replacement may allow time for bowel wall edema or torsion of the mesentery to resolve.**

**If resolution is prolonged and the patient’s nutritional status is marginal, the use of TPN may be necessary.**

**Conservative medical management of postoperative small bowel obstruction usually results in complete resolution.** If persistent evidence of small bowel obstruction remains after full evaluation and an adequate trial of medical management, exploratory laparotomy may be necessary to manage the obstruction. In most cases, lysis of adhesions is all that is required, although a segment of small bowel that is badly damaged or extensively sclerosed from adhesions may require resection and reanastomosis.

**Colonic Obstruction**

Postoperative colonic obstruction following surgery for most gynecologic conditions is exceedingly rare. It is associated with a pelvic malignancy, which in most cases was known at the time of the initial operation. Advanced ovarian carcinoma is the most common cause of colonic obstruction in postoperative gynecologic surgery patients, and it is caused by extrinsic impingement on the colon by the pelvic malignancy. Intrinsic colonic lesions may be undetected, especially in a patient with some other benign gynecologic condition. When colonic obstruction is manifested by abdominal distention and abdominal radiography reveals a dilated colon and enlarging cecum, further evaluation of the large bowel is required by barium enema or colonoscopy. **Dilation of the cecum to more than 10 to 12 cm in diameter as viewed by abdominal radiography requires immediate evaluation and surgical decompression by performing colectomy or colostomy.** Surgery should be performed as soon as the obstruction is documented. Conservative management of colonic obstruction is not appropriate because the complication of colonic perforation has an exceedingly high mortality rate. In patients who are too ill to undergo surgery, the interventional radiologist may be able to place a cecostomy tube or the gastroenterologist may place a colonic stent (124).

**Diarrhea**

Episodes of diarrhea often occur following abdominal and pelvic surgery as the gastrointestinal tract returns to its normal function and motility. Prolonged and multiple episodes may represent a pathologic process such as impending small bowel obstruction, colonic obstruction, or pseudomembranous colitis. Excessive amounts of diarrhea should be evaluated by abdominal radiography and stool samples tested for the presence of ova and parasites, bacterial culture, and *Clostridium difficile* toxin. Proctoscopy and colonoscopy may be advisable in severe cases. Evidence of intestinal obstruction should
be managed as outlined previously. Infectious causes of diarrhea should be managed with the appropriate antibiotics and fluid and electrolyte replacement. **C. difficile–associated pseudomembranous colitis** may result from exposure to any antibiotic. Discontinuation of these antibiotics (unless they are needed to treat another severe infection) is advisable, along with the institution of appropriate therapy. Oral metronidazole is a suitable agent for instituting therapy and is less expensive than vancomycin. Therapy should be continued until the diarrhea abates, and several weeks of oral therapy may be required to obtain complete resolution of the pseudomembranous colitis.

**Fistula**

Gastrointestinal fistulas are relatively rare following gynecologic surgery. They are most often associated with malignancy, prior radiation therapy, intestinal resection with anastomosis, or surgical injury to the large or small bowel that was improperly repaired or unrecognized. Signs and symptoms of gastrointestinal fistula are often similar to those of small bowel obstruction or ileus, except that fever is usually a more prominent component of the patient’s symptoms. When fever is associated with gastrointestinal dysfunction postoperatively, evaluation should include early assessment of the gastrointestinal tract to confirm its continuity. **When fistula is suspected, the use of water-soluble gastrointestinal contrast material is advised to avoid the complication of barium peritonitis.** Evaluation with abdominal pelvic CT scan may assist in identification of a fistula and associated abscess. **Recognition of an intraperitoneal gastrointestinal leak or fistula formation usually requires immediate surgery, unless the fistula drained spontaneously through the abdominal wall or vaginal cuff.**

**An enterocutaneous fistula arising from the small bowel and draining spontaneously through the abdominal incision may be managed successfully with medical therapy.** Therapy should include nasogastric decompression, replacement of intravenous fluids as well as TPN, and appropriate antibiotics to treat an associated mixed bacterial infection. If the infection is under control and there are no other signs of peritonitis, the surgeon may consider allowing potential resolution of the fistula over a period of up to 2 weeks. Some authors suggested the use of somatostatin to decrease intestinal tract secretion and allow earlier healing of the fistula. In some cases, the fistula will close spontaneously with this mode of management. If the enterocutaneous fistula does not close with conservative medical management, surgical correction with resection, bypass, or reanastomosis will be necessary.

A rectovaginal fistula that occurs following gynecologic surgery is usually the result of surgical trauma that may have been aggravated by the presence of extensive adhesions and scarring in the rectovaginal septum associated with endometriosis, pelvic inflammatory disease, or pelvic malignancy. **A small rectovaginal fistula may be managed with a conservative medical approach, in the hope that decreasing the fecal stream will allow closure of the fistula.** A small fistula that allows...
continence except for an occasional leak of flatus may be managed conservatively until the inflammatory process in the pelvis resolves. At that point, usually several months later, correction of the fistula is appropriate. Large rectovaginal fistulas for which there is no hope of spontaneous closure are best managed by performing an initial diverting colostomy followed by repair of the fistula after inflammation resolves. After the fistula closure is healed and deemed successful, the colostomy can be reversed.
Thromboembolism

Risk Factors

Deep venous thrombosis and pulmonary embolism are largely preventable, yet significant complications in postoperative patients. The magnitude of this problem is relevant to the gynecologist, because 40% of all deaths following gynecologic surgery are directly attributed to pulmonary emboli, and it is the most frequent cause of postoperative death in patients with uterine or cervical carcinoma (125,126).

The causal factors of venous thrombosis were first proposed by Virchow in 1858 and include a hypercoagulable state, venous stasis, and vessel endothelial injury. Risk factors include major surgery; advanced age; nonwhite race; malignancy; history of deep venous thrombosis, lower extremity edema, or venous stasis changes; presence of varicose veins; being overweight; a history of radiation therapy; and hypercoagulable states, such as factor V Lieden, pregnancy, and use of oral contraceptives, estrogens, or tamoxifen. Intraoperative factors associated with postoperative deep venous thrombosis include increased anesthesia time, increased blood loss, and the need for transfusion in the operating room. It is important to recognize these risk factors and to provide the appropriate level of venous thrombosis prophylaxis (127,128). The levels of thromboembolism risk are listed in Table 22.11.

Table 22.11 Thromboembolism Risk Stratification

Risk factors: obesity, varicose veins, history of deep venous thrombosis or pulmonary embolism, current estrogen, tamoxifen, or oral contraceptive use.

Prophylactic Methods
A number of prophylactic methods significantly reduced the incidence of deep venous thrombosis, and a few studies included a large enough patient population to show a reduction in fatal pulmonary emboli (129). The ideal prophylactic method would be effective, free of significant side effects, well accepted by the patient and nursing staff, widely applicable to most patients, and inexpensive.

**Low-Dose Heparin**

The use of small doses of subcutaneously administered heparin for the prevention of deep venous thrombosis and pulmonary embolism is the most widely studied of all prophylactic methods. More than 25 controlled trials demonstrated that heparin given subcutaneously 2 hours preoperatively and every 8 to 12 hours postoperatively is effective in reducing the incidence of deep venous thrombosis. The value of low-dose heparin in preventing fatal pulmonary emboli was established by a randomized, controlled multicenter international trial, which demonstrated a significant reduction in fatal postoperative pulmonary emboli in general surgery patients receiving low-dose heparin every 8 hours postoperatively (129). Trials of low-dose heparin in gynecologic surgery patients showed a significant reduction in postoperative deep venous thrombosis.

Although low-dose heparin is considered to have no measurable effect on coagulation, most large series noted an increase in the bleeding complication rate, especially a higher incidence of wound hematoma (130). Although relatively rare, thrombocytopenia is associated with low-dose heparin use and was found in 6% of patients after gynecologic surgery (130). If patients remain on low-dose heparin for more than 4 days, it is reasonable to check their platelet count to assess the possibility of heparin-induced thrombocytopenia.

**Low-Molecular-Weight Heparin**

Low-molecular-weight heparins (LMWH) are fragments of heparin that vary in size from 4,500 to 6,500 Da. When compared with unfractionated heparin, LMWH have more anti-Xa and less antithrombin activity, leading to less effect on partial thromboplastin time and possibly leading to fewer bleeding complications (131). An increased half-life of 4 hours results in increased bioavailability when compared with unfractionated heparin. The increase in half-life of LMWH allows the convenience of once-a-day dosing.

Randomized controlled trials compared LMWH with unfractionated heparin in patients undergoing gynecologic surgery. In all studies, there was a similar incidence of deep venous thrombosis (DVT). Bleeding complications were similar between the unfractionated heparin and LMWH groups (132). A meta-analysis of general surgery and gynecological surgery patients from 32 trials indicated that daily LMWH administration is as effective as unfractionated heparin in DVT prophylaxis without any difference in hemorrhagic complications (133).
Mechanical Methods

Stasis in the veins of the legs occurs while the patient is undergoing surgery and continues postoperatively for varying lengths of time. Stasis occurring in the capacitance veins of the calf during surgery, plus the hypercoagulable state induced by surgery, are the prime factors contributing to the development of acute postoperative DVT. Prospective studies of the natural history of postoperative DVT showed that the calf veins are the predominant site of thrombi and that most thrombi develop within 24 hours of surgery (134).

Although probably of only modest benefit, reduction of stasis by short preoperative hospital stays and early postoperative ambulation should be encouraged for all patients. Elevation of the foot of the bed, raising the calf above heart level, allows gravity to drain the calf veins and should further reduce stasis.

Graduated Compression Stockings

Controlled studies of graduated compression stockings are limited but do suggest modest benefit when they are carefully fitted (135). Poorly fitted stockings may be hazardous to some patients who develop a tourniquet effect at the knee or midthigh (126). Variations in human anatomy do not allow perfect fit of all patients to available stocking sizes. The simplicity of graduated compression stockings and the absence of significant side effects are probably the two most important reasons that they are included in routine postoperative care. Compared to thigh length stockings, calf-high stockings appear to offer the same degree of venous thromboembolism protection.

Intermittent Pneumatic Compression

The largest body of literature dealing with the reduction of postoperative venous stasis deals with intermittent compression of the leg by pneumatically inflated sleeves placed around the calf or leg during intraoperative and postoperative periods. Various pneumatic compression devices and leg sleeve designs are available, and the literature has not demonstrated superiority of one system over another. Calf compression during and after gynecologic surgery significantly reduces the incidence of DVT on a level similar to that of low-dose heparin. In addition to increasing venous flow and pulsatile emptying of the calf veins, intermittent pneumatic compression appears to augment endogenous fibrinolysis, which may result in lysis of very early thrombi before they become clinically significant (136).

The duration of postoperative external pneumatic compression differed in various trials. External pneumatic compression may be effective when used in the operating room and for the first 24 hours postoperatively in patients with benign conditions who will ambulate on the first postoperative day (136,137).

External pneumatic compression used in patients undergoing major surgery for gynecologic malignancy reduced the incidence of postoperative venous thromboembolic complications by nearly threefold, but only if calf compression
was applied intraoperatively and for the first 5 postoperative days \((138,139)\). Patients with gynecologic malignancies may remain at risk for a longer period than general surgical patients because of stasis and hypercoagulable states; therefore, these patients appear to benefit from longer use of intermittent pneumatic compression.

Intermittent pneumatic leg compression has no significant side effects or risks and is considered slightly more cost-effective when compared with pharmacologic methods of prophylaxis \((140)\). Compliance in wearing the leg compression while in bed is of utmost importance, and the patient and nursing staff should be educated to the proper regimen for maximum benefit.

The use of low-dose heparin or LMWH or intermittent pneumatic compression is a reasonable strategy in the care of women at moderate risk for postoperative venous thromboembolism. In high-risk patients, consideration should be given to using a pharmacologic method along with intermittent pneumatic compression.

**Management of Postoperative Deep Venous Thrombosis and Pulmonary Embolism**

Because pulmonary embolism is the leading cause of death following gynecologic surgical procedures, identification of high-risk patients and the use of prophylactic venous thromboembolism regimens are essential parts of management \((125,126,141)\).

The early recognition of DVT and pulmonary embolism and immediate treatment are critical. Most pulmonary emboli arise from the deep venous system of the leg following gynecologic surgery; the pelvic veins are a known source of fatal pulmonary emboli.

The signs and symptoms of DVT of the lower extremities include pain, edema, erythema, and prominent vascular pattern of the superficial veins. These signs and symptoms are relatively nonspecific; 50% to 80% of patients with these symptoms will not have DVT \((142)\). Conversely, approximately 80% of patients with symptomatic pulmonary emboli have no signs or symptoms of thrombosis in the lower extremities \((143)\). Because of the lack of specificity when signs and symptoms are recognized, additional tests should be performed to establish the diagnosis of DVT.

**Diagnosis**

**Doppler Ultrasound B-mode duplex**

Doppler imaging is the most common technique for the diagnosis of symptomatic venous thrombosis, especially when it arises in the proximal lower extremity. With duplex Doppler imaging, the femoral vein can be visualized and clots may be seen directly \((144)\). Compression of the vein with the ultrasound probe tip allows assessment of venous collapsibility; the presence of a thrombus diminishes vein wall collapsibility. Doppler imaging is less accurate when evaluating the calf and the pelvic veins.
Venography

Although venography is the standard technique for diagnosis of DVT, other diagnostic studies are accurate when performed by a skilled technologist and, in nearly all patients, may replace the need for contrast venography. Venography is moderately uncomfortable, requires the injection of a contrast material that may cause allergic reaction or renal injury, and may result in phlebitis in approximately 5% of patients (145). If the results of noninvasive imaging are normal or inconclusive and the clinician remains concerned given clinical symptoms, venography should be performed to obtain a definitive answer.

Magnetic Resonance Venography

In addition to having a sensitivity and specificity comparable to venography, magnetic resonance venography (MRV) may detect thrombi in pelvic veins that are not imaged by venography (146). The primary drawback to MRV is the time involved in examining the lower extremity and pelvis and the expense of this technology.

Treatment

Deep Venous Thrombosis

The treatment of postoperative DVT requires the immediate institution of anticoagulant therapy. Treatment may be with either unfractionated heparin or LMWH, followed by 6 months of oral anticoagulant therapy with warfarin (Coumadin).

Unfractionated Heparin

After venous thromboembolism is diagnosed, unfractionated heparin should be initiated to prevent proximal propagation of the thrombus and allow physiological thrombolytic pathways to dissolve the clot. An initial bolus of 80 U per kilogram is given intravenously, followed by a continuous infusion of 1,000 to 2,000 U per hour (18 U/kg/hour). Heparin dosage is adjusted to maintain activated partial thromboplastin time (APTT) levels at a therapeutic level 1.5 to 2.5 times the control value. Initial APTT should be measured after 6 hours of heparin administration and the dose adjusted as necessary. Patients having subtherapeutic APTT levels in the first 24 hours have a 15-fold increased risk of recurrent VTE when compared to patients who are adequately anticoagulated. Patients should be managed aggressively using intravenous heparin to achieve prompt anticoagulation. A weight-based nomogram is helpful in achieving a therapeutic APTT level (Table 22.12) (147). Oral anticoagulant (warfarin) administration may be started on the first day of heparin infusion. The international normalized ration (INR) should be monitored daily until a therapeutic level is achieved (2.0 to 3.0 times normal value). The change in the INR resulting from warfarin administration often precedes the anticoagulant effect by approximately 2 days, during which time low protein C levels are associated with a transient hypercoagulable state. Therefore, heparin should be administered until the INR was maintained in a therapeutic range for at least 2
days, confirming proper warfarin dose. Intravenous heparin may be discontinued in 5 days if an adequate IRN level is established.

Table 22.12 Heparin Administration for Treatment of Deep Venous Thrombosis or Pulmonary Embolism: Weight-Based Nomogram

<th>Time of Administration</th>
<th>Dose</th>
</tr>
</thead>
<tbody>
<tr>
<td>Initial dose</td>
<td>80-U/kg bolus, then 18 U/kg/h</td>
</tr>
</tbody>
</table>

The APTT should be measured every 6 h and the heparin dose adjusted as follows:

- APTT <35 seconds (<1.2 × control): 80-U/kg bolus, then 4 U/kg/h
- APTT 35–45 seconds (1.2–1.5 × control): 40-U/kg bolus, then 2 U/kg/h
- APTT 46–70 seconds (1.5–2.3 × control): No change
- APTT 71–90 seconds (2.3–3 × control): Decrease infusion rate by 2 U/kg/h
- APTT >90 seconds (>3 × control): Hold infusion for 1 h, then decrease infusion rate by 3 U/kg/h

APTT, activated partial thromboplastin time.

Low-Molecular-Weight Heparin

Two LMWH preparations (enoxaparin and dalteparin) were effective in the treatment of venous thromboembolism and have a cost-effective advantage over intravenous heparin in that they may be administered in the outpatient setting. The dosages used in treatment of thromboembolism are unique and weight adjusted according to each LMWH preparation. Because LMWH has a minimal effect on APPT, serial laboratory monitoring of these levels is not necessary. Similarly, monitoring of anti-Xa activity (except in difficult cases or those with renal impairment) is not of significant benefit in a dose adjustment of LMWH. The increased bioavailability associated with LMWH allows for twice-a-day dosing, potentially making outpatient management an option for a subset of patients. A meta-analysis involving more than 4,000 patients from 22 trials suggests that LMWH is more effective, safer, and less costly when compared with unfractionated heparin in preventing recurrent thromboembolism (148).

Pulmonary Embolism

Many of the signs and symptoms of pulmonary embolism are associated with other, more commonly occurring pulmonary complications following surgery. The classic findings of pleuritic chest pain, hemoptysis, shortness of breath, tachycardia, and
Tachypnea should alert the physician to the possibility of a pulmonary embolism. Many times the signs are subtle and may be demonstrated only by a persistent tachycardia or a slight elevation in the respiratory rate. Patients suspected of pulmonary embolism should be evaluated initially by chest x-ray, electrocardiography, and arterial blood gas assessment. Any evidence of abnormality should be further evaluated by a spiral CT scan of the chest or a ventilation-perfusion lung scan. A high percentage of lung scans may be interpreted as “indeterminate.” In this setting, careful clinical evaluation and judgment are required to decide whether pulmonary arteriography should be performed to document or exclude the presence of a pulmonary embolism.

The treatment of pulmonary embolism is as follows:

- Immediate anticoagulant therapy, identical to that outlined for the treatment of DVT, should be initiated.
- Respiratory support, including oxygen and bronchodilators and an intensive care setting, if necessary.
- Although massive pulmonary emboli are usually quickly fatal, rarely pulmonary embolectomy is successful.
- Pulmonary artery catheterization with the administration of thrombolytic agents bears further evaluation and may be important in patients with massive pulmonary embolism.
- Vena cava interruption may be necessary in situations in which anticoagulant therapy is ineffective in the prevention of rethrombosis and repeated embolization from the lower extremities or pelvis. A vena cava filter may be inserted percutaneously above the level of the thrombosis and caudad to the renal veins. In most cases, anticoagulant therapy is sufficient to prevent repeat thrombosis and embolism and to allow the patient’s own endogenous thrombolytic mechanisms to lyse the pulmonary embolus.
Management of Medical Problems

Endocrine Disease

The three most frequent endocrine disorders that occur in patients undergoing gynecologic surgery are diabetes mellitus, thyroid disease, and adrenal abnormalities. The pathophysiology of these disorders aids in understanding the effects of surgery on patients with these problems.

Diabetes Mellitus

According to the American Diabetes Association, 9.3 million American women, or 10.2% of all women older than 20 years, suffer from diabetes (149). Approximately 50% of individuals with diabetes mellitus (DM) will require surgery during their lives (150). Many of these procedures are a direct result of the complications of DM: retinopathy, nephropathy, large- and small-vessel occlusive disease, and coronary artery disease. It is the direct effect of DM on the end organs that determines the risk of surgery, rather than the type or duration of surgery, or the management of the condition itself. Diabetes mellitus is a complicated medical disorder of glucose metabolism that is related to a lack of production of, or resistance to, insulin.

Patients with DM experience exaggerated hyperglycemia during surgery. This hyperglycemia is multifactorial in origin and is secondary to increased catecholamine production, which inhibits pancreatic release of insulin and causes increased insulin resistance at the end organs. Elevations in instrumental hormones, such as cortisol, growth hormone, and glucagon, enhance gluconeogenesis and glycogenolysis (151). Goals of the preoperative assessment and perioperative management are to ensure metabolic homeostasis and to anticipate problems arising from preexisting complications.

Preoperative Risk Assessment

Preoperative risk assessment for diabetes should begin with a review of systems. Nocturia, polyuria, polydipsia, glucosuria, obesity, previous gestational diabetes, ethnicity, and family history are relevant aspects of the history. The current criteria for diagnosis of diabetes include (152):

- Polyuria, polydipsia, or unexplained weight loss with a random nonfasting glucose of ≥200 mg/dL, or
- Fasting glucose ≥126 mg/dL (in which fasting is defined as no food intake for 8 hours), or
- Two-hour oral glucose tolerance test of 75 g, with serum glucose ≥200 mg/dL, or
- Hemoglobin A1c ≥6.5%.

Confirmation of the diagnosis requires repeating the same test on a different day or concordant results of two different tests simultaneously.
Preoperative risk assessment in the previously diagnosed individual with diabetes should begin with the knowledge of the type of diabetes. Type 1 (insulin dependent) diabetes, or type 2 diabetes (noninsulin dependent), should be established because the perioperative management of each differs. The patient’s routine glucose management strategies, glucose levels, medications, and baseline hemoglobin A\textsubscript{1c} should be assessed (153). The presence of end-organ complications of diabetes should be documented.

**Large- and small-vessel arterial occlusive disease is the single most important risk factor in the preoperative setting.** A careful history and physical examination should be performed to determine the presence or absence of coronary artery or cerebral vascular disease (150). When extended surgery is possible, as with surgery for gynecologic cancer, exercise stress testing or dipyridamole-thallium imaging should be considered to rule out occult coronary artery disease. Perioperative beta-blockade should be continued for patients already on beta-blockers at baseline. For patients with inducible ischemia, coronary artery disease, or multiple clinical risk factors for heart disease, perioperative beta-blockade should be considered, with initiation and careful titration of medication several weeks prior to surgery (154,155). Assessment of end-organ disease in the retina, kidney, and carotid arteries or evidence of peripheral vascular disease by the presence of foot ulcers should alert the clinician to the presence of small- or large-vessel disease. Diabetic nephropathy should be documented carefully preoperatively. Imaging studies using contrast dye should be avoided, and alternative testing should be performed to reduce the incidence of acute tubular necrosis. If a contrast study must be performed, adequate hydration both before and after the procedure is essential, and oral metformin should be withheld for 24 to 48 hours after the procedure.

Diabetes is associated with increased perioperative infections (156). Preoperative evaluation should include examination of the skin and urine sediment to detect asymptomatic infection. Wound infections, skin infections, pneumonia, and urinary tract infections account for two-thirds of the postoperative complications in patients with diabetes (151). There is a known predisposition for patients with DM to have increased colonization by methicillin-resistant Staphylococcus aureus, increased infections by gram-negative and staphylococcal bacteria, and an increased incidence of gram-negative and group B streptococcal sepsis (157–159). Seven percent of individuals with diabetes will have postoperative gram-negative sepsis, a rate approximately seven times higher than that of the nondiabetic population. These complications occur more often in patients with poor glucose control, probably caused by impaired leukocyte function in the presence of hyperglycemia (160,161). Individuals with DM have an increased risk of wound dehiscence and wound infection, possibly related to an impaired immune function, with changes in phagocytosis, cell-mediated immunity, and intracellular bactericidal activity (162). Autonomic neuropathy was documented in patients with DM, and these autonomic impairments can lead to intraoperative hypotension, cardiac arrhythmias, sudden death and abnormal motility of the esophagus, stomach, and small intestine (151). Peripheral sensory and motor neuropathies may or may not be present. The presence of any manifestations of autonomic neuropathy intraoperatively should prompt close monitoring.
of the affected organ system in the postoperative period.

The traditional goal for glucose control perioperatively is to maintain the glucose level below 200 mg/dL (151,153). Significant debate continues regarding whether strict glycemic control below 110 mg/dL may be beneficial in critically ill patients (163,164). Perioperative hyperglycemia (>250 mg/dL) is associated with increased susceptibility to infection and poor wound healing. Extreme hyperglycemia predisposes type 1 DM patients to metabolic acidosis, and surgery should be canceled until normal acid-base balance is documented. Hyperosmolar hyperglycemic nonketotic states must be recognized before surgery. Electrolyte disturbances, especially those related to sodium and potassium, should be corrected preoperatively. Hypoglycemia should be avoided during the perioperative period.

The history and type of DM are important factors to consider when devising a perioperative management plan. Patients with noninsulin-dependent diabetes (type 2) whose condition is controlled with oral hypoglycemic agents or diet are best treated with intravenous fluids containing no dextrose and should not be given insulin intraoperatively. Oral administration of hypoglycemic agents should be discontinued when the patient ceases oral intake of food, and hyperglycemic episodes in the perioperative period are treated with sliding-scale regular insulin if blood sugar levels exceed 200 mg/dL (151,153).

Insulin-dependent or type 1 diabetes poses a more difficult problem. These patients are insulin deficient and therefore require a basal rate of insulin at all times. Likewise, they require a baseline intake of glucose. They risk developing diabetic ketoacidosis whether or not they are eating (153). Preoperatively, the goals include avoiding ketoacidosis and hypoglycemia, and, to a lesser extent, hyperglycemia. Traditionally, approximately one-third to one-half of the patient’s usual daily dose of NPH insulin (intermediate acting) is given subcutaneously the morning of surgery. Omit any short-acting insulin without oral intake. An infusion of 5% dextrose should be given while being restricted from oral intake. Additional regular insulin can be administered in the operating room as needed (150,153). If patients are normally on a continuous insulin infusion, they may continue at their usual infusion rate. There is no single regimen that is superior for the intraoperative management of type 1 diabetic patients. A continuous intravenous insulin infusion is indicated for patients with unstable type 1 diabetes, those who require emergency surgery while in ketoacidosis, and those undergoing long, complex procedures (161). Consultation with endocrine and anesthesia colleagues can be helpful in managing these complex regimens.

Postoperative Management
Postoperative monitoring of patients with DM includes careful monitoring of serum glucose levels. If an intravenous insulin regimen is used, blood glucose levels must be checked every 1 to 2 hours. If a sliding-scale insulin administration is used, blood glucose should be checked and documented approximately every 6
hours until the patient is eating and stable on her preoperative regimen. The serum glucose level should be maintained at less than 250 mg/dL, and ideally below 140 mg/dL when fasting and below 180 mg/dL with random draws (165,166). For type 2 diabetics, oral hypoglycemics can be restarted when the patient resumes eating, except with metformin, which requires normal renal and liver function (153).

It is essential to prevent the development of severe hypoglycemia or hyperglycemia and the associated complications of diabetic ketoacidosis or a hyperosmolar state. Rigorous perioperative management may obviate some of the infectious and wound-healing complications that are more common in these patients (167).

**Thyroid Syndromes**

Thyroid dysfunction should be suspected in any patient with a history of hyperthyroidism, use of thyroid replacement medication or antithyroid medication, prior thyroid surgery, or radioactive iodine therapy.

**Hyperthyroidism**

Diffuse toxic goiter (Grave’s disease) is the most common cause of hyperthyroidism and results from abnormal stimulation of the thyroid gland by antithyroid antibodies. Other causes of hyperthyroidism include multinodular goiter, excess thyroid hormone, or thyroiditis. Any signs or symptoms suggestive of weight loss, tachycardia, atrial fibrillation, goiter, or proptosis should initiate a more extensive laboratory evaluation of thyroid function. Total thyroxin, free triiodothyronine (T$_3$), free thyroxin (T$_4$), and thyroid-stimulating hormone (TSH) tests are useful in diagnosis. In hyperthyroidism, the free T$_4$ level will be elevated, and the TSH level will be suppressed (154). A new diagnosis of hyperthyroidism necessitates postponement of elective surgery until adequate treatment with antithyroid medication is received because of the risk of thyroid storm. Thyroid storm is associated with mortality of up to 40% (168). Stable thyroid conditions do not require any special preoperative treatments or tests. Ideally, an euthyroid state should be maintained for 3 months before elective surgery. In emergent situations, beta-blockers can be used to counter sympathomimetic drive such as palpitations, diaphoresis, and anxiety. Antithyroid medications such as propylthiouracil (PTU) or radioactive iodine do not render patients euthyroid quickly enough for urgent surgery. Radioactive iodine requires 6 to 18 weeks to establish a euthyroid state (154). When thyroid dysfunction is corrected and maintained for several months, elective surgery can proceed without additional perioperative monitoring. Antithyroid medications should be resumed with return of bowel function. If a prolonged delay in resumption of oral intake is encountered, PTU and methimazole can be administered rectally (169). When time does not permit establishment of a euthyroid state preoperatively, oral administration of PTU and a beta-blocker can be implemented for 2 weeks before surgery, and with careful monitoring, optimal results can be achieved (170). Alternatively, oral beta-blockers, glucocorticoids, and sodium iopanoate can be...
used for 5 days, followed by surgery on day 6 (169). In the emergent setting, close monitoring of the patient for tachycardia, arrhythmias, and hypertension is necessary. Beta-blockers can control these symptoms until definitive therapy can be initiated after recovery from surgery.

Any signs suggestive of the development of thyroid storm—including hemodynamic instability, tachycardia, arrhythmias, hyperreflexia, diarrhea, fever, delirium, or congestive heart failure—mandate transfer to an intensive care setting for optimal monitoring and management in consultation with a medical endocrinologist. Such thyroid instability can be triggered by underlying infection, which requires diagnosis and treatment to facilitate management of this medical emergency. The mortality rate from thyroid storm is reportedly between 10% and 75% (169). Treatment of thyroid storm consists of beta-blockers, thioamides, iodine, iodinated contrast agents, and corticosteroids (151). Aspirin should not be given for fever in the patient with thyroid storm because it may interfere with the protein binding of T_4 and T_3, resulting in increased free serum concentrations (151).

**Hypothyroidism**

The incidence of hypothyroidism is approximately 1% in the adult population, and 5% in adults older than 50 years (154). In women older than 60 years, the incidence of hypothyroidism may approach 6% (168). Hypothyroidism is 10 times more common in women than in men (154). Many such cases are secondary to previous antithyroid therapy (radioactive iodine or thyroidectomy) for hyperthyroidism. The most common primary cause of hypothyroidism is Hashimoto's thyroiditis, an autoimmune condition (154). A history of lethargy, cold intolerance, lassitude, weight gain, fluid retention, constipation, dry skin, hoarseness, periorbital edema, and brittle hair can be indicative of inadequate thyroid function. In this setting, physical findings of increased relaxation phase of deep tendon reflexes, cardiomegaly, pleural or pericardial effusions, or peripheral edema should stimulate further investigation of thyroid function by assessment of TSH and free T_4 levels. Hypothyroidism decreases cardiac output by 30% to 50% as a result of decreased stroke volume and heart rate (171). Hyponatremia may be associated with hypothyroidism because of the inability of the kidneys to excrete water (171). When elective surgery is planned for severely hypothyroid patients, surgery should be postponed until thyroid replacement therapy is initiated (154). In patients with mild or moderate hypothyroidism, the delay of surgery is controversial (154).

For young patients with mild to moderate hypothyroidism, a starting dose of 1.6 μg/kg of thyroid hormone replacement can be given. In elderly patients, thyroxin dosage (0.025 mg once a day) should be given with interval dose increases every 4 to 6 weeks until the patient is euthyroid (168). **Dosage levels can ultimately be titrated against TSH levels.** In severely hypothyroid patients requiring urgent or emergent surgery, intravenous T_3 or T_4 may be given, along with intravenous corticosteroids to avoid consequences of unrecognized adrenal insufficiency (151,154).
In the immediate postoperative setting, T₄ therapy can be held for 5 to 7 days while waiting for return of bowel function because the half-life of circulating T₄ is approximately 5 to 9 days (170). If more than 5 to 7 days of decreased bowel function are expected, T₄ can be given by the intramuscular or intravenous route at approximately 80% of the oral dose (171,172).

**Adrenal Insufficiency**

Adrenal insufficiency may result in catastrophic postoperative complications, including death. The most common cause of adrenal insufficiency in the surgical patient is secondary to the exogenous use of corticosteroids. The physician should ascertain whether a patient used exogenous steroids for asthma (including inhaled steroids), malignant conditions, arthritis, or irritable bowel syndrome. The type of steroid use, the route, the dose, the duration, and the temporal relationship to the timing of the surgical procedure must be determined. The type of surgical procedure and its associated stress should be taken into consideration. The use of high doses of exogenous steroids for prolonged periods can cause circulatory collapse, and they have adverse effects on wound healing and immunocompetence.

The daily replacement dose of cortisol is approximately 5 to 7.5 mg of prednisone. Suppression of the hypothalamic–pituitary–adrenal (HPA) axis by exogenous steroids for more than a few weeks may produce relative adrenal insufficiency. When systemic steroids are used for longer periods, adrenal insufficiency may persist for up to 1 year. Short courses of low-dose oral steroids (<5 mg of prednisone in a single morning dose for any duration of time, alternate-day dosing of short-acting glucocorticoids, and any dose of corticosteroids given for less than 3 weeks) are not thought to cause clinically significant suppression of the HPA axis (151,172). Use of inhaled corticosteroids of over 0.8 mg per day or class I topical glucocorticoids of 2 g per day or more may cause suppression (172).

If either the dose or duration of glucocorticoid administration exceeds the preceding regimen, biochemical tests are recommended to preoperatively evaluate the function of the adrenal gland. The easiest and safest test to assess HPA function is the cosyntropin stimulation test. Cosyntropin, a synthetic analogue of adrenocorticotropic hormone, is given in a dose of 250 μg intravenously, and a blood sample is collected 30 minutes after the injection and assayed for plasma cortisol. A plasma cortisol value of greater than 18 to 20 μg/dL indicates adequate adrenal function (151,154). If the history regarding exogenous steroid use is unclear, the cosyntropin stimulation test should be considered as a preoperative test to determine whether the patient will need perioperative glucocorticoid coverage. The amount of glucocorticoid replacement should be equivalent to the normal physiologic response to surgical stress (Table 22.13) (173).

Surgical Stress

**Minor**
- Inguinal hernia repair
- Colonoscopy
- Mild febrile illness
- Mild-moderate nausea/vomiting
- Gastroenteritis

**25 mg of hydrocortisone or 5 mg of methylprednisolone IV on day of procedure only**

**Moderate**
- Open cholecystectomy
- Hemicolectomy
- Significant febrile illness
- Pneumonia
- Severe gastroenteritis

**50–75 mg of hydrocortisone or 10–15 mg of methylprednisolone IV on day of procedure**
**Taper quickly over 1–2 days to usual dose**

**Severe**
- Major cardiothoracic surgery
- Whipple procedure
- Liver resection
- Pancreatitis

**100–150 mg of hydrocortisone or 20–30 mg of methylprednisolone IV on day of procedure**
**Rapid taper to usual dose over next 1–2 days**

**Critically Ill**
- Sepsis-induced hypotension or shock

**50–100 mg of hydrocortisone IV every 6–8 h or 0.18 mg/kg/h as a continuous infusion + 50 μg/d of fludrocortisone until shock resolved.**
  **May take several days to a week or more, then gradually taper, following vital signs and serum sodium.**

**IV, intravenously.**

*Patients receiving 5 mg/d or less of prednisone should receive their normal daily replacement but do not require supplementation. Patients who receive greater than 5 mg/d of prednisone should receive the above therapy in addition to their maintenance therapy.*
For minor surgical stress, such as colonoscopy, the glucocorticoid target is approximately 25 mg of hydrocortisone equivalent on the day of the procedure (173). For moderate surgical stress, for example, open cholecystectomy, the glucocorticoid target is 50 to 75 mg of hydrocortisone equivalent on the day of the procedure and tapered quickly for 1 to 2 days (173). The patient should receive her normal daily dose preoperatively, followed by 50 mg of hydrocortisone intravenously administered intraoperatively. For major surgical stress, such as liver resection, the glucocorticoid target range is 100 to 150 mg hydrocortisone equivalent on the day of the procedure, tapering rapidly over the next 1 to 2 days to the usual dosage (173). The patient should receive her normal daily dose preoperatively.

Administration of high-dose steroids should be stopped as soon as possible postoperatively because they can inhibit wound healing and promote infection. Hypertension and glucose intolerance can develop. When a prolonged or involved procedure is performed and longer steroid use is necessary, careful tapering may be required. The previously recommended approach was to halve the dose of hydrocortisone on a daily basis until a dose of 25 mg is reached. Eliminating one daily dose each day until the drug is stopped was considered the safest method of withdrawal; no consensus on the timing or duration of steroid tapering exists. Addison’s disease is uncommon but should be considered in the differential diagnosis if the patient develops perioperative hypotension after steroids are withdrawn. In addition to blood and isotonic fluid replacement, a “stress” dose of steroids should be given if adrenal insufficiency is suspected and sepsis and hypovolemia are excluded.
Cardiovascular Diseases
The incidence of perioperative cardiovascular complications decreased markedly as a result of improvements in preoperative detection of high-risk patients, preoperative preparation, and surgical and anesthetic techniques (174).

Preoperative Evaluation
The goal of a preoperative cardiac evaluation is to determine the presence of heart disease, its severity, and the potential risk to the patient during the perioperative period. Every patient should be questioned about symptoms of cardiac disease including chest pain, dyspnea on exertion, peripheral edema, wheezing, syncope, claudication, or palpitations. Patients with a history of cardiac disease should be evaluated for worsening of symptoms, which indicates progressive or poorly controlled disease. Records of previous treatment should be obtained. Prescriptions for antihypertensive, anticoagulant, antiarrhythmic, antilipid, or antianginal medications may be the only indication of cardiac problems. In patients without known heart disease, the presence of DM, hyperlipidemia, hypertension, tobacco use, or a family history of heart disease identifies patients at higher risk for heart disease who should be more carefully screened.

On physical examination, the presence of findings such as hypertension, jugular venous distention, laterally displaced point of maximum impulse, irregular pulse, third heart sound, pulmonary rales, heart murmurs, peripheral edema, or vascular bruits should prompt a more complete evaluation. Laboratory evaluation of patients with known or suspected heart disease should include a blood count and serum chemistry analysis. Patients with heart disease tolerate anemia poorly. Serum sodium and potassium levels are particularly important in patients taking diuretics and digitalis. Blood urea nitrogen and creatinine values provide information on renal function and hydration status. Assessment of blood glucose levels may detect undiagnosed DM. Chest radiography and electrocardiography are mandatory as part of the preoperative evaluation, and the results may be particularly helpful when compared with those of previous studies.

Coronary Artery Disease
Coronary artery disease is a major risk factor for patients undergoing abdominal surgery. In an adult population without a prior history of myocardial infarction, the incidence of myocardial infarction following surgery is 0.1% to 0.7% (175). In patients who had a prior myocardial infarction, the reinfarction rate is 2.8% to 7% (176). The risk of reinfarction is inversely proportional to the length of time between infarction and surgery. At 3 months or less, the risk of reinfarction is 5.7%, and from 3 to 6 months, the rate falls to 2.3%. Six months after myocardial infarction, the reinfarction rate is 1.5% (175). Careful perioperative management can lower the reinfarction rate in patients who had recent
Because of the high mortality and morbidity associated with perioperative myocardial infarction, considerable effort is made to predict perioperative cardiac risk. **A prospective evaluation of preoperative cardiac risk factors using a multivariate analysis identified independent cardiac risk factors for patients undergoing noncardiac surgery** (177). Using these factors, a cardiac risk index was created that placed a patient in one of four risk classes. This cardiac risk index was further modified and validated prospectively, resulting in a tool for clinical risk assessment in nonemergent major noncardiac surgery, the Revised Cardiac Risk Index (178). Risk factors include high-risk surgical procedures, history of ischemic heart disease, history of congestive heart failure, history of transient ischemic attack or stroke, preoperative insulin therapy, and preoperative serum creatinine levels greater than 2.0 mg/dL. Depending on the number of risk factors, the risk of major cardiac events (myocardial infarction, cardiac arrest, pulmonary edema, and complete heart block) range from 0.5% to 9.1% (Table 22.14).

Cl, confidence interval.

Risk assessment is stratified into three major categories: (i) clinical predictors, (ii) functional capacity, and (iii) surgery-specific risk (179). Clinical predictors of increased perioperative cardiac risk were formerly divided into major, intermediate, and minor factors. The intermediate category was replaced by clinical risk factors from the revised cardiac risk index (Table 22.15). The patient’s functional status is assessed by a thorough history (Table 22.16), and self-reported exercise tolerance can be used to predict perioperative risk, based on a system of metabolic equivalents (METS) (180). Surgery-specific risk is subdivided into high-risk procedures (emergent major operations, aortic and vascular procedures, and prolonged surgical procedures associated with large fluid shifts or blood loss), intermediate-risk procedures (intraperitoneal and intrathoracic), and low-risk procedures (endoscopic, breast surgery, and ambulatory procedures). Patients with poor functional capacity and any clinical risk factor undergoing more than low-risk nonemergent surgery should undergo preoperative testing, based on American Heart Association (AHA) guidelines (179).
Major
Unstable coronary syndromes: acute (≤ 7 days) or recent (7 < days ≤ 1 month) MI, unstable or severe angina
Decompensated congestive heart failure
Significant arrhythmias (high-grade AV block, symptomatic ventricular arrhythmias, supraventricular arrhythmias with uncontrolled ventricular rate)
Severe valvular disease

Intermediate
History of cerebrovascular disease
Prior ischemic cardiac disease
Compensated or prior congestive heart failure
Diabetes mellitus
Renal insufficiency

Minor
Advanced age
Abnormal ECG (LVH, LBBB, ST-T abnormalities)
Rhythm other than sinus
Uncontrolled systemic hypertension

MI, myocardial infarction; AV, atrioventricular; ECG, electrocardiogram; LVH, left ventricular hypertrophy; LBBB, left bundle branch block.

Table 22.16 Functional Capacity Assessment from Clinical History

Excellent
Carry 24 lb up eight steps
Carry objects that weigh 80 lb
Outdoor work (shovel snow, spade soil)
Recreation (ski, basketball, squash, handball, jog or walk 5 mph)

Moderate
Have sexual intercourse without stopping
Walk at 4 mph on ground level
Outdoor work (garden, rake, weed)
Recreation (roller-skate, dance)

Poor
In an effort to quantify preoperative cardiac risk, several tests are used to assess cardiovascular function. Electrocardiogram should be considered for anyone other than asymptomatic persons undergoing low risk procedures. Echocardiography may be used to evaluate left ventricular function (179). Patients who have dyspnea of unknown origin, current or past heart failure, prior cardiomyopathy, or with any of the above factors and no cardiac assessment in the past 12 months should consider echocardiogram testing preoperatively (179). Exercise stress testing before surgery can identify patients who have ischemic heart disease not apparent at rest. AHA guidelines recommend noninvasive stress testing for patients with one to two clinical risk factors, undergoing intermediate risk surgery with poor functional capacity of METS less than 4. Likewise, it is recommended for patients with greater clinical risk factors or those undergoing high-risk surgery (179). These patients are at increased risk of developing cardiac complications in the perioperative period. In a study of patients undergoing peripheral vascular surgery, a high-risk group of patients was identified who had ischemic electrocardiographic changes when they exercised to less than 75% of their maximal predicted heart rate. In this group, the incidence of perioperative myocardial infarction was 25% and the overall cardiac mortality rate was 18.5%. Conversely, no perioperative infarctions occurred in patients who were able to exercise to more than 75% of their maximal predicted heart rate and who had no electrocardiographic evidence of ischemia (181). The prognostic value of stress testing was not supported in another prospective study that found that only an abnormal preoperative resting electrocardiography result was an independent risk factor (182). The exercise stress test must be selectively applied to a high-risk population because its predictive value depends on the prevalence of the disease. It is not prudent to screen all patients preoperatively; it is preferable to rely on a careful history to identify patients with symptoms of cardiac disease for whom the test would be most predictive.

Exercise stress testing is limited in some patients who cannot exercise because of musculoskeletal disease, pulmonary disease, or severe cardiac disease. Dipyridamole-thallium scanning may be used to overcome the limitations of exercise stress testing. This study has a high degree of sensitivity and specificity but a low positive predictive value (179,183). It relies on the ability of dipyridamole to dilate normal coronary arteries but not stenotic vessels. Normally perfused myocardium readily takes up thallium when it is given intravenously. Conversely, hypoperfused myocardium does not show good uptake of thallium when scanned 5 minutes after injection. Reperfusion and uptake of thallium 3 hours after injection identify viable but high-risk myocardium. Old infarctions are identified as areas without uptake. Several studies show an increasing risk of
perioperative myocardial infarction dependent on the extent of reperfusion of thallium, or reversible defect, ranging from 3% to 49% (184,185). The dipyridamole-thallium scan is applicable to clinically high-risk patients who are unable to exercise because it uses a medically induced “stress.”

Dobutamine stress echocardiography is another test to evaluate cardiac risk in patients who are unable to exercise. This method identifies regional cardiac wall motion abnormalities after dobutamine infusion to identify patients at high risk for cardiac events. Positive and negative predictive values are similar to those of dipyridamole-thallium testing for a perioperative event (186,187). Dipyridamole-thallium testing is preferred for patients with known cardiac arrhythmias, and dobutamine is preferred for patients with bronchospastic lung disease and in those with severe cardiac stenosis (188). Coronary angiography should be considered only in patients who have an indication for angiography independent of the planned surgery, such as patients with acute coronary syndromes, unstable angina, angina refractory to medical therapy, or high-risk results on noninvasive testing.

Preoperative testing should be used discriminately in intermediate-risk patients. Controversy exists regarding the accuracy of these tests to provide prognostic information beyond what is obtained from clinical risk stratification for nonvascular procedures. Diagnostic testing should not lead to unnecessary additional testing or harmful delays in surgery. The American College of Cardiology and the American Heart Association present an updated detailed algorithm that incorporates risk-factor stratification to guide clinicians to proceed directly to surgery, to delay surgery and obtain preoperative noninvasive testing, or to attempt risk factor modification (179).

It is rare for patients who are younger than 50 years and who do not have diabetes, hypertension, hypercholesterolemia, or coronary artery disease to suffer a perioperative myocardial infarction. In contrast, patients with coronary artery disease are at increased risk of myocardial infarction in the postoperative period. Prevention, early recognition, and treatment are important because myocardial infarctions that occur in the postoperative period have mortality rates of up to 25% and are associated with increased rates of cardiovascular death in the 6 months following surgery (189).

Nearly two-thirds of postoperative myocardial infarctions occur during the first 3 days postoperatively (189). Although the pathophysiologic factors are complex, the causes of postoperative myocardial ischemia and infarction are related to decreased myocardial oxygen supply coupled with increased myocardial oxygen requirements. In postoperative patients, conditions that decrease oxygen supply to the myocardium include tachycardia, increased preload, hypotension, anemia, and hypoxia (190). Conditions that increase myocardial oxygen consumption are tachycardia, increased preload, increased afterload, and increased contractility. Tachycardia and increased preload are the most important causes of ischemia, because both conditions decrease oxygen supply to the myocardium while simultaneously increasing myocardial oxygen
demand. Tachycardia decreases the diastolic time, which, when the coronary arteries are perfused, decreases the volume of oxygen available to the myocardium. Increased preload increases the pressure exerted by the myocardial wall on the arterioles within it, thus decreasing myocardial blood flow.

Other factors associated with perioperative myocardial ischemia include physiologic responses to the stress of intubation, intravenous or arterial line placement, emergence from anesthesia, pain, and anxiety. These stresses result in catecholamine stimulation of the cardiovascular system, resulting in increased heart rate, blood pressure, and contractility, which may induce or worsen myocardial ischemia. Loss of intravascular volume because of third spacing of fluids or postoperative hemorrhage can induce ischemia.

**Postoperative myocardial infarction is often difficult to diagnose.** Chest pain, which is present in 90% of nonsurgical patients with myocardial infarction, may be present in only 50% of patients with postoperative infarction because myocardial pain may be masked by coexisting surgical pain and the use of analgesics (175). It is important to maintain a high level of suspicion for postoperative infarction in patients with coronary artery disease. The presence of arrhythmia, congestive heart failure, hypotension, dyspnea, or elevations of pulmonary artery pressure may indicate infarction and should prompt a thorough cardiac investigation and electrocardiographic monitoring. **Measurement of creatinine phosphokinase myocardial band (CPK-MB) isoenzyme and troponin T levels are the most sensitive and specific indicators of myocardial infarction, and assessments should be obtained for all patients suspected of myocardial infarction (189).**

Despite the high incidence of silent myocardial infarction, routine use of postoperative electrocardiography (ECG) for all patients with cardiovascular disease is controversial. Many patients will exhibit P-wave changes that spontaneously resolve and do not represent ischemia or infarction. Conversely, patients with proven myocardial infarctions may show few, if any, ECG abnormalities. The American College of Cardiology and American Heart Association advise consideration of postoperative surveillance via ST-segment monitoring for myocardial infarction in patients with known or suspected coronary artery disease (191). In a review of over 2,400 patients, the sensitivity of predicting postoperative cardiac events was 55% to 100%, specificity 37% to 85%, positive predictive value 7% to 57%, and negative predictive value 89% to 100% (192). If routine screening of asymptomatic patients is desired, ECG should be performed 24 hours following surgery because significant ECG changes that occur immediately postoperatively will persist for 24 hours. It is prudent to continue serial ECG assessments for at least 3 days postoperatively.

**Postoperative management of patients with coronary artery disease is based on maximizing delivery of oxygen to the myocardium and decreasing myocardial oxygen utilization.** Most patients benefit from supplemental oxygen in the postoperative period, although special care should be exercised in patients with COPD.
Oxygenation can easily be monitored by pulse oximetry. Anemia is detrimental because of loss of oxygen-carrying capacity and resultant tachycardia and should, therefore, be carefully corrected in high-risk patients. Although transfusion criteria are not absolute, all patients with a hemoglobin less than 6 mg/dL, and hemoglobin of 6 to 10 mg/dL with significant cardiac risk factors should be offered blood transfusion (193).

**Patients with coronary artery disease may benefit from pharmacologic control of hyperadrenergic states that result from increased postoperative catecholamine production.** Beta-blockers decrease heart rate, myocardial contractility, and systemic blood pressure, all of which are increased by adrenergic stimulation. Perioperative use of $\beta_1$ selective beta-blocker is shown to significantly reduce perioperative ischemia, myocardial infarction, and overall mortality caused by cardiac death and congestive heart failure in the perioperative period (194–196). The POISE (Perioperative Ischemic Evaluation) trial, a randomized controlled trial of metoprolol, enrolling 8,000 patients undergoing noncardiac surgery, revealed a reduction in cardiovascular death, myocardial infarction, and cardiac arrest. There was an increased risk of stroke and total mortality (197). The AHA provides the following guidelines: Continue beta-blocker therapy in patients on baseline beta-blockers for treatment of cardiac disease. Consider initiating and titrating beta-blockers in patients with coronary artery disease or high cardiac risk (as defined by the presence of more than one clinical risk factor) who are undergoing intermediate-risk surgery (155). Therapy should be initiated at least 1 week before surgery to allow for proper titration. The timing and optimal duration of beta-blocker therapy remains an area of uncertainty. Nevertheless, for patients already on beta-blocker therapy, they should continue it perioperatively because abrupt withdrawal results in a rebound hyperadrenergic state.

**Prophylactic use of other agents such as nitroglycerin and calcium-channel blockers remains controversial, as data did not show a consistent benefit toward reducing risk of ischemic cardiac events. Nitroglycerin may cause hypotension, which may worsen cardiac status** (155).

**Congestive Heart Failure**

**Patients with congestive heart failure (CHF) face a substantially increased risk of myocardial infarction during and after surgery** (177). The postoperative development of pulmonary edema may be associated with a high mortality rate, especially if it occurs in the setting of cardiac ischemia (198,199). Because patients with heart failure at the time of surgery are significantly more likely to develop complications, every effort should be made to diagnose and treat CHF before surgery (178,200). The signs and symptoms of CHF are listed in Table 22.17 and should be assessed based on preoperative history and physical examination. Patients who are able to perform usual daily activities without developing CHF are at limited risk of perioperative heart failure.

**Table 22.17 Signs and Symptoms of Congestive Heart Failure**
Presence of an S₃ gallop
Jugular venous distention
Lateral shift of the point of maximal impulse
Lower-extremity edema
Basilar rales
Increased voltage on electrocardiogram
Evidence of pulmonary edema or cardiac enlargement on chest radiograph
Tachycardia

To prevent severe postoperative complications, CHF must be corrected preoperatively. Treatment usually relies on aggressive diuretic therapy, although care must be taken to avoid dehydration, which may result in hypotension during the induction of anesthesia. Hypokalemia can result from diuretic therapy and is especially deleterious to patients who are taking digitalis. In addition to diuretics and digitalis, treatment often includes the use of preload- and afterload-reducing agents. Optimal use of these drugs and correction of CHF may be aided by consultation with a cardiologist. It is preferable to continue the usual regimen of cardioactive drugs throughout the perioperative period.

Postoperative CHF frequently results from excessive administration of intravenous fluids and blood products. Other common postoperative causes are myocardial infarction, systemic infection, pulmonary embolism, and cardiac arrhythmias. The cause of postoperative heart failure must be diagnosed because, to be successful, treatment should be directed simultaneously to the underlying cause. Postoperative diagnosis of CHF is more difficult than preoperative diagnosis because the signs and symptoms of CHF are not specific and may result from other causes. The most reliable method of detecting CHF is chest radiography, in which the presence of cardiomegaly or evidence of pulmonary edema is a helpful diagnostic feature.

Acute postoperative CHF frequently manifests as pulmonary edema. Treatment of pulmonary edema may include the use of intravenous furosemide, supplemental oxygen, morphine sulfate, and elevation of the head of the bed. Intravenous aminophylline may be useful if cardiogenic asthma is present. Electrocardiography, in addition to laboratory evaluation, including arterial blood gas, serum electrolyte, and renal function chemistry measurements, should be obtained expediently. If the patient’s condition does not improve rapidly, she should be transferred to an intensive care unit.

Arrhythmias

Nearly all arrhythmias found in otherwise healthy patients are asymptomatic and of limited consequence. In patients with underlying cardiac disease, however, even brief episodes of arrhythmias may result in significant cardiac morbidity and mortality.

Preoperative evaluation of arrhythmias by a cardiologist and anesthesiologist is important because many anesthetic agents and surgical stress contribute to the development or
Patients with heart disease have an increased risk of arrhythmias, most commonly ventricular arrhythmias. Patients without cardiac disease are more likely to develop supraventricular arrhythmias during surgery. Patients taking antiarrhythmic medications before surgery should continue taking those drugs during the perioperative period. Initiation of antiarrhythmic medications is rarely indicated preoperatively, but consultation with a cardiologist is recommended for patients in whom arrhythmias are detected before surgery.

Patients with first-degree atrioventricular (AV) block or asymptomatic Mobitz I (Wenckebach) second-degree AV block require no preoperative therapy. A pacemaker is appropriate in patients with symptomatic Mobitz II second- or third-degree AV block before elective surgery. In emergency situations, a pacing pulmonary artery catheter can be used. Before performing surgery on patients with a permanent pacemaker, the type and location of the pacemaker should be determined because electrocautery units may interfere with demand-type pacemakers. When performing gynecologic surgery on patients with pacemakers, it is preferable to place the electrocautery unit ground plate on the leg to minimize interference by preventing the pacemaker generator from sitting within the electrocautery circuit and to maximize distance from the pacemaker device. If possible, use of bipolar cautery devices are recommended rather than monopolar devices. In patients with a demand pacemaker in place, the pacemaker should be converted preoperatively to the fixed-rate (or asynchronous) mode. Although this can be accomplished oftentimes by placing a magnet over the pacemaker, it may be better to reprogram the pacemaker preoperatively and then again postoperatively. Patients should be monitored continuously intraoperatively with both telemetry and continuous pulse oximeter. Close coordination with anesthesia and cardiology is imperative. Patients with an implantable cardioverter defibrillator device should have their device programmed off prior to surgery and reprogrammed postoperatively.

Surgery is not contraindicated in patients with bundle branch blocks or hemiblocks. Perioperative mortality rates are not increased by bundle-branch block. Complete heart block rarely develops during noncardiac surgical procedures in patients with conduction system disease. The presence of a left bundle-branch block may indicate the presence of aortic stenosis, which can increase surgical mortality if it is severe.

Valvular Heart Disease
Although there are many forms of valvular heart disease, two types—aortic and mitral stenosis—primarily are associated with significantly increased operative risk. Patients with significant aortic stenosis appear to be at greatest risk, which is increased in the presence of atrial fibrillation, congestive heart failure, or coronary artery...
disease. Significant stenosis of aortic or mitral valves should be repaired before elective gynecologic surgery (176).

Severe valvular heart disease usually is evident during physical exertion. Common findings in such patients are listed in Table 22.18. The classic history presented by patients with severe aortic stenosis includes exercise dyspnea, angina, and syncope, whereas symptoms of mitral stenosis are paroxysmal and effort dyspnea, hemoptysis, and orthopnea. Most patients have a remote history of rheumatic fever. Severe stenosis of either valve is considered to be a valvular area of less than 1 cm$^2$, and diagnosis can be confirmed by echocardiography or cardiac catheterization.

**Table 22.18 Signs and Symptoms of Valvular Heart Disease**

**Aortic stenosis**
- Systolic murmur at right sternal border, which radiates into carotids
- Decreased systolic blood pressure
- Apical heave
- Chest radiograph with calcified aortic ring, left ventricular enlargement
- Electrocardiogram with high R waves, depressed T waves in lead I, and precordial leads

**Mitral stenosis**
- Precordial heave
- Diastolic murmur at apex
- Mitral opening snap
- Suffused face and lips
- Chest radiograph with left atrial dilation
- Electrocardiogram with large P waves and right axis deviation

Patients with valvular abnormalities are subdivided by the American Heart Association into risk groups for the development of subacute bacterial endocarditis following surgery. **Patients in the highest risk groups should receive prophylactic antibiotics immediately preoperatively to prevent subacute bacterial endocarditis** (Table 22.8). As defined by the American Heart Association, only patients with prosthetic cardiac valves, congenital heart disease, and cardiac transplantation who develop cardiac valvulopathy should receive perioperative endocarditis prophylaxis (76). All other patients do not require antibiotics for subacute bacterial endocarditis prophylaxis. Routine prophylaxis for GI or GU procedures is not recommended. Only in cases of a known infection of the GI or GU tract should antibiotics coverage for enterococcus with amoxicillin or ampicillin or vancomycin be provided.

Patients with aortic and mitral stenosis tolerate sinus tachycardia and other tachyarrhythmias poorly. In patients with aortic stenosis, sufficient levels of digitalis should be provided to correct preoperative tachyarrhythmias, and propranolol may be
used to control sinus tachycardia. Patients with mitral valve stenosis often have atrial fibrillation and, if present, digitalis should be used to reduce rapid ventricular response.

Patients with mechanical heart valves usually tolerate surgery well (206). These patients should receive antibiotic prophylaxis (Table 22.8). If the patient is taking aspirin therapy, it should be discontinued 1 week before the procedure and restarted as soon as it is considered safe by the surgeon. Patients with a bileaflet aortic valve with no risk factors (atrial fibrillation, previous thromboembolism, left ventricular dysfunction, a hypercoagulable state, older generation thrombogenic valve) generally do not require anticoagulation bridging. Warfarin should be stopped 72 hours prior to the procedure and resumed 24 hours after the procedure. In contrast, patients with a mechanical aortic valve and any above mentioned risk factor, or a mechanical mitral valve, should be bridged with intravenous unfractionated heparin when the INR falls below 2. The heparin drip should be stopped approximately 6 to 8 hours before the procedure and restarted as soon as possible after surgery when the patient is deemed stable from postoperative bleeding risk. The heparin bridge can be stopped when the INR reaches therapeutic levels (207).

**In the postoperative period, patients with mitral stenosis should be carefully monitored for pulmonary edema** because they may not be able to compensate for the amount of intravenous fluid administered during surgery. Prevention of tachycardia is important, as it may lead to pulmonary edema. Patients with mitral stenosis frequently have pulmonary hypertension and decreased airway compliance. They may require more pulmonary support and therapy postoperatively, including prolonged mechanical ventilation.

**For patients with significant aortic stenosis, it is imperative that a sinus rhythm be maintained during the postoperative period.** Even sinus tachycardia can be deleterious because it shortens the diastolic time. Bradycardia less than 45 beats per minute should be treated with atropine. Supraventricular dysrhythmias may be controlled with verapamil or direct-current cardioversion. Particular attention should be provided to the maintenance of proper fluid status, digoxin levels, electrolyte levels, and blood replacement.

**Hypertension**

Patients with controlled essential hypertension have no increased risk of perioperative cardiac morbidity or mortality (208). Patients with concomitant heart disease are at elevated risk and should be completely evaluated by a cardiologist preoperatively. Laboratory studies should include an ECG, chest radiography, blood count, urinalysis, and serum electrolytes and creatinine measurement. Antihypertensive medications should be continued perioperatively. Beta-blockers should be continued, parenterally if necessary, to avoid rebound tachycardia, hypercontractility, and hypertension. Clonidine may cause significant rebound hypertension if withdrawn acutely. Angiotensin converting enzyme inhibitor agents and angiotensin II receptor antagonists
are associated with increased intraoperative hypotension and perioperative renal dysfunction possibly resulting from a hypovolumic state. It may be prudent to withhold these agents on the morning of surgery and resume them postoperatively when good renal function and euvolumia is confirmed (155).

**Patients with diastolic pressures higher than 110 mm Hg or systolic pressures higher than 180 mm Hg should receive medication to control their hypertension before surgery.** Beta-blockers may be particularly effective agents for treatment of preoperative hypertension (179). Chronically hypertensive patients are very susceptible to intraoperative hypotension because of impaired autoregulation of blood flow to the brain and require a higher mean arterial pressure to maintain adequate perfusion (209). During induction of anesthesia, episodes of hypertension occur, and such episodes are seen more frequently in patients with baseline hypertension.

Postoperative hypertension is usually treated parenterally because gastrointestinal absorption may be diminished, and transdermal absorption can be erratic in patients who are cold and rewarming. Commonly used parenteral antihypertensives are listed in Table 22.19.

**Perioperative Antiplatelet Agents**

Increasing numbers of patients undergo coronary revascularization procedures, otherwise known as coronary artery bypass grafting, or percutaneous coronary intervention, typically stent placement. With the evolution of bare metal and drug-eluting stents, perioperative management of cardiovascular thrombotic risk versus perioperative bleeding and mortality is challenged. Given that drug-eluting stents generally require 12 months' treatment with dual agent aspirin and thienopyridine (i.e., clopidogrel), the American College of Cardiology and American Heart Association (ACC/AHA) guidelines recommend avoiding elective surgery within 12 months of drug-eluting stent placement. When surgery cannot wait, the ACC/AHA recommends continuation of aspirin perioperatively, discontinuation of thienopyridine 5 days prior to surgery, and resuming it as soon as possible postoperatively. Ultimately the risk of perioperative morbidity secondary to bleeding must be weighed against the risk of repeat thrombosis and cardiovascular morbidity and mortality. If a patient requires new placement of a cardiac
stent and requires a noncardiac surgery in the following 12 months, placement of a bare metal stent is recommended rather than a drug-eluting stent, as these require only 4 to 6 weeks of dual-antiplatelet therapy. Again, aspirin should be continued perioperatively. Following a newly placed bare metal stent, noncardiac surgery should be scheduled at least 30 to 45 days after the stent placement to decrease cardiac morbidity (179).

**Hemodynamic Monitoring**

Hemodynamic monitoring is integral to the perioperative management of patients with cardiovascular and pulmonary diseases. The major impetus for this advancement resides in the need for the quantitative estimate of cardiac function, resulting in the development of bedside pulmonary artery catheterization. The impact of monitoring cardiac function is demonstrated by the significant reduction of myocardial infarctions in high-risk patients who are aggressively monitored for 72 to 96 hours postoperatively (175).

Before the development of the pulmonary artery catheter, central venous pressure (CVP) measurement was used to assess intravascular volume status and cardiac function. To measure the CVP, a catheter is placed in the central venous system, most frequently the superior vena cava. A water manometer or a calibrated pressure transducer is connected to the CVP line, allowing an estimation of right atrial pressure. Right atrial pressure is determined by the balance between cardiac output and venous return. Cardiac output is determined by heart rate, myocardial contractility, preload, and afterload. If the pulmonary vascularity and left ventricular function are normal, the CVP accurately reflects the left ventricular end-diastolic pressure (LVEDP). The LVEDP reflects cardiac output or systemic perfusion and was considered the standard estimator of left ventricular pump function. Venous return is determined primarily by the mean systemic pressure, which propels blood toward the heart, balanced against resistance to venous return, which acts in the opposite direction. If right ventricular function is normal, the CVP accurately reflects intravascular volume.

Left and right ventricular function is frequently abnormal or discordant; therefore, the relationship of CVP to cardiac function and to intravascular volume is not maintained. When this occurs, measurement of pulmonary artery occlusion pressure can be used to accurately assess volume status and cardiovascular function. The use of a pulmonary artery catheter allows detection of changes in cardiovascular function with more sensitivity and rapidity than clinical observation.

The balloon-tipped pulmonary artery catheter (Swan-Ganz catheter) can measure pulmonary artery and pulmonary artery occlusion pressures (210). The catheter can measure cardiac output, be used to perform intracavitary electrocardiography, and provide temporary cardiac pacing. The standard pulmonary artery occlusion catheter is a 7-French, radiopaque, flexible, polyvinyl chloride, 4-lumen catheter with a 1.5-mL latex balloon at its distal tip. Most often, a right internal jugular cannulation is used for placement of the catheter, because this site provides the most direct access into the right atrium and has fewer complications when compared with a subclavian route of
placement. After the catheter is placed into the right atrium, the balloon is inflated, and the catheter is pulled by blood flow through the right ventricle into the pulmonary artery. The position of the catheter can be identified and followed by the various pressure waveforms generated by the right atrium, right ventricle, and pulmonary artery. As the catheter passes through increasingly smaller branches of the pulmonary artery, the inflated balloon eventually occludes the pulmonary artery.

The distal lumen of the catheter, which is beyond the balloon, measures left atrial pressure (LAP) and, in the absence of mitral valvular disease, LAP approximates LVEDP. Pulmonary–capillary wedge pressure (PCWP) equals the LAP, which equals LVEDP and is normal at 8 to 12 mm Hg. Because the standard pulmonary artery catheter has an incorporated thermistor, thermodilution studies can be performed to determine cardiac output. This thermodilution method is performed by injecting cold 5% dextrose in water through the proximal port of the catheter, which cools the blood entering the right atrium. The change in temperature measured at the more distal thermistor (4 cm from the catheter tip) generates a curve proportional to cardiac output. Knowledge of the cardiac output is helpful in establishing cardiovascular diagnoses. For example, a patient with hypotension, low-to-normal wedge pressure, and a cardiac output of 3 L per minute is most likely hypovolemic. The same patient with a cardiac output of 8 L per minute is probably septic with resultant low systemic vascular resistance.

Pulmonary artery catheters are associated with a small but significant complication rate. The complications can be grouped into those occurring during venous cannulation or insertion, during maintenance and use, and those related to interpretation of hemodynamic data (210). The most common problems encountered during venous access are cannulation of the carotid or subclavian artery and introduction of a pneumothorax. Problems resulting from the catheter itself include dysrhythmias, sepsis, and disruption of the pulmonary artery. Pulmonary artery catheters (PAC) should be placed under the supervision of experienced personnel in a setting in which complications can be rapidly diagnosed and treated. Accessory equipment such as resuscitation equipment and an external pacing device must be immediately available. Ultrasound and fluoroscopic equipment if available may aid in PAC placement (211).

The effect of PAC use on patient outcome is controversial. Several large trials did not confer a definite benefit to PAC use. One multi-institutional study examined the association of PAC placement within the first 24 hours of hospital stay and its associated outcomes. They found a higher mortality rate in patients who received a PAC than those who did not have a PAC (212). The study was limited because it was retrospective and not randomized. A randomized controlled trial of 1,994 high-risk (American Society of Anesthesiologists class III or IV risk) patients age 60 or older undergoing urgent or elective major noncardiac surgery compared outcomes of those who underwent PAC placement versus standard care. Results analyzed by a blinded assessor revealed no benefit of PAC over standard care with central venous catheters (213). Another randomized controlled trial enrolling 65 intensive care units in the United Kingdom found...
no difference in mortality among critically ill patients managed with or without a PAC (214). A meta-analysis of 13 randomized controlled trials of PAC use found no significant difference in mortality rates and an increased use of ionotropes and intravenous vasodilators (215). **Routine preoperative use of PAC in noncardiac surgery patients is no longer indicated. Use of PAC in critically ill patients postoperatively remains controversial.**
Hematologic Disorders

The presence of hematologic disorders, although uncommon in gynecologic patients, significantly affects operative morbidity and mortality and should be considered routinely in preoperative evaluation. Preoperative assessment should include consideration of anemia, platelet and coagulation disorders, white blood cell function, and immunity.

Anemia

Moderate anemia is not in itself a contraindication to surgery because it can be corrected by transfusion. If possible, surgery should be postponed until the cause of the anemia can be identified and the anemia corrected without resorting to transfusion. By tradition, anesthetic and surgical practice recommended a hemoglobin level of greater than 10 g/dL or a hematocrit of greater than 30%. Data suggest a lower tolerance for pre- and intraoperative transfusion threshold to improve intra- and postoperative morbidity and mortality (216–219). It remains that no universal “transfusion threshold” is agreed upon, but that a hematocrit of less than 24% should prompt strong consideration (219). The circulating blood volume provides oxygen-carrying capacity and tissue oxygenation. Usually this capacity is reflected by the hemoglobin level and hematocrit. Under certain circumstances this is not the case. After an acute blood loss or before plasma expansion by extracellular fluid occurs, hematocrit measurements may be normal despite a low circulating blood volume. Conversely, overhydration may result in low hematocrit and hemoglobin levels despite adequate red blood cell mass.

Individual tolerance of anemia depends on overall physical fitness and cardiovascular reserve. The effects of anemia depend on its magnitude, the rate at which it occurs, the oxygen requirement of the patient, and the ability of physiologic mechanisms to compensate (220). Maintenance of adequate tissue perfusion requires an increase in cardiac output as hemoglobin concentration falls (193). In the healthy patient, oxygen delivery is unchanged when it falls below 7 g/dL (221). In contrast, a patient with ischemic heart disease will not tolerate anemia as well (222). The presence of cardiac, pulmonary, or other serious illness justifies a more conservative approach to the management of anemia. Patients with longstanding anemia may have normal blood volume levels and tolerate surgical procedures well. There is no evidence that mild to moderate anemia increases perioperative morbidity or mortality (222).

Autologous blood transfusion may be an acceptable option for patients. Patients with normal hematocrit levels may store autologous blood preoperatively to reduce the need for allogenic blood transfusion and minimize the risk of infections and immunologic problems (193). Recombinant human erythropoietin may increase collection and reduce preoperative anemia in these patients (223,224). Intraoperative blood collection and homologous transfusion can be employed to limit the need for allogenic blood transfusion.

Autologous blood donation is advocated as a safer alternative for the patient; however, the use of preoperative autologous blood donation has come under scrutiny (225,226).
Preoperative autologous blood may lead to more liberal blood transfusion, iatrogenic anemia, volume overload, and bacterial contamination (227). Preoperative autologous blood donation is poorly cost-effective (228). The National Heart, Lung, and Blood Institute does not recommend collection of autologous blood for procedures with a likelihood of transfusion less than 10%, such as uncomplicated abdominal and vaginal hysterectomies (229).

**Platelet and Coagulation Disorders**

Surgical hemostasis is provided by platelet adhesion to injured vessels, which plugs the opening as the coagulation cascade is activated, resulting in the formation of fibrin clots. Functional platelets and coagulation pathways are necessary to prevent excessive surgical bleeding. Platelet dysfunction is encountered preoperatively more frequently than coagulation disorders.

Platelets may be deficient in both number and function. The normal peripheral blood count is 150,000 to 400,000 per mm$^3$, and the normal lifespan of a platelet is approximately 10 days. Although there is no clear-cut correlation between the degree of thrombocytopenia and the presence or amount of bleeding, several generalizations can be made. If the platelet count is higher than 100,000/mm$^3$ and the platelets are functioning normally, there is little chance of excessive bleeding during surgical procedures. Patients with a platelet count higher than 75,000/mm$^3$ almost always have normal bleeding times, and a platelet count higher than 50,000/mm$^3$ is probably adequate. **A platelet count lower than 20,000/mm$^3$ often will be associated with severe and spontaneous bleeding.** Platelet counts higher than 1,000,000/mm$^3$ are often, paradoxically, associated with bleeding.

**If the patient’s platelet count is lower than 100,000/mm$^3$, an assessment of bleeding time should be obtained.** If the bleeding time is abnormal and surgery must be performed, an attempt should be made to raise the platelet count by administering platelet transfusions immediately before surgery. In patients with immune destruction of platelets, human leukocyte antigen (HLA)–matched donor-specific platelets may be required to prevent rapid destruction of transfused platelets. If surgery can be postponed, a hematology consultation should be obtained to identify and treat the cause of the platelet abnormality.

Abnormally low platelet counts result from either decreased production or increased consumption of platelets. Although there are numerous causes of thrombocytopenia, most are exceedingly uncommon. Decreased platelet production may be drug induced and is associated with the use of sulfonamides, cinchona alkaloids, thiazide diuretics, NSAIDs, gold salts, penicillamine, anticonvulsants, and heparins (230). Decreased platelet count is a feature of several diseases, including vitamin B$_{12}$ and folate deficiency, aplastic anemia, myeloproliferative disorders, renal failure, and viral infections. Inherited congenital thrombocytopenia is extremely rare. More commonly, thrombocytopenia results from immune destruction of platelets by
diseases such as idiopathic thrombocytopenia purpura and collagen vascular disorders. **Consumptive thrombocytopenia is a feature of disseminated intravascular coagulation, which is encountered most frequently in conjunction with sepsis or malignancy in the preoperative population.**

Platelet dysfunction most often is acquired, but may be inherited. Occasionally, a patient with von Willebrand disease, the second most common inherited disorder of coagulation, may be encountered in the preoperative setting. More commonly, platelet dysfunction results from the use of drugs (e.g., aspirin and amitriptyline), and in patients with resulting prolonged bleeding time, the drug should be withheld for 7 to 10 days before surgery. Uremia and hepatic diseases can affect platelet function.

Platelet dysfunction is more difficult to diagnose than abnormalities of platelet count. A history of easy bruising, petechiae, bleeding from mucous membranes, or prolonged bleeding from minor wounds may signify an underlying abnormality of platelet function. Such dysfunction can be identified with the help of a bleeding time, but full characterization of the underlying etiology should be carried out with hematologic consultation. If at all possible, surgery should be postponed until therapy is instituted.

Disorders of the coagulation cascade often are diagnosed through a personal or family history of excessive bleeding during minor surgery, childbirth, or menses. Many women with menorrhagia are referred for surgical intervention and require a thorough preoperative evaluation for possible inherited disorders of hemostasis, such as factor VIII (hemophilia), factor IX (Christmas disease), factor XI deficiencies, and von Willebrand disease. Von Willebrand disease is the most common hereditary bleeding disorder, with prevalence in the general population of roughly 1% (231). Seventy percent to 90% of patients with von Willebrand disease have menorrhagia (231). Identified women can be treated effectively with desmopressin nasal spray, avoiding unanticipated or excessive bleeding during surgery (232). In the absence of a genetic diagnosis, the diagnosis of von Willebrand disease is difficult and involves a combination of clinical and laboratory assessments, including von Willebrand factor antigen and von Willebrand factor functional activity or ristocetin cofactor assay (232). Physiologic fluctuations occur with von Willebrand factor levels, requiring repeat testing and consultation or referral to a hematologist. It is recommended that women presenting with menorrhagia without obvious pelvic abnormalities should be routinely screened for inherited bleeding disorders before undergoing invasive procedures.

There are few commonly prescribed drugs that affect coagulation factors, the exceptions being warfarin and heparin. Disease states that may be associated with decreased coagulation factor levels are primarily liver disease, vitamin K deficiency (secondary to obstructive biliary disease, intestinal malabsorption, or antibiotic reduction of bowel flora), and disseminated intravascular coagulation.

Preoperative laboratory screening for coagulation deficiencies is controversial. Routine screening is not warranted in patients who do not have historical evidence of a bleeding problem (233). Patients who are seriously ill or who will be undergoing extensive surgical
procedures should undergo testing preoperatively to determine prothrombin time, partial thromboplastin time, fibrinogen level, and platelet count.

**White Blood Cells and Immune Function**

Abnormally high or low white blood cell counts are not an absolute contraindication to surgery; they should be considered relative to the need for surgery. Evaluation of an elevated or decreased white blood cell count should be undertaken before elective surgery. **Patients with absolute granulocyte counts lower than 1,000/mm\(^3\) are at increased risk of severe infection and perioperative morbidity and mortality and should undergo surgery only for life-threatening indications** (234).

**Blood Component Replacement**

Packed red blood cells, which may be stored for several weeks, are used for most postoperative transfusions. Most clotting factors are stable for long periods. The exceptions are factors V and VIII, which decrease to 15% and 50% of normal, respectively. Most hematologic problems observed in the postoperative period are related to perioperative bleeding and blood component replacement. Although the primary cause of the bleeding is usually lack of surgical hemostasis, other factors, including deranged coagulation, may compound the problem. Such coagulopathy can result from massive transfusion (less than one blood volume) and is thought to be caused by dilution of platelets and labile coagulation factors by platelet- and factor-poor packed red blood cells (PRBCs), fibrinolysis, and disseminated intravascular coagulation.

A review in *Transfusion* questioned the traditional practice of limiting blood component replacement in massive transfusion. Summarizing 14 articles and encompassing nearly 4,600 patients, the conclusions note a decrease in all-cause mortality with more liberal transfusion of platelets and fresh frozen plasma (FFP) (235).

A task force for the American Society of Anesthesiologists **recommended critical values for replacement in patients with massive transfusion and microvascular bleeding** (193):

- **Platelet transfusion usually is indicated** for counts less than 50,000/mm\(^3\) (with intermediate platelet counts, i.e., 50,000/mm\(^3\) to 100,000/mm\(^3\), the transfusion of platelet concentrates should be based on the risk of more significant bleeding).
- **Fresh frozen plasma therapy** is indicated if the prothrombin or activated partial thromboplastin time values exceed 1.5 times the normal value.
- **Cryoprecipitate transfusion** is indicated if fibrinogen concentrations decrease to less than 80 to 100 mg/dL.

Cryoprecipitate transfusions are recommended for prophylaxis in nonbleeding perioperative patients with fibrinogen deficiencies or von Willebrand disease refractory to desmopressin acetate and bleeding patients with von Willebrand disease (232).
Donor blood is stored in the presence of citrate, which chelates calcium to prevent clotting, increasing the theoretical risk of hypocalcemia following massive transfusion. Citrate is metabolized at a rate equivalent to 20 U of blood transfused per hour; thus, routine supplementation of calcium is unnecessary. Close monitoring of calcium levels is required in patients with hypothermia, liver disease, or hyperventilation because citrate metabolism may be slowed. Hepatic metabolism of citrate to bicarbonate can result in metabolic alkalosis following transfusion, resulting in subsequent hypokalemia, despite the high level of extracellular potassium in stored blood.

**Pulmonary Disease**

In patients undergoing abdominal surgery, several pulmonary physiologic changes manifest secondary to immobilization, anesthetic irritation of the airways, and the splinting of breathing that inevitably occurs secondary to incisional pain. Pulmonary physiologic changes include a decrease in the functional residual capacity (FRC), an increase in ventilation perfusion mismatching, and impaired mucociliary clearance of secretions from the tracheobronchial tree (236). **Risk factors for postoperative pulmonary complications include the following** (237,238) (Table 22.20):

**Table 22.20 Predictors of Postoperative Pulmonary Complications**

FEV, forced expiration volume; FVC, forced vital capacity; Pa<sub>O2</sub>, partial pressure of oxygen, arterial; Pa<sub>CO2</sub>, partial pressure of carbon dioxide, arterial.

Complication defined as atelectasis or pneumonia.

Upper abdominal or thoracic, or abdominal aortic aneurysm surgery
Surgical procedure time longer than 3 hours
COPD
Smoking within 2 months of surgery
Use of pancuronium for general anesthesia
New York Heart Association Class II pulmonary hypertension
Probable risk factors include general anesthesia, preoperative partial pressure of carbon dioxide, arterial (PaCO\textsubscript{2}) greater than 45 mm Hg, and emergency surgery. Risk factors that could increase the postoperative risk are upper respiratory infection, abnormal chest x-ray, and age. Preoperative pulmonary function testing is of unproven value in patients not undergoing thoracic surgery (237). This is based on multiple reasons: first, a lower limit of forced expiration volume (FEV\textsubscript{1}) did not correlate with pulmonary complications; second, pulmonary complications can occur in the context of a normal FEV\textsubscript{1}; and third, if an FEV\textsubscript{1} were able to predict a pulmonary complication putting the patient at increased risk, it would not change the need for aggressive postoperative prophylactic measures (237). The routine performance of preoperative arterial blood gas measurements does not improve assessment of risk (236). Noninvasive pulse-oximetry measurements can detect patients with hypoxemia (236). The presence of hypercarbia on arterial blood gas measurements does not predict postoperative pulmonary complications (236).

Young, healthy patients rarely have abnormal chest x-rays. Chest x-rays should not be performed routinely in these patients. Most patients with abnormal chest x-rays have history or physical examination findings suggestive of pulmonary disease. Chest x-rays should be limited to patients older than 50 years of age, with a history of smoking or of pulmonary disease, who have evidence of cardiopulmonary disease and in whom a metastatic malignancy is suspected. Although they have limited usefulness in predicting postoperative pulmonary complications, chest x-rays provide a valuable baseline in elderly patients, patients with chronic pulmonary diseases, and those with known lung metastases (236–238).

**Asthma**

Asthma affects approximately 22 million individuals in the United States, including 6% of children (239). It is characterized by a history of episodic wheezing, physiologic evidence of reversible obstruction of the airways either spontaneously or following bronchodilator therapy, and pathologic evidence of chronic inflammatory changes in the bronchial submucosa. Asthma is not a disease of airway physiology in which hypertrophy and increased contractility of bronchial smooth muscle is the dominant lesion; rather, it is an inflammatory disease affecting the airways that secondarily results in epithelial damage, leukocytic infiltration, and increased sensitivity of the airways to a number of stimuli. The treatment of asthma is directed toward relaxing the airways and alleviating inflammation (239).

Multiple stimuli are noted to precipitate or exacerbate asthma, including environmental allergens or pollutants, respiratory tract infections, exercise, cold air, emotional stress,
nonselective beta-adrenergic blockers, and NSAIDs (239). Management of asthma includes removal of the inciting stimuli as well as use of appropriate pharmacologic therapy. The optimal therapy for asthma involves managing the acute symptoms and long-term management of the inflammatory component of the disease.

**Pharmacotherapy of Asthma**

The treatment of asthma is divided into long-term control modalities and short-term modalities. **Recognizing the underlying pathophysiology in asthma as an inflammatory condition, inhaled corticosteroids are the cornerstone for maintenance therapy.** Onset of action is slow (several hours), and up to 3 months of steroid therapy may be required for optimal improvement of bronchial hyperresponsiveness. Even with acute bronchospasm, steroid treatment can enhance the beneficial effect of beta-adrenergic treatment. During acute exacerbations of asthma, a short course of oral steroids, in addition to inhaled steroids, may be necessary. For adults with chronic asthma, only a minority will require chronic oral steroid therapy. Patients taking oral steroids should receive intravenous steroid support in the form of 100 mg of hydrocortisone IV every 8 hours perioperatively, sharply tapering within 24 hours of surgery to avoid adrenal insufficiency. Other long-term control therapies include (239):

- **Leukotriene modifiers** (i.e., montelukast): These agents interfere with leukotrienes, substances released from mast cells, eosinophils, and basophils important in the inflammatory response.
- **Cromolyn sodium**: Highly active in the treatment of seasonal allergic asthma in children and young adults. It is usually not as effective in older patients or in patients in whom asthma is not allergic in nature.
- **Immunomodulators**: Omalizumab, a monoclonal antibody to immunoglobulin E (IgE), has gained support for prevention and may be an important adjunct in symptomatic suppression.
- **Long term beta₂-adrenergic agonists** (i.e., salmeterol): Although not appropriate for single agent management or use in mild disease, they are an important adjunct in the suppression of symptoms in patients with significant disease.
- **Methylxanthines** (i.e., theophylline): These were relegated to third-line status in the management of asthma. Theophylline toxicity can develop when other drugs such as ciprofloxacin, erythromycin, allopurinol, Inderal, or cimetidine are concomitantly administered. Therapeutic serum levels must be monitored closely.

**β₂-adrenergic agonists remain the first-line drugs for acute asthma attacks.** These drugs, inhaled four to six times daily, rapidly relax smooth muscle in the airways and are effective for up to 6 hours. Studies of beta₂ agonists in chronic asthma failed to show any influence of these agents on the inflammatory component of asthma. β₂ agonists are recommended for short-term relief of bronchospasm (“rescue inhalers”) or as first-line treatment for patients with very infrequent symptoms or symptoms provoked solely by exercise (239).
Anticholinergic agents are weak bronchodilators that work via inhibition of muscarinic receptors in the smooth muscle of the airways. The quaternary derivatives such as ipratropium bromide (Atrovent) are available in an inhaled form that is not absorbed systemically. Anticholinergic drugs may provide additional benefit in conjunction with standard steroid and bronchodilator therapy but should not be used as single-agent therapy because they do not inhibit mast cell degranulation, do not have any effect on the late response to allergens, and do not have an anti-inflammatory effect (239).

Perioperative Management of Asthma

In patients with asthma, elective surgery should be postponed whenever possible until pulmonary function and pharmacotherapeutic management are optimized. The most recent guidelines of the American Academy of Allergy, Asthma and Immunology’s recommend three interventions to reduce perioperative pulmonary complications related to asthma (239):

- Review the patient’s asthmatic control, including the need for oral steroids.
- Optimize the patient’s symptomatic control through the use of long-acting pharmacotherapy, including oral steroids if needed.
- For patients on oral steroid therapy within 6 months of therapy or for patients using large doses of inhaled corticosteroids, consider perioperative stress dose steroids.

For mild asthma, the use of inhaled beta-adrenergic agonists preoperatively may be all that is required. For chronic asthma, optimization of steroid therapy will greatly decrease alveolar inflammation and bronchiolar hyperresponsiveness. Inhaled beta₂-agonists should be added to therapy as needed for further control of asthma. Each drug prescribed should be used in maximal dosage before adding an additional agent. Preoperative treatment with combined corticosteroids and an inhaled beta₂-adrenergic agonist for a 5-day period may decrease the risk of postoperative bronchospasm in patients with asthma (240). For patients undergoing emergent surgery who have significant bronchoconstriction, a multimodal approach should be instituted, including aggressive bronchodilator inhalation therapy and intravenous steroid therapy. The role of spirometry, outside of cardiothoracic procedures, has limited value in predicting postoperative pulmonary complications and should be limited to the confirmation of undiagnosed obstructive pulmonary disease (241).

Chronic Obstructive Pulmonary Disease

COPD is the greatest risk factor for the development of postoperative pulmonary complications. COPD encompasses both chronic bronchitis and emphysema, disease entities that often occur in tandem. Cigarette smoke is implicated in the pathogenesis of both, and any treatment plan must include cessation of smoking (242). Chronic bronchitis is defined as the presence of productive cough on most days for at least 3 months per year and for at least 2 successive years (243). It is characterized by chronic airway inflammation and excessive mucus production. The
Histologic changes of emphysema include destruction of alveolar septa and distension of airspaces distal to terminal alveoli. The destruction of alveoli results in air trapping, loss of pulmonary elastic recoil, collapse of the airways in expiration, increased work of breathing, and significant ventilation-perfusion mismatching (243). The impaired ability to cough effectively and clear secretions predisposes patients with COPD to atelectasis and pneumonia in the postoperative period.

**Patients with COPD and a history of heavy smoking account for most postoperative pulmonary complications in gynecologic surgical patients.** The severity of COPD can be determined preoperatively via a thorough history and physical examination. According to recommendations regarding the use of preoperative pulmonary function tests by the American College of Physicians, these should be reserved for individuals in whom COPD is suspected, but unconfirmed (237,241). Typically, patients with COPD demonstrate impaired expiratory air flow, manifested by diminished FEV\(_1\), forced vital capacity (FVC).

Data suggest that arterial blood gas measurements may show varying degrees of hypoxemia and hypercapnia: routine use of preoperative arterial blood gas measurement does not stratify patients into a higher risk subset for postoperative complications (236).

**The preoperative preparation of the patient at risk for postoperative pulmonary complications should include cessation of smoking for as long as possible preoperatively; whereas 2 to 3 days of smoking abstinence are sufficient for carboxyhemoglobin levels to return to normal.** One to 2 weeks of cessation decreases sputum volume. Two months of smoking abstinence is required to significantly lower the risk of postoperative pulmonary complications (236). Longer periods of abstinence can be counseled in patients undergoing elective surgery.

In patients with severe COPD, maximum improvement in airflow limitation can be achieved with a therapeutic trial of high-dose oral corticosteroids followed by a 2-week trial of high-dose inhaled steroid (beclomethasone 1.5 mg per day or the equivalent) in addition to inhaled bronchodilator therapy. Ideally, oral and inhaled steroid therapy should be initiated 1 to 2 weeks preoperatively. Inhaled steroids, in particular, address the inflammatory component of COPD. Oral steroid therapy initiated preoperatively should be maintained throughout the perioperative period and then tapered postoperatively. Beta-adrenergic agonist therapy can be initiated at least 72 hours preoperatively and is beneficial in patients who demonstrate either clinical or spirometric improvement on bronchodilators.

**Patients with COPD and an active bacterial infection suggested by purulent sputum should undergo a full course of antibiotic therapy before surgery.** The antibiotic used should cover the most likely etiologic organisms, Streptococcus pneumoniae and Haemophilus influenzae. In any patient with acute upper respiratory infection, surgery should be delayed if possible. The use of antibiotics to sterilize the sputum in the absence of evidence of an acute infection should be avoided because this practice may lead to bacterial resistance.
Aggressive pulmonary toilet, including incentive spirometry, chest physical therapy, and continuous positive airway pressure devices, reduced the risk of perioperative pulmonary complications in patients undergoing upper abdominal surgery, many of which can be instituted preoperatively (237).

Postoperative Pulmonary Management

Atelectasis

Atelectasis accounts for more than 90% of all postoperative pulmonary complications. The pathophysiology involves a collapse of the alveoli, resulting in ventilation-perfusion mismatching, intrapulmonary venous shunting, and a subsequent drop in the PaO$_2$. Collapsed alveoli are susceptible to superimposed infection, and if managed improperly, atelectasis will progress to pneumonia. Patients with atelectasis have a decreased FRC as well as decreased lung compliance, resulting in increased work during breathing. Despite the decrease in PaO$_2$, the partial pressure of carbon dioxide (PCO$_2$) remains unaffected unless atelectatic changes progress to large volumes of the lung or preexisting lung disease is present.

Physical findings associated with atelectasis may include a low-grade fever. Auscultation of the chest may reveal decreased breath sounds at the bases or dry rales upon inspiration. Percussion of the posterior thorax may suggest elevation of the diaphragm. Radiologic findings include the presence of horizontal lines or plates on posteroanterior chest x-rays, occasionally with adjacent areas containing hyperinflation. These changes are most pronounced during the first 3 postoperative days.

Therapy for atelectasis should be aimed at expanding the alveoli and increasing the FRC. The most important maneuvers are those that promote maximal inspiratory pressure, which is maintained for as long as possible. This exercise promotes an expansion of the alveoli and secretion of surfactant, which stabilizes alveoli. It can be achieved with aggressive supervised use of incentive spirometry, deep breathing exercises, coughing, and in some cases, the use of positive expiratory pressure with a mask (continuous positive airway pressure). Oversedation should be avoided, and patients should be encouraged to ambulate and change positions frequently. Fiberoptic bronchoscopy for removal of mucopurulent plugs should be reserved for patients who fail to improve with the usual measures.

Cardiogenic (High-Pressure) Pulmonary Edema

Cardiogenic pulmonary edema can result from myocardial ischemia, myocardial infarction, or from intravascular volume overload, particularly in patients who have low cardiac reserve or renal failure. The process usually begins with an increase in the fluid in the alveolar septa and bronchial vascular cuffs, ultimately seeping into the alveoli. Complete filling of the alveoli impairs secretion and production of surfactant. Concomitant with alveolar flooding, there is a decrease in lung compliance,
impairment of the oxygen diffusion capacity, and an increase in the arteriolar–alveolar oxygen gradient. Ventilation-perfusion mismatching in the lung results in a decrease in the PaO$_2$, resulting eventually in decreased oxygenation of the tissues and impairment of cardiac contractility.

Symptoms may include tachypnea, dyspnea, wheezing, and use of the accessory muscles of respiration. Clinical signs may include distention of the jugular veins, peripheral edema, rales upon auscultation of the lungs, and an enlarged heart. Radiographic findings may include the presence of bronchiolar cuffing and increased interstitial fluid markings extending to the periphery of the lung. The diagnosis can be confirmed with the use of central hemodynamic monitoring, which will denote an elevated central venous pressure and, more specifically, an elevation in the pulmonary capillary wedge pressure.

The patient’s volume status should be evaluated thoroughly. In addition, myocardial ischemia or infarction should be ruled out by performing ECG and analyzing cardiac enzyme levels. The management of cardiogenic pulmonary edema includes oxygen support, aggressive diuresis, and afterload reduction to increase the cardiac output. In the absence of myocardial infarction, an inotropic agent may be used. Mechanical ventilation should be reserved for cases of acute respiratory failure.

**Noncardiogenic Pulmonary Edema (Adult Respiratory Distress Syndrome)**

In contrast with cardiogenic pulmonary edema, in which alveolar flooding is a result of an increase in the hydrostatic pressure of the pulmonary capillaries, alveolar flooding in patients with adult respiratory distress syndrome (ARDS) is the result of an increase in pulmonary capillary permeability. The primary pathophysiologic process is one of damage to the capillary side of the alveolar–capillary membrane. This damage results in rapid movement of fluid containing high concentrations of protein from the capillaries to the pulmonary parenchyma and alveoli. Lung compliance decreases and oxygen diffusion capacity is impaired, resulting in hypoxemia. If not managed aggressively, respiratory failure may result; when managed aggressively, the mortality rate associated with ARDS is high. There are a number of causes and several distinct states of ARDS. The causes of ARDS include shock, sepsis, multiple red blood cell transfusions, aspiration injury, inhalation injury, pneumonia, pancreatitis, disseminated intravascular coagulation, and fat emboli (244). Twenty-eight-day mortality is reported between 25% to 40%, with overall mortality as high as 70% (244,245). Irrespective of the cause, which should be identified and treated if possible, the evolving clinical picture and management are very similar.

Clinically, ARDS passes through several stages. Initially, patients develop tachypnea and dyspnea with no remarkable findings on clinical evaluation or on chest x-ray. Chest x-rays eventually reveal bilateral diffuse pulmonary infiltrates. As lung compliance becomes impaired, functional residual capacity, tidal volume, and vital capacity decrease. The PaO$_2$ decreases and, characteristically, increases only marginally with oxygen supplementation. An attempt should be made to maintain the arterial oxygen level above
90%. This may be achievable initially by administering oxygen by mask. For patients with severe hypoxemia, endotracheal intubation with positive-pressure ventilation should be instituted. Traditionally, the goal was to maintain normal arterial gases, with increased minute ventilation and pressure as needed to maintain these, with little insight into the long-term repercussions that this modality employs. Data over the past 5 to 10 years show that “normal” or increased tidal volumes and pressures are linked to significant barotrauma and injury to alveoli. Elevated positive end-expiratory pressure (PEEP) increasingly was used to recruit alveoli, with decreases in the amount of fraction of inspired oxygen (F\textsubscript{\text{O}}\text{2}) and minute ventilation required to maintain oxygenation in this setting, with limited success when compared to lower PEEP levels, controlling for tidal volume and end-inspiratory pressures (246).

Attempts to manage and treat the cause of ARDS must include aggressive efforts toward hemodynamic and circulatory resuscitation in patients with shock. Nosocomial pneumonia is present in 50% of patients with ARDS, and broad-spectrum antibiotic therapy should be administered appropriately for patients with suspected pneumonia or sepsis. Patients who have disseminated intravascular coagulopathy may require replacement with cryoprecipitate or FFP. Other measures for general care should include the placement of a nasogastric tube, gastric acid suppression with H\textsubscript{2} blockers, and administration of steroids in patients with the fat emboli syndrome.

**Hemodynamic monitoring is invaluable and should be initiated early in the course of the disease process in the appropriate intensive care unit setting.** Patients with any evidence of fluid overload should receive aggressive diuresis, whereas others may require fluid resuscitation for maintenance of tissue perfusion while the pulmonary–capillary wedge pressure is maintained below 15 mm Hg. Pulmonary wedge pressure may be falsely elevated when PEEP is being applied. The goal of management is to maintain the lowest pulmonary–capillary wedge pressure, with acceptable cardiac output and blood pressure. In the setting of hypotension and oliguria, inotropic support with dopamine or dobutamine or both is helpful.

**With aggressive management, particularly if the inciting cause is identified and treated, ARDS can be reversed during the first 48 hours with few sequelae.** After the first 48 hours, progression of the ARDS will cause lung damage that may leave residual pulmonary fibrosis. The long-term outcome is usually apparent within the first 10 days, at which time approximately half of patients are weaned from ventilatory support or they die (244).
Renal Disease

The need for surgical intervention in patients with renal impairment resulted in the development of a very specialized medical approach to their care. Precautions are necessary to compensate for the kidneys' impaired ability to regulate fluids and electrolytes and excrete metabolic waste products. Equally important are the unique problems that develop in patients with chronic renal impairment, including an increased risk of sepsis, coagulation defects, impaired immune function and wound healing, and a propensity to develop specific acid-base abnormalities. Special consideration must be given to a variety of different medications, anesthetic agents, and numerous hematologic and nutritional factors that are important in the successful surgical care of patients with renal insufficiency.

Management of fluid levels and cardiovascular hemodynamics in patients with acute or chronic renal impairment is paramount. Intravascular fluid volume changes that lead to hypertension or hypotension are very common in these patients and often are difficult to manage secondary to autonomic dysfunction, acidosis, and other problems that are inherent to the underlying kidney disease. Patients undergoing dialysis in whom major abdominal or pelvic surgery is contemplated should be treated using invasive monitoring, both intra- and postoperatively. The results of physical examination and CVP monitoring correlate poorly with left cardiac filling pressures. Swan-Ganz catheter measurements will help guide fluid replacement and avoid volume overload. Invasive hemodynamic monitoring should be continued as needed throughout the first postoperative week because third spacing will occur during this period.

Postoperative dialysis usually is necessary to avoid problems associated with fluid overload and hyperkalemia. Dialysis-dependent patients should undergo dialysis approximately 24 hours following surgery. A short-lived but rather significant fall in the number of platelets occurs during dialysis; in addition, heparin is used in hemodialysis equipment to prevent clotting. Because of these factors and concerns about postoperative bleeding, dialysis is usually avoided during the first 12 to 24 hours following surgery. Although ischemic heart disease is the most common cause of death in patients with renal insufficiency, it is not a major cause of perioperative mortality (247). A large percentage of perioperative deaths of patients with renal insufficiency are associated with hyperkalemia that is controlled most effectively by dialysis (248).

Patients with chronic renal failure are at an increased risk for postoperative infections resulting from abnormalities in neutrophil and monocyte function (249). Appropriate preoperative antibiotic prophylaxis and accurate assessment of nutritional status help lower the incidence of postoperative infectious complications.

The major hematologic concern in patients with chronic renal insufficiency is the increased incidence of bleeding. These bleeding problems are secondary to abnormal bleeding times and, in particular, disorders of platelet function related to a decreased amount of factor VIII and von Willebrand antigen in the serum of uremic patients. Anemia, which is common in patients with renal insufficiency, can contribute to
prolonged bleeding times (250). Abnormalities in arachidonic acid metabolism, acquired platelet storage pool deficiency, and disturbed regulation of platelet calcium content all contribute to an increased tendency for uremic patients to have significant bleeding during surgery (251). The bleeding time should be routinely checked preoperatively in these patients, and abnormalities should be corrected before surgery. Options for the correction of bleeding time in uremic patients include infusion of desmopressin or cryoprecipitate, both of which act to increase plasma levels of factor VIII and von Willebrand antigen (252,253).

Normal renal function is essential for maintenance of acid-base balance in the body. Patients with renal insufficiency can have a normal anion gap or an elevated anion gap acidosis. When mild renal insufficiency develops, a normal anion gap is present, whereas in more significant and severe renal dysfunction, an elevated anion gap acidosis occurs. Hemodialysis corrects metabolic acidosis. If a patient is severely acidotic (pH <7.15) and emergency surgery is planned, correction of the blood pH to 7.25 using intravenous sodium bicarbonate is indicated. However, correction of metabolic acidosis should be carried out slowly, because in patients with hypocalcemia, seizures may be precipitated (254). It is important to exclude other causes of elevated anion gap acidosis, such as ketoacidosis secondary to diabetes, lactic acidosis secondary to infection, or in rare instances, poisoning with ethylene glycol, methanol, or aspirin.

Impaired kidney function causes phosphate retention by the kidney and impaired vitamin D metabolism. Therefore, hypocalcemia is common in patients with renal insufficiency, but tetany and other signs of hypocalcemia are relatively uncommon because metabolic acidosis increases the level of ionized calcium. Oral phosphate binders, such as aluminum hydroxide (1 to 2 g per meal), and dietary phosphate restriction (1 g per day) is the usual treatment for hypocalcemia–hyperphosphatemia in patients with renal insufficiency. In chronic situations, because of central nervous system toxicity associated with elevated aluminum levels, it is preferable to treat hypocalcemia–hyperphosphatemia with large doses of calcium carbonate (6 to 12 g per day) rather than with the standard aluminum-containing antacids (255).

Approximately 20% of patients with renal insufficiency exhibit clinical evidence of protein calorie malnutrition. Vitamin deficiencies, most notably with water-soluble vitamins, occur with dialysis. Nutritional disturbances in patients with chronic renal insufficiency arise secondary to deficiencies in protein intake, and studies show that, in patients with chronic renal insufficiency, their kidneys are hyperfiltrating (256). Postoperatively, both protein and caloric intake may need to be increased dramatically to meet catabolic demands in surgical patients. As much as 1.5 g/kg of protein and 45 kcal/kg of calories may be needed (256).

Wound healing is impaired in patients with chronic renal failure, and wound dehiscence and evisceration are potential problems. Wound healing is most appropriately aided by nutritional assessment preoperatively and maintenance of adequate caloric and protein intake in the perioperative setting. Antibiotic prophylaxis
should be used in these patients, and uremia should be treated with dialysis as indicated. A running mass closure of the midline vertical incision with continuous monofilament sutures should be used to decrease the risk of wound dehiscence and evisceration (256).

Patients with chronic renal disease have an altered ability to excrete drugs and are prone to significant metabolic derangements secondary to the altered bioavailability of many commonly used medications. Because of this, and the effect of dialysis on drug pharmacokinetics, the gynecologic surgeon and nephrologist must be aware of the lowered metabolism and bioavailability of narcotics, barbiturates, muscle relaxants, antibiotics, and other drugs that require renal clearance. Of particular note is the inability of patients with renal insufficiency to clear the neuromuscular blockade caused by pancuronium (257). Care must be taken with D-tubocurarine, especially if repeated doses are given (258). Midazolam, propofol, vecuronium, and atracurium are used safely in patients with renal failure (254). Succinylcholine is reported to cause significant hyperkalemic responses in patients with renal failure (259). When succinylcholine is used in patients with chronic renal insufficiency, careful monitoring of the serum potassium level is necessary (260).

Perioperative acute renal failure in previously normal patients may be caused by decreased renal perfusion, nephrotoxins, or both. Patients with impaired cardiac function, intravascular volume depletion, sepsis, or hypotension fall under the first category. Nephrotoxic medications such as aminoglycosides, chemotherapeutic agents such as cisplatin, or iodinated contrast agents fall under the second category (261–263). The risk of renal impairment becomes cumulative if more than one of these factors exist at the same time, and especially if a variety of factors are associated with intervascular volume depletion (264). Several measurements should be used to avoid acute renal failure. All nephrotoxic drugs should be discontinued when possible. When it is not practical to withdraw medication, strict attention should be paid to the pharmacokinetic characteristics of each drug and to the regular measurements of serum creatinine levels. Patients with diabetes should be given reduced doses of radiocontrast agents and should be well hydrated because they are particularly susceptible to renal injury from these materials (265). Volume repletion is essential to lower the incidence of renal impairment (266).
Liver Disease
Management of perioperative problems in gynecologic patients with liver disease requires a comprehensive understanding of normal liver physiology and the pathophysiology underlying diseases of the liver that may complicate surgery or recovery. Patients with liver disease often have numerous complicated problems involving nutrition, coagulation, wound healing, encephalopathy, and infection.

History and Physical Examination
Patients with a history of alcohol abuse, drug use, hepatitis, jaundice, blood product exposure, or a family member with liver disease should undergo biochemical evaluation. During the physical examination, note should be made of any jaundice, signs of muscle wastage, ascites, right upper quadrant tenderness, palmar erythema, or hepatomegaly.

Laboratory Testing
The biochemical profile (alkaline phosphatase, calcium, lactate dehydrogenase, bilirubin, serum glutamic–oxaloacetic transaminase, cholesterol, uric acid, phosphorous, albumin, total protein, and glucose) is not useful for routine preoperative evaluation (267). Mild abnormalities can result in further extensive testing that requires consultation, delays in surgery, and increased cost without net benefit. A possible exception is selected use of biochemical testing when the history or physical examination reveals abnormalities. Patients with known liver disease should undergo albumin and bilirubin testing using the Child’s risk classification (Table 22.21). This system was originally designed to predict mortality following portosystemic shunt surgery. It divides patients into three classes of severity based on five easily assessed clinical parameters. Measurement of prothrombin time may be helpful in patients with significant histories of liver disease. If a history of hepatitis is ascertained, the patient should be tested for serum aminotransferase, alkaline phosphatase, bilirubin, albumin levels, and prothrombin time. Serologic documentation of hepatitis is important. If a patient has a known malignancy, biochemical testing of the liver may be of some benefit as a screen for metastatic disease, although this was not proven conclusively.

Anesthesia
With few exceptions, most anesthetic agents, including those administered by epidural or spinal routes, reduce hepatic blood flow and decrease oxygenation of the liver. Other perioperative factors—hemorrhage, intraoperative hypotension, hypercarbia, congestive heart failure, and intermittent positive pressure ventilation, especially in critically ill patients—lead to decreased hepatic perfusion and hypoxia (268).

Drug Metabolism
Patients with altered liver function should be carefully monitored because of the prolonged action of many medications used during surgery. In addition to impaired metabolism, hypoalbuminemia decreases drug binding, which alters serum levels and biliary clearance rates. The degree of hepatic metabolism varies greatly, depending on the type of medication considered. For inhalation anesthetics, isoflurane is preferred because it undergoes minimal hepatic metabolism in comparison with halothane or enflurane. Narcotics, induction agents, sedatives, and neuromuscular blocking agents all undergo abnormal metabolism in patients with decompensated liver disease. Diazepam, meperidine, and phenobarbital cause prolonged depression of consciousness and may precipitate hepatic encephalopathy because of their altered rates of clearance. Sufentanil and fentanyl are the preferred narcotics. Oxazepam, a benzodiazepine that does not undergo hepatic metabolism, is considered safe. Muscle relaxants, such as D-tubocurarine, pancuronium, and vecuronium, cause prolonged neuromuscular blockade in patients with impaired liver function and are not ideal drugs to use in this situation. Atracurium is not metabolized by the liver and is the preferred muscle relaxant for patients with abnormal hepatic function. Succinylcholine metabolism is prolonged in patients with hepatic dysfunction and must be used with great caution (269).

Determination of Operative Risk
Although it is well known that acute hepatobiliary damage results in increased morbidity and mortality in the surgical patient, estimating the operative risk in patients with hepatic dysfunction is difficult based on the history and physical examination. The most accurate method for risk assessment of surgery in patients with hepatic dysfunction is Child’s classification (Table 22.21). Using this system, accurate assessment of morbidity and mortality can be directly related to the degree of liver dysfunction (270). The Child’s classification is useful for patients undergoing a variety of different types of abdominal surgery. Data show operative mortalities of 10%, 30%, and 82% for each of the three Child’s classifications, respectively, while other data called this into question with operative mortality of 2%, 12%, and 12% (271,272). The major cause of perioperative death was often sepsis. This classification correlated significantly with postoperative complications such as bleeding, renal failure, wound dehiscence, and sepsis. Another method for determining operative risk in patients with cirrhosis is the Model for End-Stage Liver Disease (MELD), which takes into account the patient’s
prothrombin time, bilirubin, and creatinine with various iterations used to better predict perioperative morbidity and mortality (273,274). Originally designed to predict outcomes in cirrhotic patients undergoing the transjugular intrahepatic portosystemic shunt (TIPS) procedure, it was further studied to include patients undergoing other surgical procedures. In patients with a MELD score greater than 15, elective surgery should be deferred (275).

**Acute Viral Hepatitis**

Acute viral hepatitis poses an increased risk of operative complications and perioperative mortality and is a contraindication for elective surgery (276). Elective surgery should be delayed for approximately 1 month after the results of all biochemical tests have returned to normal (277). In patients with ectopic pregnancy, hemorrhage, or bowel obstruction secondary to malignancy, surgical intervention must take place before normalization of serum transaminase levels (276). In these situations, the perioperative morbidity (12%) and mortality (9.5%) rates are much higher than when they are performed under ideal situations (269).

**Chronic Hepatitis**

Chronic hepatitis is a group of disorders characterized by inflammation of the liver for at least 6 months. The disease is divided by morphologic and clinical criteria into chronic persistent hepatitis and chronic active hepatitis. A liver biopsy is usually required to establish the extent and type of injury. The surgical risk in these patients correlates most closely with the severity of disease. The risk of surgery in patients with asymptomatic or mild disease is minimal in contrast to a significant risk for those patients who have symptomatic chronic active hepatitis (278). Elective surgery is contraindicated in symptomatic patients, and nonelective surgery is associated with significant morbidity (277). In the nonelective situation, patients taking long-term glucocorticoid therapy should be given appropriate stress coverage with a higher dose of glucocorticoids during the perioperative period. Preoperatively, patients who are not taking steroids should receive prednisone and azathioprine, which are shown to reduce the perioperative risk of complications and may result in remission in as many as 80% of patients (279).

Asymptomatic carriers of the hepatitis B virus (HBV; individuals who test positive for the HBV surface antigen) are not at increased risk for postoperative complications in the absence of elevated aminotransferase levels and liver inflammation. There is a significant risk to the health care professional operating on these individuals. In cases of needlestick in which the patient’s hepatitis status is unknown, both the health care worker and the patient should be tested for hepatitis C virus (HCV) antibody and HBV serologic markers. If markers for HBV infection are present, hepatitis B immune globulin should be administered to unvaccinated medical personnel. A vaccination series should be initiated during the early postoperative period. If the health care worker is immune (surface antibody positive), no treatment is necessary (269). All medical personnel, and especially those in the surgical
subspecialties, should receive a full course of recombinant hepatitis B vaccine as recommended by the CDC (280). Treatment for chronic hepatitis B in the 1990s centered around interferon-α with data in the 2000s showing increased benefit from the use of nucleoside analogues, including lamivudine and tenofovir (281,282). Pegylated interferon and ribavirin are used in the standard treatment of HCV (283). Consideration should be given to using these medications for patients in whom surgery cannot be avoided but is not emergent.

Alcoholic Liver Disease
Alcoholic liver disease encompasses a spectrum of diseases including fatty liver, acute alcoholic hepatitis, and cirrhosis. Elective surgery is not contraindicated in patients with fatty liver because liver function is preserved. **If nutritional deficiencies are discovered, they should be corrected before elective surgery.** Acute alcoholic hepatitis is characterized on biopsy by hepatocyte edema, polymorphonuclear leukocyte infiltration, necrosis, and the presence of Mallory bodies. Elective surgery in these patients is contraindicated (284). Abstinence from alcohol for approximately 6 to 12 weeks along with clinical resolution of the biochemical abnormalities are recommended before surgery is considered. Severe alcoholic hepatitis may persist for several months despite abstinence and, if any question of continued activity exists, a liver biopsy should be repeated (285). In cases of urgent or emergent surgery on patients with alcohol dependence, administration of tapered doses of benzodiazepine is appropriate as prophylaxis against alcohol withdrawal.

Cirrhosis
Cirrhosis is an irreversible liver lesion characterized histologically by parenchymal necrosis, nodular degeneration, fibrosis, and a disorganization of hepatic lobular architecture. The most serious complication of cirrhosis is portal venous hypertension, which ultimately leads to bleeding from esophageal varices, ascites, and hepatic encephalopathy. Conventional liver biochemical test results correlate poorly with the degree of liver impairment in patients with cirrhosis. Hepatic dysfunction, may be somewhat quantified by low albumin levels and prolonged prothrombin times.

**Surgical risk is increased in patients with advanced liver disease, although it is substantially greater in emergency surgery than in elective surgery.** Perioperative mortality correlates with the severity of cirrhosis and can be estimated through the use of the Child’s classification (Table 22.21). In patients with Child’s class A cirrhosis, surgery can usually be performed without significant risk, whereas in patients with Child’s class B or C, surgery poses a major risk and requires careful preoperative consideration. Preoperative preparation should include the following measures: (i) optimizing nutritional status by enteral and parenteral nutrition and supplementation with vitamin B₁, (ii) correcting coagulopathy with administration of FFP or cryoprecipitate or both, (iii) minimizing preexisting encephalopathy, (iv) preventing sepsis from spontaneous bacterial peritonitis by administering prophylactic antibiotic therapy, and (v)
optimizing renal function and carefully correcting electrolyte abnormalities (286). Meticulous preoperative preparation focused on correcting abnormalities associated with advanced liver disease may improve surgical outcomes (287).

Positioning the insufflation needle and the primary cannula are best accomplished with the patient in an unaltered horizontal position. Proper patient selection is critical for laparoscopic management of ovarian cysts because of concerns about an adverse effect on prognosis with malignant tumors.

Laparoscopic myomectomy often requires laparoscopic suturing; thus, more technical skills are needed than with many other endoscopic procedures. Laparoscopic hysterectomy comprises any removal of the uterus where at least part of the dissection is accomplished laparoscopically while the remainder, if any, is finished vaginally.

Dehiscence and hernia risk appear to significantly increase when the fascial incision is larger than 10 mm in diameter. The incidence of unintended electrosurgical activation injuries can be reduced if the surgeon always remains in direct control of electrode activation and if all electrosurgical hand instruments are removed from the peritoneal cavity when not in use.

Patients recovering from laparoscopic surgery usually experience daily improvement. Pain diminishes, gastrointestinal function returns rapidly, and fever is extremely unusual. Therefore, if a patient’s condition is not improving, possible complications of anesthesia or surgery should be considered.

Endoscopy is a procedure that uses a narrow telescope to view the interior of a viscus or preformed space. Although the first medical endoscopic procedures were performed more than 100 years ago, the potential of this method was realized only recently. Endoscopes are used to perform a variety of operations. In gynecology, endoscopes are used most often to diagnose conditions by direct visualization of the peritoneal...
cavity (laparoscopy) or the inside of the uterus (hysteroscopy).
When used appropriately, endoscopic surgery offers the benefits of reduced pain, improved cosmesis, lower cost, and faster recovery. The indications for endoscopic surgery are outlined here and described in more detail in the appropriate chapters. The technology, potential uses, and complications of laparoscopy and hysteroscopy are summarized here.
Laparoscopy

The past four decades have witnessed rapid progress and technologic advances in gynecologic laparoscopy. Operative laparoscopy was developed in the 1970s, and in the early 1980s, laparoscopy was first used to direct the application of electrical or laser energy for the treatment of advanced stages of endometriosis. The use of high-resolution, and, more recently, high-definition video cameras in operative laparoscopy made it easier to view the pelvis during the performance of complex procedures (1,2). Most procedures that previously were performed using traditional techniques are feasible with the laparoscope, including adnexal procedures such as ectopic pregnancy and ovarian cystectomy; uterine surgery, such as myomectomy and hysterectomy; and reconstruction of the pelvic floor, such as retropubic urethropexy and sacral colposuspension. The endoscopic approach may have drawbacks in some patients. Although many laparoscopic procedures appear to reduce the cost and morbidity associated with surgery, others were replaced by even less invasive procedures, and a few were not effective replacements for more traditional operations. The use of microprocessor-assisted laparoscopy allows the surgeon to operate remotely from the operative field, in a sitting position, with the “robot” allowing translation of natural hand manipulations to the peritoneal cavity with the specially designed instruments. The value of this and other techniques and indications for operative endoscopy are still under investigation and constantly in a state of evolution.
Diagnostic Laparoscopy

The lens of a laparoscope can be positioned to allow wide-angle or magnified views of the peritoneal cavity. The clarity and illumination of the optics allow a better appreciation of fine detail than is possible with the naked eye. Laparoscopy is the standard method for the diagnosis of endometriosis and adhesions because no other imaging technique provides the same degree of sensitivity and specificity.

There are limitations to laparoscopy. The view of the operative field may be restricted, and if tissue or fluid becomes attached to the lens, vision may be obscured. Soft tissues, intramural myomas, or the inside of a hollow viscus cannot be palpated. For assessment of these tissues, an imaging modality, such as ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI), is superior. Because of its ability to view soft tissue, ultrasonography is more accurate than laparoscopy for the evaluation of the inside of adnexal masses. The intraluminal contour of the uterus can be shown only by hysteroscopy or contrast imaging such as saline infusion sonography, hysterosalpingography, or MRI. Ultrasonography, in combination with serum assays of \( \beta \)-human chorionic gonadotropin (\( \beta \)-hCG) and progesterone, can be used to diagnose ectopic pregnancy, usually allowing medical therapy to be given without laparoscopic confirmation (3). As a result of the advances in blood tests and imaging technology, laparoscopy more often is used to confirm a clinical impression than for initial diagnosis.

Laparoscopy may disclose abnormalities that are not necessarily related to the patient’s problem. Although endometriosis, adhesions, leiomyomas, and small cysts in the ovaries are common, they are frequently asymptomatic. Thus, diagnostic laparoscopy must be performed prudently, interpreting findings in the context of the clinical problem and other diagnoses.
Therapeutic (Operative) Laparoscopy

The role of laparoscopy in the operative management of gynecologic conditions is evolving. Many procedures previously performed as traditional abdominal and vaginal operations are feasible or even readily performed under laparoscopic direction. **Operative laparoscopy has the benefit of shorter hospital stays, less postoperative pain, and faster return to normal activity.** These general features of laparoscopic procedures contribute to a reduction in the “indirect costs” of surgical care, including less time away from work and a diminished need for postdischarge supportive care in the home (4). In addition to the other benefits of endoscopic procedures, adhesions are less likely to form with laparoscopic surgery than with laparotomy. Because sponges are not used, the amount of direct peritoneal trauma is reduced substantially, and contamination of the peritoneal cavity is minimized. The reduced exposure to the drying effect of room air allows the peritoneal surface to remain more moist and, therefore, less susceptible to injury and adhesion formation.

Despite these advantages, there are potential limitations: exposure of the operative field can be reduced; instruments are small and can be used only through fixed ports; and the ability to manipulate the pelvic viscera is limited. In some cases, the cost of hospitalization increases, despite a shortened stay, because of prolonged operating room time and the use of more expensive surgical equipment and supplies. Efficacy may be reduced if a surgeon cannot adequately replicate the abdominal operation. In some patients, there is an increased risk of complications, which can be attributed to the innate limitations of laparoscopy, the level of surgical expertise, or both. With an adequate combination of ability, training, and experience, however, operative time is comparable to those of traditional abdominal surgery and complications may be reduced.

Tubal Surgery

Sterilization

Laparoscopic sterilization has been used extensively since the late 1960s, and while it can be performed with local anesthetics, it is usually accomplished under general anesthesia. The fallopian tubes can be occluded by suture, clips, silastic rings, or with radiofrequency electrocoagulation, most commonly with a bipolar electrocoagulation instrument (see Chapter 10). When an “operative laparoscope” is used, only one incision is required because the sheath in such a system contains an instrument channel. Otherwise, a second port is needed for the introduction of the occluding instrument. Patients generally remain in the hospital only for a few hours; even when general anesthesia is used. Postoperative pain is usually minor and related to gas that remains in the peritoneal cavity (shoulder pain, dyspnea), and in the case of occlusive devices, pain at the surgical site. These effects normally disappear within a few days. The failure rate is about 5.4 per 1,000 woman-years (5,6). The use of laparoscopic tubal sterilization was impacted by the availability of office vasectomy, effective intrauterine contraception, and the development...
Ectopic Gestation

Medical therapy with methotrexate is considered first-line therapy for tubal pregnancies that meet criteria that may include the following: no cardiac activity, tubal mass smaller than 4 cm as determined by ultrasonography, and β-hCG level less than 10,000 (7,8). When surgical therapy is required, ectopic gestation can usually be managed successfully by using laparoscopic salpingotomy, salpingectomy, or segmental resection of a portion of the oviduct (see Chapter 20) (9,10). Salpingotomy is performed with scissors, a laser, or an electrosurgical electrode after carefully injecting the mesosalpinx with a dilute vasopressin-containing solution (20 U in 100 mL of normal saline). For salpingectomy, the vascular pedicles are usually secured with electrosurgical desiccation or coagulation, but it is possible using ligatures or clips. Tissue is usually removed from the peritoneal cavity through one of the laparoscopic cannulas.

When salpingotomy is performed, regardless of the route, there is about a 5% chance that trophoblastic tissue remains. In such instances, medical treatment with methotrexate is appropriate (see Chapter 20). Consequently, β-hCG levels should be measured weekly until there is confidence that complete excision occurred (11–13).

Ovarian Surgery

Ovarian Masses

Laparoscopic removal of selected ovarian masses is a well-established technique supported by high quality evidence (14–16). Proper patient selection is critical for laparoscopic management of adnexal masses because of the possible adverse effect of laparoscopic approaches on prognosis with malignant tumors (17,18). Preoperative ultrasonography is mandatory. Sonolucent lesions with thin walls and no solid components are at very low risk for malignancy and, therefore, are suitable for laparoscopic removal. For postmenopausal women, the measurement of CA125 levels is useful in identifying candidates for laparoscopic management (19,20). Combining age, menopausal status, an ultrasound score, and the serum CA125 level into a “risk of malignancy index” seems to offer an effective approach to the identification of cysts at high risk for epithelial malignancy (21–23). Lesions with ultrasonographic findings suggestive of mature teratoma (dermoid), endometrioma, or hemorrhagic or other cysts presenting with torsion or other causes of acute pain may be suitable for endoscopic management (24–27). Ovarian tumors should be assessed by frozen histologic section, and any frank malignancy should be managed expeditiously by laparotomy (14,18,20).

The technique for performing laparoscopy for oophorectomy and cystectomy is similar to that used for laparotomy (13). For cystectomy, scissors are used to incise the ovarian capsule, and blunt dissection or aqua dissection is used to separate the cyst from the ovary. If oophorectomy is performed, the vascular pedicles are occluded and
transected, usually with radiofrequency electrosurgical coagulation and cutting systems, but in some instances with sutures, clips, or linear cutting and stapling devices. The ureter should be identified and should be clear of the pedicle to be transected. Cysts that appear to be benign may be drained before extraction through a laparoscopic cannula or, less commonly, a posterior culdotomy. If there is concern about the impact of spilled cyst contents, the specimen should be removed in a retrieval bag inserted into the peritoneal cavity through a laparoscopic port. Some authors describe a minilaparotomy technique, or enlarging one port site incision, to exteriorize the mass, drain it externally without intraperitoneal spill, remove the cyst or ovary, and then reintroduce the adnexa into the peritoneal cavity (28).

Although in the past the ovary routinely was closed after cystectomy, this practice may be unnecessary and could contribute to the formation of adhesions (29). There is controversy about this point as at least one randomized clinical trial (class 1) suggested that suture-based closure of the ovary is associated with fewer adhesions than using electodesiccation alone (30).

**Other Ovarian Surgery**

**Ovarian torsion, previously treated by laparotomy and oophorectomy, often can be managed laparoscopically** (31,32). Even if there is apparent necrosis, the adnexa can be untwisted, usually with preservation of normal ovarian function (26,33). Performing a cystectomy at the same time that the ovary is untwisted greatly reduces the likelihood that ovarian function will be maintained. Rarely is adnexectomy indicated.

**Polycystic ovarian syndrome can be treated laparoscopically using electrosurgery or laser vaporization to perform ovarian “drilling.”** This procedure reduces the volume of ovarian stromal tissue and may lead to a temporary return of normal ovulation (34–36). Although such procedures were successful in a number of randomized trials, postoperative adhesions form in 15% to 20% of patients, which underscores the need to first exhaust medical treatment (37–39).

**Uterine Surgery**

**Myomectomy**

Laparoscopic myomectomy, although feasible, may be difficult to perform because proper closure of the myometrium requires laparoscopically directed suturing and, thus, requires more technical skills than many other endoscopic procedures. While it is possible that microprocessor-assisted (robotic) laparoscopic myomectomy may allow more surgeons to suture effectively under laparoscopic guidance, even in expert hands there appears to be no benefit to robotic surgery in any measurable perioperative outcome (40).

There remain some questions regarding the efficacy of laparoscopic myomectomy, especially as it relates to the treatment of infertility and heavy
menstrual bleeding, each of which are thought to be secondary to submucosal myomas. Although there are some well-designed studies evaluating infertility outcomes (class 1 randomized clinical trials) comparing laparoscopic myomectomy to that performed by laparotomy, the sample sizes are still relatively small, and the cases are highly selected, limiting the size and number of the lesions to be removed (41,42). In these trials, fertility outcomes were similar between the laparoscopic and the laparotomic approaches. These and other trials evaluating perioperative outcomes, such as duration of admission, surgical pain, and operative complications, found the laparoscopic approach to be superior (43).

Proper patient selection for myomectomy, regardless of route, is extremely important, particularly because, by age 50, the prevalence of leiomyomas may be as high as 70% in whites and 80% in women of African ancestry (44). It is relatively easy to mistakenly ascribe symptoms to the presence of leiomyomas. Unless the myoma involves the endometrial cavity, it is unlikely to contribute to heavy menstrual bleeding or infertility; the impact of intramural myomas on infertility is not well understood (45). Leiomyomas that cause pressure are often large and may be located near vital vascular structures that may preclude the laparoscopic approach even in expert hands. Many women will do well with expectant or medical management or with procedural alternatives such as uterine artery embolization. The surgeon should freely select a laparotomic approach, either at the outset or during the procedure, if technical limitations put the patient at risk or otherwise compromise the potential relevant clinical outcomes (46). Patients who have pedunculated or subserosal leiomyomas that cause bothersome discomfort or pain in association with torsion are especially good candidates for laparoscopic excision (13,47).

Hysterectomy

Laparoscopic hysterectomy encompasses a variety of procedures, including the facilitation of vaginal hysterectomy with variable extents of endoscopic dissection, supracervical hysterectomy by dissection, amputation and mechanical removal of the fundus, and the removal of the entire uterus under laparoscopic direction (48–50). In most environments, the procedure is performed with a combination of electrosurgical vessel sealing devices and mechanical cutting systems, often incorporated into a single instrument. In some instances sutures, clips, and linear cutting and stapling devices are employed in the process of dissecting or occluding vascular pedicles.

Compared to vaginal hysterectomy, there is a slightly higher risk of complications with laparoscopic hysterectomy, but this risk is probably lower than for abdominal hysterectomy (51). As experience is gained with laparoscopic hysterectomy, these outcomes may approach those of vaginal hysterectomy. The procedural costs of laparoscopic hysterectomy are greater than either vaginal or abdominal hysterectomy but can be dramatically reduced when reusable instruments are employed (4,52). Most studies show less postoperative pain, shorter hospital stays, and
faster postoperative recovery with laparoscopic hysterectomy than with abdominal hysterectomy (51,53). There is evidence that pain scores and quality-of-life measures, including sexual activity and physical and mental functioning, were significantly better for women who underwent laparoscopic versus abdominal hysterectomy (54). These differences were present at 6 weeks following surgery and remained at the 12-month follow-up visit. When the societal benefits of faster return to work or family are considered, the cost of laparoscopic surgery is significantly less (4).

Selection of the route of hysterectomy must be done considering the anatomy, the disorder or disease state, the patient’s wishes, and the training and experience of the surgeon. Laparoscopic hysterectomy offers no advantage for women in whom vaginal hysterectomy is possible because the endoscopic approach is more expensive and probably has a higher risk for perioperative morbidity (51). The ideal place for laparoscopic hysterectomy is as a replacement for abdominal hysterectomy.

Outside of physician training, there are relatively few remaining indications for abdominal hysterectomy, which should be reserved for the minority of women for whom a laparoscopic or vaginal approach is not appropriate, including (i) patients with medical conditions, such as cardiopulmonary disease, where the risks of either general anesthesia or the increased intraperitoneal pressure associated with laparoscopy are deemed unacceptable; or (ii) where morcellation is known or likely to be required and uterine malignancy is either known or suspected. For both laparoscopic and vaginal hysterectomy the reasons include: (i) hysterectomy is indicated but there is no access to the surgeons or facilities required for vaginal or laparoscopic hysterectomy and referral is not feasible; or (ii) circumstances where anatomy is so distorted by uterine disease or adhesions that a vaginal or laparoscopic approach is not deemed safe or reasonable by individuals with recognized expertise in either vaginal or laparoscopic hysterectomy techniques (52,54). For surgeons without the skill and training to perform minimally invasive hysterectomy (either vaginal or laparoscopic), for benign indications, consideration should be given for referral to a gynecologist with such training.

Infertility Operations

When infertility occurs secondary to disruption of the normal anatomy or anatomic relationships by an inflammatory process, laparoscopically directed operations used to restore anatomy include fimbrioplasty, adhesiolysis, and salpingostomy for distal obstruction (55). Fimbrioplasty is distinguished from salpingostomy because it is performed in the absence of preexisting complete distal obstruction. Endometriosis associated with adnexal distortion can be treated by laparoscopic adhesiolysis. Whereas there is no known additional benefit of medical treatment of coexistent active endometriosis, the evidence relating to ablation of minimal and mild endometriosis is mixed, although when subjected to meta-analytic technique, there is a slight fecundity benefit for those undergoing laparoscopic ablation (56–58). Laparoscopy is used for procedures in which gametes (gamete intrafallopian transfer) or zygotes (zygote intrafallopian transfer) are placed into the fallopian tube after oocytes are removed either
Adhesiolysis may be accomplished by blunt or sharp dissection with scissors, ultrasonic shears, or an electrosurgical electrode. There is no evidence that laser-based instruments provide any additional value over less expensive techniques such as electrosurgery \( (59–61) \). The dissecting instruments are usually passed through an ancillary port; when laser energy is used, the channel of the operating laparoscope may be used for this purpose. Although there is controversy regarding the most appropriate modality for adhesiolysis, these methods are probably equally effective in appropriately trained hands.

Laparoscopic operations for the treatment of mechanical infertility are probably equally effective to similar procedures performed by laparotomy. In patients with extensive adhesions, successful outcomes are unlikely regardless of the approach. Consequently, assisted reproductive technologies such as in vitro fertilization and embryo transfer are necessary in these situations \( \text{(see Chapter 32) (13,55).} \)

## Endometriosis

The laparoscopic management of endometriomas parallels that of adnexal masses, although the ultrasonographic complexity of endometriomas sometimes makes it difficult to distinguish them preoperatively from a neoplasm \( (62) \). The close attachment of the endometrioma to the ovarian cortex and stroma may make it difficult to find surgical dissection planes, and incomplete removal increases the risk of recurrence. In such instances there may be a tendency either to compromise the function of the remaining ovary by attempting complete removal or to risk recurrence by leaving part of the endometrioma in place. A Cochrane review found good evidence that excisional surgery for endometriomas decreases the recurrence of the endometrioma, decreases the recurrence of pain symptoms, and in women who were previously subfertile, increases subsequent spontaneous pregnancy \( (63) \). Consequently, where possible the excisional approach should be the goal. Multifocal endometriosis may be treated by mechanical excision or ablation, the latter using coagulation or vaporization with either electrical or laser energy. With proper use, each energy source creates about the same amount of thermal injury \( (59–61) \). Endometriosis frequently is deeper than appreciated initially, making excisional techniques valuable in many instances \( \text{(64,65).} \)

## Pelvic Floor Disorders

Laparoscopy can be used to guide procedures to treat pelvic support defects, including culdoplasty, enterocele repair, vaginal vault suspension, paravaginal repair, and retropubic cystourethropexy for urinary stress incontinence. Although these conditions can be treated vaginally, the laparoscopic approach may offer benefits, particularly with retropubic urethropexy. There is some evidence that the laparoscopic approach is effective when compared with the traditional
methods, but, in most instances, vaginal or laparoscopic mesh-based techniques seem to be the most frequently used approaches (66,67). Using the same surgical principles applied during traditional pelvic floor repair, laparoscopy promises better access to key anatomical landmarks and potentially more accurate suture placement (68). Whereas apical and anterior compartment defects can be successfully corrected via laparoscopy, posterior and perineal defects are best visualized and repaired using vaginal techniques. The laparoscopic treatment of enterocele and vault prolapse may be useful in patients who require abdominal approaches after failure of a previous vaginal procedure. Because of the anatomical proximity of the pelvic ureter to the uterosacral ligament and anterolateral vagina, bilateral ureteral patency should be confirmed cystoscopically after laparoscopic vaginal vault suspension, enterocele repair, culdoplasty, cystourethropexy, or paravaginal repair.

**Gynecologic Malignancies**

The role of laparoscopy in the management of gynecologic malignancy is not clearly established (69–71). A study performed by the Gynecology Oncologic Group showed that laparoscopic management of presumed stage I endometrial cancer was feasible (72). Larger-scale studies suggest that women treated with a laparoscopic approach do not fare worse than those treated via laparotomy (73,74). The potential for laparoscopic lymphadenectomy fostered a resurgence of interest in vaginal radical hysterectomy for stage I carcinoma of the cervix. Laparoscopy is being investigated for the staging of early ovarian malignancy and for second-look surgery (75,76).
Patient Preparation and Communication

The rationale, alternatives, risks, and potential benefits of the selected approach should be explained to the prospective patient. She should be advised concerning the likely outcome of expectant management if the procedure was not performed.

The expectations and risks of diagnostic laparoscopy, and those of any other procedures that may be needed, must be explained. It may be helpful to compare risks and recovery with the same procedure performed via abdominal surgery. The risks of laparoscopy include those associated with anesthesia, infection, bleeding, and injury to the abdominal and pelvic viscera. The possibility of conversion to laparotomy if a complication should occur or if the procedure cannot be completed via laparoscopic surgery should also be discussed. Infection is uncommon with laparoscopic surgery. For procedures involving extensive dissection, there is a higher risk for visceral injury. These risks should be clearly presented in a fashion that includes both the possibilities of immediate and delayed recognition. The patient should be given realistic expectations regarding postoperative disability. Because pain and visceral dysfunction normally continue to improve after uncomplicated laparoscopy, the patient should be instructed to communicate immediately any regression in her recovery. After diagnostic or brief operative procedures, patients can be discharged on the day of surgery and usually require 24 to 72 hours off work or school. If extensive dissection—a major surgical procedure performed laparoscopically—is necessary or if the surgery lasts longer than 4 hours, hospital admission may be necessary, and the period of disability may then be as long as 10 to 14 days.

Preoperative mechanical bowel preparation was perceived as reducing the morbidity of colonic surgery should an injury occur and improving visualization and exposure of the operative field at laparoscopy. There is an abundance of high-quality evidence demonstrating that preoperative mechanical bowel preparation does not reduce the morbidity of colonic surgery (77). There is one high-quality trial that shows that mechanical bowel preparation may not improve visualization at gynecologic laparoscopy (78). It is premature to abandon preoperative bowel preparation to improve visualization, because, in a small subset of patients, it may facilitate surgery. Mechanical bowel preparation should be considered to help improve visualization in selected instances where stool in the colon might compromise visualization of the operative field.

Communication with the family or other designated individuals should be arranged prior to the procedure. The patient should arrange for a friend or family member to be present to discuss the results of the procedure with the physician and to drive her home if she is discharged the same day.
Equipment and Technique

To facilitate the discussion of laparoscopic equipment, supplies, and techniques, it is useful to divide procedures into “core competencies,” which are as follows:

- Patient positioning
- Operating room organization
- Peritoneal access
- Visualization
- Manipulation of tissue and fluid
- Cutting, hemostasis, and tissue fastening
- Tissue extraction
- Incision management

Patient Positioning

Proper positioning of the patient is essential for patient safety, comfort of the operator, and optimal visualization of the pelvic organs. There may be advantages to positioning the patient while awake to reduce the frequency of positioning-related complications. Laparoscopy is performed on an operating table that can be tipped to create a steep, head-down (Trendelenburg) position that allows the bowel to move out of the pelvis to facilitate visualization after the cannulas is placed. The footrest can be dropped to allow access to the perineum. The patient is placed in the low lithotomy position, with the legs appropriately supported in stirrups and the buttocks protruding slightly from the lower edge of the table. The thighs are usually kept in the neutral position to preserve the sacroiliac angle, reducing the tendency of bowel to slide into the peritoneal cavity. The feet should rest flat, and the lateral aspect of the knee should be protected with padding or a special stirrup to avoid peroneal nerve injury. The knees should be kept in at least slight flexion to minimize stretching of the sciatic nerve and to provide more stability in the Trendelenburg position. The arms are positioned at the patient’s side by adduction and pronation to allow freedom of movement for the surgeon and to lower the risk for brachial plexus injury. Care must be exercised to protect the patient’s fingers and hands from injury when the foot of the table is raised or lowered. After the patient is properly positioned, the bladder should be emptied with a catheter and a uterine manipulator positioned in the endometrial cavity and secured either by an intracavitary balloon or attached to the cervix as appropriate.

Figure 23.1 Patient positioning: the low lithotomy position. The patient’s buttocks are positioned so that the perineum is at the edge of the table. The legs are well supported with stirrups, with the thighs in slight flexion. Too much flexion may impede the manipulation of laparoscopic instruments while in the Trendelenburg (head-down) position.
Figure 23.2 Operating room organization. The patient’s arms are at the sides. The right-handed surgeon stands on the patient’s left. Instruments and equipment are distributed around the patient within view of the surgeon. For pelvic surgery, the monitor should be located between the patient’s legs.
Operating Room Organization

The arrangement of instruments and equipment is important for safety and efficiency. The orientation depends on the operation, the instruments used, and whether the surgeon is right- or left-handed. An orientation for a right-handed operator is shown in Figure 23.2.

For pelvic surgery, the television monitor is typically placed at or over the foot of the table within the angle formed by the patient’s legs. If two monitors are available, one may be positioned at each foot of the patient allowing both the surgeon and the assistant the opportunity to view the surgical field without having to turn the head.

The surgeon usually stands by the patient’s left side, at an angle facing the patient’s contralateral foot. The nurse or technician and instrument table are positioned near the foot of the operating table to avoid obscuring the video monitor. The insufflator may be placed on the patient’s right side, in front of the surgeon, to allow continuous monitoring of the inflation rate and intra-abdominal pressure. The energy source (e.g., electrosurgical or ultrasonic generator) may be positioned on the patient’s right side to permit visualization of the power output.
Peritoneal Access

Before inserting the laparoscope, a primary cannula (or port) must be positioned in the abdominal wall to establish access to the peritoneal cavity. **The closed technique is a blind approach in which the cannula is introduced with an obturator designed to penetrate the abdominal layers.** In open laparoscopy, initial entry into the peritoneal cavity is achieved with minilaparotomy using either a transverse subumbilical or midline infraumbilical incision down to the rectus fascia, to which the cannula is fixed into position with sutures or other suitable techniques. Gynecologists generally favor a closed technique, preinflating the peritoneal cavity with CO\(_2\) through a hollow insufflation needle. In either case, additional cannulas are subsequently inserted under direct vision to allow the use of laparoscopic hand instruments such as scissors, probes, and other manipulating devices.

**Insertion of the insufflation needle and primary cannula is aided by an understanding of the normal underlying anatomy, especially the location of the larger retroperitoneal vessels (Fig. 23.3).** A “safety zone” exists inferior to the sacral promontory in the area bounded cephalad by the bifurcation of the aorta, posteriorly by the sacrum, and laterally by the iliac vessels (79). In women placed in the Trendelenburg position, the great vessels are oriented more cephalad and anterior, making them more vulnerable to injury unless appropriate adjustments are made in the angle of insertion (Fig. 23.4) (80). Therefore, positioning of the insufflation needle and the primary cannula is best accomplished with the patient in an unaltered supine (horizontal) position. This approach facilitates the evaluation of the upper abdomen, which is limited if the intraperitoneal contents are shifted cephalad by the head-down (Trendelenburg) position.

**Figure 23.3** Vascular anatomy of the anterior abdominal wall relative to the sites of port insertion. The location of the vessels that can be traumatized when inserting trocars into the anterior abdominal wall is indicated. The lateral trocars should be placed lateral to the inferior epigastric vessels that course medially to lie under the rectus muscle anterior to the posterior rectus sheath. The relative anatomy of the left upper quadrant port site is shown: the closest structure is the stomach (A) (approximately 4 cm away) and the left lobe of the liver (B) approximately (4 cm away). The spleen (C) is approximately 12 cm away.
Insufflation Needles

Virtually all insufflation needles are modifications of the hollow needle designed by Verres (Fig. 23.5). In cases uncomplicated by previous pelvic surgery, the preferred site for insertion is the base of the umbilicus, where the abdominal wall is the thinnest and usually avascular.

Figure 23.5 Insufflation needle. When pressed against tissue such as fascia or peritoneum, the spring-loaded blunt obturator (inset) is pushed back into the hollow needle, revealing its sharpened end. When the needle enters the peritoneal cavity, the obturator springs back into position, protecting the intraabdominal contents from injury. The handle of the hollow needle allows the attachment of a syringe or tubing for insufflation of the distention gas.
A midline infraumbilical incision adequate for the needle is made at the base of the umbilicus with a small scalpel, and the abdominal wall is maximally lifted, either manually or with instruments. Elevation is accomplished manually after affixing towel clips to the abdominal wall on either side lateral to the umbilicus or opposite one another within the edge of the umbilical incision itself (81).

**Safe insertion of the insufflation needle mandates that the instrument be maintained in a midline, sagittal plane while the operator directs the tip between the iliac vessels, anterior to the sacrum but inferior to the bifurcation of the aorta and the proximal aspect of the vena cava. Because the sacral promontory is commonly covered in part by the left common iliac vein, vascular injury may occur in the midline below the bifurcation (82).**

To reduce the risk of retroperitoneal vascular injury while minimizing the chance of inadvertent preperitoneal insufflation, in women of average weight, the insufflation needle is directed to the patient’s spine at a 45-degree angle. In heavy to obese individuals, this angle may be increased incrementally to nearly 90 degrees, accounting for the increasing thickness of the abdominal wall and the tendency of the umbilicus to gravitate caudad with increasing abdominal girth (79,83). The needle’s shaft is held by the tips of the fingers and steadily but purposefully guided into position only far enough to allow the tip’s entry into the peritoneal cavity. The tactile and visual feedback created when the needle passes through the facial and peritoneal layers of the abdominal wall may provide guidance and help prevent overaggressive insertion attempts. This proprioceptive feedback is less apparent with disposable needles than with the classic Verres needle. With the former, the surgeon must listen to the “clicks” as the needle obturator retracts when it passes through the rectus fascia and the peritoneum. The needle should never be forced. Regardless of technique, the underlying retroperitoneal vessels are protected ultimately by limiting the insertion depth of the insufflation needle.

**In instances where known or suspected intra-abdominal adhesions surround the umbilicus, alternative sites should be used for insufflation needle insertion.** These sites include the left upper quadrant, most often at the left costal margin, the pouch of Douglas, and the fundus of the uterus (Fig. 23.6). The left upper quadrant is preferred if hepatosplenomegaly is not present and the patient has not previously had surgery in this area. In such patients, the stomach must be decompressed with a nasogastric or orogastric tube before the needle is inserted (84). While at this location the distance between the skin and the posterior peritoneum is generally more than 11...
cm, in thin individuals, it may be as little as 7 cm, so the angle of insertion should take this into account. The needle should be directed medially, about 10 to 15 degrees to avoid the kidney and renal artery; in women of relatively high body mass index it can be placed at a 90-degree angle to the skin, and in thin women, this angle should be reduced to about 45 degrees (84,85).

**Figure 23.6 Insufflation needle and cannula insertion sites.** In most instances, both the insufflation needle, if used, and the primary cannula are inserted through the umbilicus. When subumbilical adhesions are known or suspected, the insufflation needle may be placed through the pouch of Douglas or in the left upper quadrant after evacuation of the gastric contents with an orogastric tube.

Before insufflation, the operator should try to detect whether the insufflation needle was malpositioned in the omentum, mesentery, blood vessels, or hollow organs such as the stomach or bowel. The most direct approach is to use a specially designed insufflation needle that has an integrated cannula through which a small diameter (2 mm) laparoscope can be passed to visualize the point of entry. Otherwise, indirect methods are necessary. Using a syringe attached to the insufflation needle, blood or gastrointestinal contents may be aspirated. To facilitate this examination, a small amount of saline may be injected into the syringe. If the needle is appropriately positioned, negative intra-abdominal pressure is created by lifting the abdominal wall. This negative pressure may be demonstrated by aspiration of a drop of saline placed over the open, proximal end of the needle or, preferably, by using the digital pressure gauge on the insufflator.

Additional signs of proper placement may be sought after starting insufflation.
The intra-abdominal pressure reading should be low, reflecting only systemic resistance to the flow of CO$_2$. Consequently, there should be little deviation from a baseline measurement, generally less than 10 mm Hg. The pressure varies with respiration and is slightly higher in obese patients. The earliest reassuring sign is the loss of liver “dullness” over the lateral aspect of the right costal margin. This sign may be absent if there are dense adhesions in the area, usually the result of previous surgery. Symmetric distention is unlikely to occur when the needle is positioned extraperitoneally. Proper positioning can be shown by lightly compressing the xiphoid process, which increases the pressure measured by the insufflator.

The amount of gas transmitted into the peritoneal cavity should depend on the measured intraperitoneal pressure, not the volume of gas inflated. Intraperitoneal volume capacity varies significantly between individuals. Many surgeons prefer to insufflate to 25 to 30 mm Hg for positioning the cannulas, and a body of evidence exists supporting this approach (86). This level usually provides extra volume and enough counter pressure against the peritoneum, facilitating introduction of the cannula and potentially reducing the chance of bowel or posterior abdominal wall and vessel trauma. After placement of the cannulas, the pressure should be dropped to 10 to 15 mm Hg, which reduces the risk of subcutaneous insufflation leading to crepitis and essentially eliminates hypercarbia or decreased venous return of blood to the heart (84,86,87).

Primary Access Cannulas

Laparoscopic cannulas (or ports) allow the insertion of laparoscopic instruments into the peritoneal cavity while maintaining the pressure created by the distending gas (Figs. 23.7 and 23.8). Cannulas are hollow tubes with a valve or sealing mechanism at or near the proximal end. The cannula may be fitted with a Luer-type port that allows attachment to tubing connected with the CO$_2$ insufflator. Larger-diameter cannulas (8 to 15 mm) may be fitted with adapters or specialized valves that allow the insertion of smaller-diameter instruments without loss of intraperitoneal pressure.

Figure 23.7 Disposable access systems. These instruments are designed for single use. A 12-mm internal diameter blunt access system is shown in (A). The next device (B) has a 12 mm internal diameter, but has a deployable blade that is used to cut through the abdominal wall. A smaller diameter blunt conical device is shown in (C) while a sharp conical access system is presented in (D). Both (C) and (D) have a 5-mm inside diameter. A narrow, 2.7-mm diameter cannula is shown in (E). The trocar for this system is a long insufflation needle with a spring deployable obturator.
Figure 23.8 Reusable access systems. A: A sharp conical device, while (B) represents a pyramidal-tipped design. C and D (and inset): Images of the so-called EndoTip device that can be positioned in the abdominal wall by simply twisting or screwing it in without the requirement of a trocar.
The obturator is a longer instrument of slightly smaller diameter that is passed through the cannula, exposing its tip. Most obturators are called trocars because their tip is designed to penetrate the abdominal wall after the creation of an appropriately sized skin incision. Many disposable trocar-cannula systems are designed with a safety mechanism—usually a pressure-sensitive spring that either retracts the trocar or deploys a protective sheath around its tip after passage through the abdominal wall. None of these protective devices makes insertion safer, and they all increase the cost of the equipment.

In the “closed” laparoscopic access technique, cannulas can be inserted either after the successful creation of a pneumoperitoneum or without previously instilling intraperitoneal gas, also referred to as direct insertion. With open laparoscopy, there is less risk of injury to the major blood vessels such as the aorta, inferior vena cava, and common iliacs. Open laparoscopy cannot prevent all insertion accidents because intestine can be entered inadvertently no matter how small the incision. There is little evidence that a pneumoperitoneum is necessary, at least in the absence of preexisting abdominal wall adhesions. In women with no previous surgery, the primary puncture can be performed with a trocar-cannula system, which reduces operating time. The first, or primary, cannula must be of sufficient caliber to permit passage of the laparoscope and usually is inserted in or at the lower border of the umbilicus. The incision should be extended only enough to allow insertion of the cannula; otherwise, leakage of gas may occur around the sheath. The patient should be in an unaltered supine position during placement of the primary cannula. For the primary puncture, either the surgeon or the assistant should elevate the abdominal wall as described previously. Both hands can be positioned on the device, using one to provide counter pressure and control to prevent “overshoot” and
resultant injury to bowel or vessels. The angle of insertion is the same as for the insufflation needle; adjustments are made according to the patient’s weight and body habitus (79). The laparoscope should be inserted to confirm proper intraperitoneal placement before the insufflation gas is allowed to flow. Previous abdominal surgery increases the incidence of adhesions of the bowel to the anterior abdominal wall, frequently near the umbilicus and in the path of the primary trocar-cannula system (88,89). In such patients, another primary insertion site, such as the left upper quadrant, should be selected, even if it is used solely for conveying a narrow “scout” laparoscope, some types of which can be inserted through a trocar cannula system with a design similar to that of an insufflation needle (Fig. 23.9). Using such a laparoscope, the presence of adhesions under the incision can be identified and the umbilical cannula can be inserted under direct vision. If adhesions are noted under the incision, appropriate placement of secondary cannulas may be used to introduce instruments for adhesiolysis. Alternate insertion sites for primary cannulas are shown in Figure 23.6.

Figure 23.9 “Scout” laparoscope. The 2-mm laparoscope from Figure 23.8 and the 2.7-mm access system from Figure 23.7 are shown here assembled. The tubing is connected to inflow gas, usually carbon dioxide.

Ancillary Cannulas

Ancillary cannulas are necessary to perform most diagnostic and operative laparoscopic procedures. Most currently available disposable ancillary cannulas are identical to those designed for insertion of the primary cannula; however, simple cannulas without the so-called safety mechanisms and insufflation ports are generally sufficient (Figs. 23.7D and 23.8D). Some investigators are evaluating the value of systems that allow the insertion of multiple cannulas through a single port, an approach that has the potential to improve surgical cosmesis by reducing the number of incisions created (90–92).

Proper positioning of these ancillary cannulas depends on a sound knowledge of the abdominal wall vascular anatomy. For the secondary puncture, the patient may be tipped head down (Trendelenburg), allowing the abdominal contents to shift from beneath the incision sites, and thus making it unnecessary to lift the abdominal wall during secondary cannula insertion. Alternatively, the intraperitoneal pressure may be maintained at 25 to 30 mm Hg to allow insertion of the secondary cannulas prior to placing the patient in the Trendelenburg position.

Ancillary cannulas should always be inserted under direct vision because injury to bowel or major vessels can occur. Before insertion, the bladder should be drained with a
urethral catheter. The insertion sites depend on the procedure, the disease, the patient’s body habitus, and the surgeon’s preference. For diagnostic laparoscopy, the most useful and cosmetically acceptable site for insertion of an ancillary cannula is in the midline of the lower abdomen, about 2 to 4 cm above the symphysis. The ancillary cannula should not be inserted too close to the symphysis because it limits the mobility of the ancillary instruments and access to the cul-de-sac. Laparoscopic cannulas can become dislodged and slip out of the incision during a procedure. There are a variety of cannula designs designed to reduce slippage, which include those with threaded exteriors and anchoring systems with balloon tips.

Lateral placement of lower-quadrant cannulas is useful for operative laparoscopy, but the superficial and inferior epigastric vessels must be located to avoid injury (Fig. 23.3). Transillumination of the abdominal wall from within permits the identification of the superficial inferior epigastric vessels in most thin women. The deep inferior epigastric vessels cannot be identified by this mechanism because of their location deep to the rectus sheath. **The most consistent landmarks are the medial umbilical ligaments (obliterated umbilical arteries) and the exit point of the round ligament into the inguinal canal.** At the pubic crest, the deep inferior epigastric vessels can often be visualized between the medially located umbilical ligament and the laterally positioned exit point of the round ligament. The cannula should be inserted medial or lateral to the vessels if they are visualized. **If the vessels cannot be seen and it is necessary to position the cannula laterally, the device should be placed 3 to 4 cm lateral to the medial umbilical ligament or lateral to the lateral margin of the rectus abdominis muscle.** If the incision is placed too far laterally, it will endanger the deep circumflex epigastric artery. The risk of injury can be minimized by placing a 22-gauge spinal needle through the skin at the desired location, in order to directly observe the entry through the laparoscope. This provides reassurance that a safe location is identified and allows visualization of the peritoneal needle hole, which provides a precise target for inserting the cannula.

Even after a properly positioned incision, the abdominal wall vessels can be injured if a trocar slides medially during placement. Large-diameter devices are more likely to cause injury; therefore, the smallest cannulas necessary to perform the procedure should be used. Ancillary cannulas should not be placed too close together because this results in hindrance of the hand instruments, which compromises access and maneuverability.

The incision made must be of adequate length to allow easy insertion of the device through the skin—a 1-cm long incision is inadequate to allow passage of a 1-cm diameter device. It is important to know that the outside diameter of a cannula is larger than the inside diameter, to allow for the thickness of the material used to create the port. In some instances, this can add two or more millimeters to the device diameter, and, therefore, increase the length of the required incision.

**Endoscopy**

During endoscopy, the image must be transferred through an optical system. Although
direct optical viewing is feasible and often used for diagnostic purposes, virtually all operative laparoscopy is performed using video guidance.

Laparoscopes are more than simple telescopes; they serve a dual purpose—transmission of light into a dark and closed cavity and provision of an image of the operative field. The light is generally transmitted from a cold light source via a fiberoptic cable to an attachment on the endoscope that passes the light to the distal end of the telescope via a peripherally arranged array of fiberoptic bundles. The image is obtained by a distally positioned lens and transmitted to the eyepiece via a series of rod shaped lenses. The eyepiece can be used to view the peritoneal contents directly or can serve as a point of attachment for a digital video camera. Some endoscopes transmit the image through a collection of densely packed fiberoptic bundles—an approach that diminishes resolution, but allows flexibility of the endoscope, and that is of great value for small-caliber telescopes or when the device is designed to be steerable with an articulated distal end. Another option is to position a digital chip on the end of the system, which then functions as a camera, obviating the need to have any lenses or fibers to transmit the image, a design that is colloquially called chip-on-a-stick.

A laparoscope with an integrated straight channel, parallel to the optical axis, is called an operating laparoscope because the channel allows for the introduction of operating instruments. This offers an additional port for the insertion of instruments and the application of laser energy. Operative endoscopes are of relatively larger caliber than standard laparoscopes, may have smaller fields of view and may present increased risks associated with the use of monopolar electrosurgical instruments. Standard, viewing only laparoscopes permit better visualization at a given diameter.

In general, the wider the diameter of the laparoscope, the brighter the image, resulting from either more light or wider lenses, which improve the viewing experience for the surgeon. Narrow-diameter laparoscopes generally allow reduced transfer of light both into and out of the peritoneal cavity; therefore, they require a more sensitive camera or a more powerful light source for adequate illumination. In the past, ideal illumination was provided by 10-mm diagnostic laparoscopes, but improvements in optics allowed the 5-mm diameter laparoscope to become the standard in many operating rooms (Fig. 23.10).

Figure 23.10 Laparoscopes. Three 0-degree laparoscopes are shown. From top to bottom, 2-mm, 5-mm and 10-mm diameter.
The viewing angle depicts the relationship of the visual field to the axis of the endoscope and typically ranges from 0 to 45 degrees to the horizontal. The 0-degree scope is the standard for gynecologic surgery. The 30-degree angle scope is invaluable in difficult situations, such as the performance of laparoscopic sacrocolpopexy, some myomectomies, and hysterectomy in the presence of large myomas.

**Imaging Visualization Systems**

The video camera is usually attached to the eyepiece of the endoscope where it captures the image and transmits it to the body of the camera located outside the operative field, where it is processed and sent to a monitor and, if desired, a recording device (Fig. 23.11). Laparoscopes without an optical path were introduced, with the sensor located on the distal tip of the endoscope, a design that requires a remote camera location. The resolution capability of the monitor should be at least equal to that provided by the camera. Most monitors have the potential to display about 800 horizontal lines of resolution while high definition (HD) systems generally possess 1,080 lines. The more light transmitted through the endoscope, the better the visualization. The best available output is achieved from 250 to 300 watts, usually using xenon or metal halide bulbs. Most camera systems are integrated with the light source to vary light output automatically, depending on the amount of exposure required. Light guides or cables transmit light from the source to the endoscope via a bundle of densely packed optical fibers (fiberoptic). Fiberoptic cables lose function over time, and the fibers can break if they are mishandled.

*Figure 23.11* Laparoscopic tower. This tower comprises a monitor (A), a camera body or base unit (B) attached to a camera sensor; a light source (C) attached to a cable, which in turn will be connected with the endoscope; a still-image printer (D), and an insufflation machine (E). A video recorder is shown in (F).
Creation of a Working Space

The peritoneal cavity is only a potential space, so it is necessary to fill it with a gas, typically CO$_2$, to create a working environment. Other approaches are being explored that use mechanical lifting systems that allow room air into the peritoneal cavity.

Carbon dioxide is injected into the peritoneal cavity under pressure by a machine called an insufflator. The insufflator delivers the CO$_2$ from a gas cylinder to the patient through tubing connected to a Luer adaptor on one of the laparoscopic cannulas. Most insufflators can be set to maintain a predetermined intra-abdominal pressure. High flow rates (9 to
20 L per minute) are especially useful for maintaining exposure when suction of smoke or fluid depletes the volume of intraperitoneal gas.

Intraperitoneal retractors attached to a pneumatic or mechanical lifting system can be used to create an intraperitoneal space much like a tent (93). This gasless or isobaric technique may have some advantages over pneumoperitoneum, particularly in patients with cardiopulmonary disease. Airtight cannulas are not necessary, and instruments do not need to have a uniform, narrow, cylindrical shape. Consequently, some conventional instruments may be used directly through the incisions.

**Manipulation of Tissue and Fluid**

**Fluid Management**

Fluid may be disseminated into the peritoneal cavity through wide-caliber arthroscopy or cystoscopy tubing using gravity pressure and an infusion cuff or a high-pressure mechanical pump. The pumps deliver fluid faster than the other techniques, and the highly pressurized stream of fluid may facilitate blunt dissection (hydro- or aqua dissection). Small volumes of fluid can be removed with a syringe attached to a cannula; for large volumes, it is necessary to use suction generated by a machine or a wall source.

The type of cannulas used for suction and irrigation depends on the irrigation fluid used and the fluid being removed. For ruptured ectopic gestations or other procedures in which there is a large amount of blood and clots, large-diameter cannulas (7 to 10 mm) are preferred. Cannulas with narrow tips are more effective in generating the high pressure needed for hydrodissection.

If large volumes of fluid are required, isotonic fluids should be used to avoid fluid overload and electrolyte imbalance. If electrosurgery is to be performed, small volumes of a nonelectrolyte-containing solution such as glycine or sorbitol can be used for hemostasis and irrigation. Heparin (1,000 to 5,000 U/L) can be added to irrigating solution to prevent blood from clotting and facilitate fluid removal.

**Uterine Manipulators**

Uterine manipulation is an important component of the strategy to maximize visualization for most pelvic procedures, especially for myomectomy and hysterectomy. A properly designed uterine manipulator should have an intrauterine component, or obturator, and a method for attaching the device to the uterus. Articulation of the instrument permits acute anteversion or retroversion, both of which are extremely useful procedural maneuvers. If the uterus is large, longer and wider obturators can be used for more effective control. Two types of uterine manipulators are shown in Figure 23.12. A hollow channel attached to a port allows intraoperative instillation of liquid dye to aid in the identification of the endometrial cavity (during myomectomy) or to demonstrate tubal patency.
Figure 23.12 Uterine manipulators. Top: The disposable “V-Care” device. At the tip is a balloon inflated to maintain the device in the endometrial cavity. Next to the tip is a cervical collar that serves to facilitate identification of the vaginal fornices and cutting of the vagina in laparoscopic total hysterectomy. The blue truncated cone maintains a seal so that gas will not leak out when culdotomy is performed. Bottom: The reusable Pelosi manipulator. The ring handle allows the surgeon to antevert the uterus.

Grasping Forceps

The forceps used during laparoscopy should, to the extent possible, replicate those used in open surgery. Disposable instruments generally do not have the quality, strength, or precision of nondisposable forceps (Fig. 23.13). Instruments with teeth (toothed forceps) are necessary to securely grasp the peritoneum or the edge of an ovary for the removal of an ovarian cyst. Instruments designed to be minimally traumatic, like Babcock clamps, are needed to retract the fallopian tube safely. Tenaculum-like instruments are desirable to retract leiomyomas or the uterus. A ratchet is useful for holding tissue without arduous hand pressure. Graspers should be insulated if unipolar radiofrequency instruments are being used to attain hemostasis.

Figure 23.13 Laparoscopic instruments for grasping and manipulating tissue. A: (top and inset) are 5-mm diameter graspers with a curved tip, often called “Maryland” graspers. Other reusable tips (B) and (C) may be positioned in the same handle as is shown for (A). D: A 10-mm claw grasper, while (E) and (F) are 5- and 2-mm manipulating probes respectively. G: A 2-mm grasping forceps.
Cutting, Hemostasis, and Tissue Fixation

Cutting can be achieved by mechanical means or by using laser, radiofrequency electrical, or ultrasonic energy. The methods for maintaining or securing hemostasis include sutures, clips, linear staplers, energy sources, and topical or injectable substances. Secure apposition or tissue fixation may be accomplished with sutures, clips, or staples. With appropriate training, a skilled surgeon can obtain good results with any combination of these techniques for cutting, hemostasis, and tissue fixation. Studies in animals have not demonstrated any difference in injury characteristics when cutting is performed with either laser or radiofrequency energy and randomized controlled studies have shown no differences in fertility outcomes (59–61,94). Therefore, differences in results are likely to be caused by other factors, such as patient selection, extent of disease, and degree of surgical expertise.

Cutting

The most useful cutting instruments are scissors (Fig. 23.14, bottom). Because it is difficult to sharpen laparoscopic scissors, most surgeons prefer disposable instruments that can be used until dull and then discarded. Another mechanical cutting tool is the linear stapler–cutter that can simultaneously cut and hemostatically staple the edges of the incision. The cost and large dimensions of the instruments limit their practical use to only a few highly selected situations, such as separation of the uterus from the ovary and fallopian tube during laparoscopic hysterectomy. Devices that coagulate tissue and mechanically transect it are designed to be narrow enough to be practical and effective enough to become the dominant devices for laparoscopic cutting, when concomitant sealing of vessels is a requirement.

Figure 23.14 Radiofrequency electrosurgical generator. Displayed is the Force FX generator with unipolar laparoscopic electrodes. The device is capable of outputting high-voltage (“coagulation”) and low-voltage (“cut”) waveforms for unipolar instruments and a low-voltage bipolar circuit for bipolar instruments.
Laser and electrical sources of energy manifest their effect by conversion of electromagnetic energy (Fig. 23.14) to mechanical energy, which is then transformed into thermal energy. Highly focused radiofrequency electrical current (high-power or current density), generated by a specially designed electrosurgical generator produces vaporization or cutting by raising the intracellular temperature above 100°C, which rapidly converts water to steam with a massive increase in intracellular volume. This expansion ruptures the already damaged cell membrane, resulting in cellular and tissue vaporization into a cloud of steam, ions, and protein particles. If the instrument used to focus this energy is moved in a linear fashion, tissue transection or cutting will result. Less focused radiofrequency energy (moderate current density) elevates intracellular temperature, causing desiccation, rupture of hydrogen bonds, and tissue coagulation, but vaporization does not occur.

Monopolar electrosurgical instruments that are narrow or pointed are capable of generating the high-power densities necessary to vaporize or cut tissue. Continuous or modulated and relatively low voltage outputs tend to be the most effective. For optimal results, the instrument should be used in a noncontact fashion, following (not leading) the energy through the tissue. Specially designed bipolar cutting probes that contain both the active and dispersive electrode are available. The active electrode is shaped as a needle, or even a blade, while the other larger-surface-area electrodes are designed to be dispersive (Fig. 23.15, top). Laparoscopic scissors are generally of unipolar design and are intended to cut mechanically; energy may be applied simultaneously for desiccation and hemostasis when cutting tissue that contains small blood vessels (Fig. 23.15, bottom).

Figure 23.15 Laparoscopic cutting devices. Top and inset left is a bipolar electrosurgical spatula. Middle
and center inset is a harmonic scalpel. This device oscillates at 55,000 Hz to cut tissue. Bottom and inset right are laparoscopic scissors. They may be connected to an electrosurgical generator to act as a unipolar electrode.

Laser energy can be focused to vaporize and cut tissue. The most efficient laser-based cutting instrument is the CO₂ laser, which has the drawback of requiring linear transmission because light cannot be conducted effectively along bendable fibers. The potassium-titanyl-phosphate (KTP) and neodymium:yttrium, aluminum, garnet (Nd:YAG) lasers are effective cutting tools. They are capable of propagating energy along bendable quartz fibers but have a slightly greater degree of collateral thermal injury than radiofrequency electrical or CO₂ laser energy. These limitations and their additional expense constrict the value of these lasers.

Ultrasonic cutting is accomplished mechanically using a blade that oscillates back and forth in a linear fashion (Fig. 23.15, center). The oscillation is achieved using an element located in a handle that vibrates the blade, hook, or one arm of the clamp 55,000 times per second (55 kHz). The distance of the oscillation can be varied and determines the efficiency of the cutting process. The tip of the device cuts mechanically, but there is a degree of collateral thermal tissue coagulation injury that can be used for hemostasis. In low-density tissue, the process of mechanical cutting is augmented by the process of cavitation, in which reduction of local atmospheric pressure allows vaporization of intracellular water at body temperature.

**Hemostasis**

Because of the visual, tactile, and mechanical limitations of laparoscopy, prevention of bleeding is important for efficient, effective, and safe procedures. Radiofrequency electricity is the least expensive and most versatile method for achieving hemostasis during laparoscopy and can be applied with either monopolar or bipolar instruments. Regardless of the type of system, the process of electrical desiccation and coagulation is best achieved by contacting the tissue with the activated electrode using continuous low-voltage or
“cutting” current. With adequate power, typically 20 to 30 watts (depending, in part, on the surface area of the electrodes), tissue will be heated, desiccated, and coagulated. Blood vessels should be compressed with the blades of the forceps before the electrode is activated so that the “heat sink” effect of flowing blood is eliminated. This allows the opposing walls of the vessel to bond, forming a strong tissue seal in a process called coaptive coagulation. Bipolar devices can be fitted with a serial ammeter that measures the current flowing through the system. When the tissue between the blades of the forceps is completely desiccated, the device is no longer able to conduct electricity, which can trigger a visual or auditory cue for the surgeon. Alternatively, the generator can be designed to stop automatically when current is no longer being conducted by the tissue between the blades of the forceps. The surgeon can reduce lateral thermal spread of radiofrequency energy by manually pulsing delivery or by simultaneously running irrigation fluid over the pedicle. Automated generators that pulse energy automatically are available, and such bipolar systems can include mechanical blades to cut tissues following coagulation of the tissue (Fig. 23.16).

Figure 23.16 Displayed are two devices that cut and coagulate or seal tissue. Top (A–C) are the ligating cutting shears (LCS) that are based on the same technology as the harmonic scalpel displayed in Figure 23.13. The bottom blade oscillates (C), while the top blade is opened to grasp the tissue and used by the surgeon to slowly transect and seal the blood vessels in the tissue being transected. The PlasmaKinetic (D–F) is a bipolar radiofrequency device that, using electrical impedance, tells the surgeon when the tissue is coagulated. Then the orange trigger (top) is pushed deploying the blade (F), thereby cutting the coagulated tissue.

Control of superficial bleeding can be achieved with fulguration, the near-contact spraying of tissue with unipolar, modulated, high-voltage radiofrequency waveforms from the “coagulation” side of the electrosurgical generator. Care must be taken to safely perform laparoscopic fulguration, ensuring that the entire shaft of the laparoscopic instrument is well away from the bowel.

Ultrasonic instruments can be used for hemostasis as well. Those with a forceps-like end effector disperse the mechanical energy in a way that allows the tissue to be heated and
coagulated. These so-called ligating-cutting shears cut when high pressure is exerted in the handle by the surgeon (Fig. 23.16A–C).

**Hemostatic clips may be applied with specially designed laparoscopic instruments.** Nonabsorbable clips made of titanium are useful for relatively narrow vessels, and longer, delayed absorbable, self-retaining clips are generally preferred for larger vessels, 3 or 4 mm or more. Clips may be of particular value when securing relatively large vessels near an important structure such as the ureter.

Laparoscopic suturing is a method for maintaining hemostasis (95–97). Compared with clips or linear staplers, suturing has a relatively low materials cost, although operating time may be longer and more expensive. The **two basic methods for securing a ligature around a blood vessel depend on where the knot is tied; ligatures are intracorporeal and extracorporeal. Intracorporeal knots replicate the standard instrument-tied knot and are formed within the peritoneal cavity. Extracorporeal knots are created outside the abdomen under direct vision and then transferred into the peritoneal cavity by knot manipulators** (Fig. 23.17). Pretied knotted suture loops attached to long introducers, called Endoloops®, may be used to secure vascular pedicles. Care should be taken to make sure that they are tightly secured and that no other tissue is incorporated in the loop. A number of devices that facilitate the formation and tying of knots are either available or in development.

**Figure 23.17 Laparoscopic suturing instruments.** The 3-mm and 5-mm diameter laparoscopic needle drivers are displayed in (A) and (C), while a knot manipulator is shown in (B) and inset left. The device is shown transferring a knot into the peritoneal cavity (inset right).

Small areas of low volume bleeding can be treated with topical hemostatic agents. **Topical agents such as microfibrillar collagen are available in 5-mm and 10-mm diameter laparoscopic applicators** (Fig. 23.13). Fibrin sealants (e.g., Tisseel®) and bovine thrombin and gelatin (Floseal®) can also be used. A solution of dilute vasopressin may be injected locally to maintain hemostasis for myomectomy or
Tissue Extraction

After excising tissue, it is usually necessary to remove it from the peritoneal cavity. Small samples can be pulled through an appropriate-sized cannula with grasping forceps; however, larger specimens may not fit. If the specimen is cystic, it may be drained by a needle or incised, shrinking it to a size suitable for removal through the cannula or one of the small laparoscopic incisions. If there is concern for malignancy, an alternative is to place the specimen in an endoscopic retrieval bag before drainage to prevent spillage (Fig. 23.18). More solid tissue may be morcellated with scissors, ultrasonic equipment, electrosurgery or electromechanical morcellators. If monopolar radiofrequency instruments are used for electrosurgical morcellation, the specimen must remain attached to the patient to preserve the integrity of the electrical circuit. Alternatively, special bipolar needles are available that do not require a dispersive electrode.

Figure 23.18 Specimen removal bag. This 10-mm diameter bag is positioned in the peritoneal cavity. Then the bag is deployed (insets), allowing the surgeon to place specimens for removal.
the cul-de-sac (posterior culdotomy) or by extending one of the laparoscopy incisions. With the exception of culdotomy (colpotomy), extension of the umbilical incision may be the most cosmetic approach because incisions up to 3 cm in length can be concealed successfully. When the umbilical location is selected, removal of the tissue can be directed from an endoscope positioned in one of the ancillary ports. Electronic morcellators are available to remove large tissue specimens by reducing them to smaller sections (Fig. 23.19). These are especially useful for laparoscopic myomectomy and laparoscopic supracervical hysterectomy.

Figure 23.19 Electromechanical morcellator. This device is positioned in the peritoneal cavity and attached to the power generator (inset). The blunt obturator is removed; a grasping instrument inserted through the lumen is used to withdraw the tissue, which is cut by a cylindrical blade. The motor is activated by a foot pedal.

Incision Management

Dehiscence and hernia risk appear to significantly increase when the fascial incision is larger than 10 mm in diameter (98,99). Closure of the fascia should take place under direct laparoscopic vision to prevent the accidental incorporation of bowel into the incisions, and the peritoneum should be included to reduce the risk of Richter’s hernia. A small-caliber laparoscope passed through one of the narrow cannulas can be used to direct the fascial closure using curved needles or a ligature carrier especially designed for this purpose.
Complications

After laparoscopic surgery patients usually experience a rapid recovery. Pain diminishes, gastrointestinal function improves quickly, and fever is extremely unusual. Therefore, if a patient’s condition is not improving, possible complications of anesthesia or surgery should be considered. Laparoscopic procedures can be complicated by infections, trauma, or hemorrhage, and by problems associated with anesthetic use. The incidence of infection is lower than with procedures performed by laparotomy. Problems associated with visualization in conjunction with the change in anatomic perspective may increase the risk of damage to blood vessels or vital structures such as the bowel, ureter, or bladder.

Anesthetic and Cardiopulmonary Complications

A review of laparoscopic tubal sterilization in 9,475 women found no deaths from complications of anesthesia (100,101). The potential risks of general anesthesia include hypoventilation, esophageal intubation, gastroesophageal reflux, bronchospasm, hypotension, narcotic overdose, cardiac arrhythmias, and cardiac arrest. These risks can be exacerbated by some of the inherent features of gynecologic laparoscopy. For example, the Trendelenburg position, in combination with the increased intraperitoneal pressure provided by pneumoperitoneum, places greater compression on the diaphragm, increasing the risk of hypoventilation, hypercarbia, and metabolic acidosis. This position, combined with anesthetic agents that relax the esophageal sphincter, promotes regurgitation of gastric content, which in turn can lead to aspiration, bronchospasm, pneumonitis, and pneumonia. Parameters of cardiopulmonary function associated with both CO\textsubscript{2} and N\textsubscript{2}O insufflation include reduced PO\textsubscript{2}, O\textsubscript{2} saturation, tidal volume, and minute ventilation and increased respiratory rate. The use of intraperitoneal CO\textsubscript{2} as a distention medium is associated with an increase in PCO\textsubscript{2} and a decrease in pH. Elevation of the diaphragm may be associated with basilar atelectasis, resulting in right-to-left shunt and ventilation–perfusion mismatch (102).

Carbon Dioxide Embolus

Carbon dioxide is the most widely used peritoneal distention medium, largely because the rapid absorption of CO\textsubscript{2} in blood reduces the significance of gas emboli. If large amounts of CO\textsubscript{2} gain access to the central venous circulation, if peripheral vasoconstriction occurs, or if the splanchnic blood flow is decreased by excessively high intraperitoneal pressure, severe cardiorespiratory compromise may result.

The signs of CO\textsubscript{2} embolus include sudden and otherwise unexplained hypotension, cardiac arrhythmia, cyanosis, and heart murmurs. The end-tidal CO\textsubscript{2} level may increase, and findings consistent with pulmonary edema may manifest (103). Accelerating pulmonary hypertension may occur, resulting in right-sided heart failure.
Because gas embolism may result from direct intravascular injection through an insufflation needle, the proper placement of the insufflation needle must be ensured. Although the initial intraperitoneal pressure may be set at 20 to 30 mm Hg for port placement, it should be maintained at 8 to 12 mm for the rest of the case (104). The risk of CO₂ embolus is reduced by careful hemostasis because open venous channels are the portal of entry for gas into the systemic circulation. The anesthesiologist should continuously monitor the patient’s color, blood pressure, heart sounds, heartbeat, and end-tidal CO₂ to allow early recognition of the signs of CO₂ embolus.

If CO₂ embolus is suspected or diagnosed, the surgeon must evacuate the CO₂ from the peritoneal cavity and place the patient in the left lateral decubitus position, with the head below the level of the right atrium. A large-bore central venous line should be inserted immediately to allow aspiration of gas from the heart. Because the findings are nonspecific, the patient should be evaluated for other causes of cardiovascular collapse.

**Cardiovascular Complications**

Cardiac arrhythmias occur relatively frequently during laparoscopic surgery and are related to a number of factors, the most significant of which are hypercarbia and acidemia. Early reports of laparoscopy-associated arrhythmia were associated with spontaneous respiration; therefore, most anesthesiologists adopted the practice of mechanical ventilation during laparoscopic surgery. The incidence of hypercarbia is reduced by operating with intraperitoneal pressures at levels less than 12 mm Hg (105).

The risk of cardiac arrhythmia may be reduced by using NO₂ as a distending medium (see the preceding discussion in “Peritoneal Access”). Although NO₂ is associated with a decreased incidence of arrhythmia, it is insoluble in blood and, therefore, its use may increase the risk of gas embolus. External lifting systems avoid the complication of hypercarbia and can provide protection against cardiac arrhythmia (106).

Hypotension can occur because of decreased venous return secondary to very high intraperitoneal pressure, and this condition may be potentiated by volume depletion. Vagal discharge may occur in response to increased intraperitoneal pressure, which can cause hypotension secondary to cardiac arrhythmias (106). These side effects should be considered when performing surgery on patients with preexisting cardiovascular disease.

**Gastric Reflux**

Gastric regurgitation and aspiration can occur during laparoscopic surgery, especially in patients with obesity, gastroparesis, hiatal hernia, or gastric outlet obstruction. In these patients, the airway must be maintained with a cuffed endotracheal tube, and the stomach must be decompressed (e.g., with a
nasogastric tube). The lowest necessary intraperitoneal pressure should be used to minimize the risk of aspiration. Patients should be moved out of the Trendelenburg position before being extubated. Routine preoperative administration of metoclopramide, H2-blocking agents, and nonparticulate antacids reduces the risk of aspiration.

Extraperitoneal Insufflation

The most common causes of extraperitoneal insufflation are preperitoneal placement of the insufflating needle and leakage of CO\textsubscript{2} around the cannula sites. Although this condition is usually mild and limited to the abdominal wall, subcutaneous emphysema can become extensive, involving the extremities, the neck, and the mediastinum. Another relatively common site for emphysema is the omentum or mesentery, a circumstance that may be mistaken for preperitoneal insufflation.

Subcutaneous emphysema may be identified by the palpation of crepitus, usually in the abdominal wall. Emphysema can extend along contiguous fascial plains to the neck, where it can be visualized directly. This finding may reflect mediastinal emphysema, which may indicate impending cardiovascular collapse (107–110).

The risk of subcutaneous emphysema is reduced by the proper positioning of the insufflation needle and by maintaining a low intraperitoneal pressure after placement of the desired cannulas. Other approaches that reduce the chance of subcutaneous emphysema include open laparoscopy and the use of abdominal wall lifting systems that make gas unnecessary.

If the insufflation occurred extraperitoneally, the laparoscope can be removed and the procedure can be repeated. Difficulty may ensue because of the altered anterior peritoneum. Open laparoscopy or the use of an alternate site, such as the left upper quadrant, should be considered. One approach is to leave the laparoscope in the expanded preperitoneal space while the insufflation needle is reinserted under direct vision through the peritoneal membrane caudad to the tip of the laparoscope (111).

In mild cases of subcutaneous emphysema, the findings quickly resolve after evacuation of the pneumoperitoneum, and no specific intraoperative or postoperative therapy is required. When the extravasation extends to the neck, it is usually preferable to terminate the procedure because pneumomediastinum, pneumothorax, hypercarbia, and cardiovascular collapse may result. Following termination of the procedure, it is prudent to obtain a chest x-ray. The patient’s condition should be managed expectantly unless a tension pneumothorax results, in which case immediate evacuation must be performed using a chest tube or a wide-bore needle (14 to 16 gauge) inserted in the second intercostal space in the midclavicular line.

Electrosurgical Complications

Complications of electrosurgery occur secondary to thermal injury from unintended or inappropriate use of the active electrode, current diversion to
an undesirable path, or injury at the site of the dispersive electrode. Such complications may occur with the use of these instruments during laparoscopic, abdominal, or vaginal surgery. Active electrode injury can occur with either unipolar or bipolar instruments, whereas trauma secondary to current diversion and dispersive electrode accidents occur only with unipolar devices. Complications of electrosurgery are reduced by adherence to safety protocols coupled with a sound understanding of the principles of electrosurgery and the circumstances that can lead to injury (112).

Active Electrode Trauma

If the foot pedal is accidentally depressed, tissue adjacent to the electrode will be traumatized. Potential sites of injury include the bowel, ureter, and other intraperitoneal structures, or, if the electrode lies on the abdomen, the skin. Injury from direct extension of thermal effect can occur when the zone of vaporization or coagulation extends to large blood vessels or vital structures such as the bladder, ureter, or bowel. Bipolar instruments may reduce but do not eliminate the risk of thermal injury to adjacent tissue (113). Blood vessels should be isolated before electrosurgical coagulation, especially when they are near vital structures, and appropriate amounts of energy must be applied to allow an adequate margin of noncoagulated tissue.

The diagnosis of direct thermal visceral injury may be difficult. If unintended activation of the electrode occurs, nearby intraperitoneal structures should be evaluated carefully. The appearance can be affected by several factors, including the output of the generator, the type of electrode, its proximity to tissue, and the duration of activation. The diagnosis of visceral thermal injury is often delayed until signs and symptoms of fistula or peritonitis appear. Because these complications may not manifest until 2 to 10 days after surgery, patients should be advised to report any postoperative fever or increasing abdominal pain.

Thermal injury to the bowel, bladder, or ureter that is recognized at the time of laparoscopy should be managed immediately, taking into consideration the potential extent of the zone of coagulative necrosis (114). Incisions made with the focused energy from a pointed electrode are associated with a minimal amount of surrounding thermal injury. Prolonged or even transient contact with a relatively large-caliber electrode may produce a zone of thermal necrosis that may be much larger than visually apparent. In such cases, wide excision or resection of up to several centimeters of bowel may be necessary. The choice of route of access for any required surgical repairs depends in part on the nature of the injury and on the skills and training of the surgeon.

The incidence of unintended activation injuries can be reduced if the surgeon is always in direct control of electrode activation and if all electrosurgical hand instruments are removed from the peritoneal cavity when not in use. When removed from the peritoneal cavity, the instruments should be detached from the electrosurgical generator, or they should be stored in an insulated pouch near the operative field. These measures prevent damage to the patient’s skin if the electrode is accidentally activated.
Current Diversion

Current diversion occurs when the radiofrequency circuit follows an unintended path between the active electrode and the electrosurgical generator. This may occur with insulation defects, direct coupling, or capacitative coupling. In older, grounded systems, unlikely to be in use, current can be diverted if any part of the patient’s body touches a conductive and grounded object. In any of these situations, if the power density becomes high enough, unintended and severe thermal injury can result.

Insulation Defects

If the insulation coating the shaft of a monopolar electrosurgical electrode becomes defective, it can allow current diversion to adjacent tissue, most often bowel, potentially resulting in significant injury. This happens in part because such defects create a zone of high current density (Fig. 23.20A). Therefore, the instruments should be examined before each procedure to detect worn or obviously defective insulation. When using monopolar laparoscopic instruments, the shaft of the device should be kept away from vital structures and, if possible, totally visible in the operative field.

Figure 23.20 Current diversion secondary to insulation defects and direct coupling. These events may occur with the use of monopolar instrumentation when there is a defect in the insulation (A) or, classically, to contact a conductive instrument that, in turn, touches other intraperitoneal structures. In the example depicted (B), the active electrode is touching the laparoscope, and current is transferred to bowel through a small enough contact point that thermal injury results. Another common target of such coupling is to noninsulated hand instruments.
Direct Coupling

Direct coupling occurs when an activated electrode touches and energizes another uninsulated metal conductor such as a laparoscope, cannula, or other instrument. Direct coupling is often used for hemostasis when a grasping instrument is used to occlude a blood vessel while a separate activated electrode is used to provide the energy for desiccation and coagulation. If this occurs while the noninsulated device rests against structures such as bowel or the urinary tract, injury may occur (Fig. 23.20B). The risk of direct coupling can be reduced by eliminating the simultaneous use of noninsulated instruments and monopolar electrodes. The surgeon should visually confirm that there is no contact with other conductive instruments before activating a monopolar electrode.

Capacitive Coupling

Capacitance is the ability of a conductor to establish an electrical current in an unconnected nearby circuit. An electrical field is established around the shaft of any activated unipolar electrode (including the cord), a circumstance that makes the electrode a potential capacitor. This field is harmless if the circuit is completed through a dispersive, low-power density pathway (Fig. 23.21). For example, if capacitative coupling occurs between a laparoscopic electrode and a metal cannula positioned in the abdominal
wall, the current is harmlessly dispersed in the abdominal wall at the point where it connects with the dispersive electrode (Fig. 23.21A). However, if the metal cannula is anchored to the skin by a nonconductive plastic retaining sleeve or “gripper” (a hybrid system), the current cannot return to the abdominal wall because the sleeve acts as an insulator (Fig. 23.21B). Instead, the capacitor will have to “look” elsewhere to complete the circuit. The bowel or any other nearby conductor can become the target of a relatively high-power density discharge (Fig. 23.21C). This situation can occur when a unipolar electrode is inserted through an operating laparoscope that, in turn, is passed through a nonconductive plastic laparoscopic cannula. In this configuration, the plastic port acts as the insulator. If the electrode capacitively couples with the metal laparoscope, nearby bowel will be at risk for significant thermal injury (115). The circumstance occurs with the relatively new “single port” systems where the laparoscope and hand instruments, including monopolar electrodes, are passed through the same concentrated array of ports. This situation is identical to that of the “operating” laparoscope with an increased risk that the laparoscope or other instruments function as capacitors.

Figure 23.21 Capacitative coupling. A: All activated monopolar electrodes emit a surrounding charge, proportional to the voltage of the current. This makes the electrode a potential capacitor. B: Generally, as long as the charge is allowed to disperse through the abdominal wall, no sequelae result. However, if the “return” to the dispersive electrode is blocked by insulation, such as a plastic anchor (C), the current can couple to a conductive cannula or directly to bowel.
The risk of capacitive coupling-related complications can be reduced in a number of ways. First, it is important to avoid the use of hybrid laparoscope-cannula systems that contain a mixture of conductive and nonconductive elements. Instead, the use of all-plastic or all-metal cannula systems is preferred. It may be best to avoid or at least minimize the use of monopolar instruments using operating laparoscopes or multiport, single site access systems. If an operating laparoscope is to be used, all-metal cannula systems should be the rule unless there is no intent to perform unipolar electrosurgical procedures through the operating channel. Finally, minimizing the use of high voltage, modulated current ("coagulation" current) will reduce the risk of capacitative coupling.

**Dispersive Electrode Burns**
Modern electrosurgical units are designed with isolated circuits and impedance monitoring systems that shut down the machine if dispersive electrode (“patient pad”) detachment occurs. The use of isolated-circuit electrosurgical generators with dispersive electrode monitors has virtually eliminated dispersive electrode–related thermal injury. Dispersive electrode monitoring is accomplished by measuring the impedance in the dispersive electrode, which should always be low because of the large surface area. Without such devices, partial detachment of the dispersive electrode could result in a thermal injury because reducing the surface area of the electrode in contact with the skin raises the current density (Fig. 23.22).

**Figure 23.22** Dispersive electrode burns. If the dispersive electrode becomes partially detached, the current density may increase to the point that a skin burn results.

Because a few ground-referenced machines without such safeguards may still be in use, it is important to know the type of electrosurgical unit used in the operating room. If the electrosurgical generator is ground referenced and if the dispersive electrode becomes detached, unplugged, or otherwise ineffective, the current seeks any grounded conductor, such as electrocardiograph patch electrodes or the conductive metal components of the operating table (Fig. 23.23). If the conductor has a small surface area, the current or power density may become high enough to cause thermal injury (Fig. 23.24).

**Figure 23.23** Risk of ground-referenced generators. Current diversion along alternate pathways is a risk associated with ground-referenced electrosurgical generators, particularly if the dispersive electrode is detached. In the example depicted, the relatively high current density at the electrocardiogram electrode site may result in a skin burn.
Hysteroscopic procedures are facilitated with an electric examination table. Distension media may be positioned on an intravenous pole, but wide, cystoscopy tubing allows maintenance of higher intrauterine pressures suitable for viewing and performing simple procedures such as polypectomy or transcervical sterilization. A light source is necessary and a camera desirable. The camera is attached to the monitor and may be connected to a printer and/or video recorder. The camera head is attached to a flexible hysteroscope.
Hemorrhagic Complications
Great Vessel Injury

The most dangerous hemorrhagic complications are injuries to the great vessels, including the aorta and the vena cava, the common iliac vessels and their branches, and the internal and external iliac arteries and veins. The most catastrophic injuries occur secondary to insertion of an insufflation needle or the tip of the obturator (trocar) used to position the primary or ancillary cannulas. The vessels most frequently damaged are the aorta and the right common iliac artery as it branches from the aorta in the midline. The anatomically more posterior location of the vena cava and the iliac veins provides relative protection, but not immunity, from injury (116). After vascular injury, patients usually develop profound hypotension with or without hemoperitoneum. In some instances, blood is aspirated through the insufflation needle before the introduction of the distending gas. In such instances, the needle should be left in place while immediate preparations are made to obtain blood products and perform laparotomy. The bleeding frequently will be contained in the retroperitoneal space, which usually delays the diagnosis; consequently, hypovolemic shock may develop. To avoid late recognition, the course of each great vessel must be identified before completing the procedure. Because it is difficult to assess the volume of blood filling the retroperitoneal space, immediate laparotomy is indicated if retroperitoneal bleeding is suspected. A midline incision should be made to allow access to the great vessels. Upon entry into the peritoneal cavity, the aorta and vena cava should immediately be compressed just below the level of the renal vessels to gain at least temporary control of blood loss. The most appropriate course of action depends on the site and extent of injury. Vascular or general surgery consultation may be necessary to evaluate and repair significant vascular injuries. Although most of these injuries are small and amenable to repair with suture, some are larger and require the insertion of a vascular graft. Deaths have occurred as a result of these injuries.

Abdominal Wall Vessel Injury

The abdominal wall vessels most commonly injured during laparoscopy are the superficial inferior epigastric vessels as they branch from the femoral artery and vein and course cephalad in each lower quadrant. They are invariably damaged by the initial passage of an ancillary trocar-cannula system or by the introduction of a wider device later in the procedure. The problem may be recognized immediately by the observation of blood dripping along the cannula or out through the incision. However, the bleeding may be obstructed by the cannula until it is withdrawn at the end of the operation.

The more serious injuries are those to the deep inferior epigastric vessels, which are branches of the external iliac artery and vein that course cephalad but are deep to the rectus fascia and often deep to the muscles (Fig. 23.3). More laterally located are the deep circumflex iliac vessels, which are not often encountered in laparoscopic surgery. Laceration of these vessels may cause profound blood loss, particularly when the trauma is unrecognized and causes extraperitoneal bleeding.
Signs of injury, in addition to blood dripping down the cannula, include the postoperative appearance of shock and abdominal wall discolorization or hematoma located near the incision. In some instances, the blood may track to a more distant site, presenting as a pararectal or vulvar mass. Delayed diagnosis may be prevented by laparoscopic evaluation of each peritoneal incision after removal of the cannula.

Superficial inferior epigastric vessel trauma usually stops bleeding spontaneously; therefore, expectant management is appropriate. A straight ligature carrier can be used to repair lacerated deep inferior epigastric vessels. Alternatively, a Foley catheter may be inserted through the cannula, inflated, put on traction, and held in place with a clamp for 24 hours. If a postoperative hematoma develops, local compression should be used initially. Open removal or aspiration of the hematoma should not be undertaken because it may inhibit the tamponade effect and increase the risk of abscess. If the mass continues to enlarge or if signs of hypovolemia develop, the wound must be explored.

**Intraperitoneal Vessel Injury**

Hemorrhage may result from inadvertent entry into a vessel or failure of a specific occlusive technique. In addition to delayed hemorrhage, there may be a further delay in diagnosis at laparoscopy as a result of the restricted visual field and the temporary occlusive pressure exerted by CO₂ in the peritoneal cavity.

Inadvertent division of an artery or vein is usually evident immediately. Transected arteries may go into spasm and bleed minutes to hours later, going unnoticed temporarily because of the limited visual field of the laparoscope. Therefore, at the end of the procedure, all areas of dissection must be carefully examined. Carbon dioxide should be vented, which decreases the intraperitoneal pressure so that blood vessels temporarily occluded by higher pressure can be recognized.

**Gastrointestinal Complications**

The stomach, the small bowel, and the colon can be injured during laparoscopy. Mechanical entry into the large or small bowel can occur 10 times more often when laparoscopy is performed in patients who have had prior intraperitoneal inflammation or abdominal surgery. Loops of intestine can adhere to the abdominal wall under the insertion site and be injured (117,118).

**Insufflation Needle Injuries**

Needle entry into the gastrointestinal tract may be more common than reported because it may go unnoticed and without further complication. Gastric entry may be identified by the increased filling pressure, asymmetric distention of the peritoneal cavity, or aspiration of gastric particulate matter through the lumen of the needle. Initially, the hollow, capacious stomach may allow the insufflation pressure to
remain normal. Signs of bowel entry are the same as those for gastric injury, with the addition of feculent odor.

If particulate debris is identified, the needle should be left in place, and an alternate insertion site should be identified, such as the left upper quadrant. Immediately after successful entry into the peritoneal cavity, the site of injury can be identified. Defects must be repaired immediately by laparoscopy or laparotomy.

**Trocar or Obturator Injuries**

Damage caused by a sharp tipped obturator or trocar is usually more serious than needle injury. Inadvertent gastric entry usually is associated with stomach distention because of aerophagia, difficult or improper intubation, or mask induction with inhalation anesthetic. Most often the injury is created by the trocar-cannula system used for primary access. Ancillary cannulas may result in visceral injury, although placement of these cannulas under direct vision helps reduce the risk of injury. **The risk of gastric perforation can be minimized with the selective use of preoperative nasogastric or oral gastric suction when left upper-quadrant entries are used or when the intubation was difficult.** Open laparoscopy likely has little impact on the risk for gastrointestinal complications, particularly those related to adhesions to the anterior abdominal wall from previous surgery. For high-risk patients, left upper quadrant needle and trocar-cannula insertion with a properly decompressed stomach may be preferable (119–122).

If the trocar of a primary cannula penetrates the bowel, the condition is usually diagnosed when the mucosal lining of the gastrointestinal tract is visualized. If the large bowel is entered, a feculent odor may be noted. However, the injury may not be recognized immediately because the cannula may not stay within the bowel or may pass through the lumen. Such injuries usually occur when a single loop of bowel is adherent to the anterior abdominal wall. The injury may not be recognized until peritonitis, abscess, enterocutaneous fistula, or death occurs (123,124). Therefore, at the end of the procedure, the removal of the primary cannula must be viewed either through the cannula or an ancillary port, a process facilitated by routine direct visualization of closure of the incision of the primary port.

**Trocar-related injuries to the stomach and bowel require repair as soon as they are recognized.** If the injury is small, a trained operator can repair the defect under laparoscopic direction using a double layer of running 2-0 or 3-0 absorbable sutures. Extensive lesions may require resection and reanastomosis, which in most instances requires at least a small laparotomy. The preoperative use of mechanical bowel preparation in selected high-risk cases minimizes the need for laparotomy or colostomy, but recent evidence suggests that bowel surgery, if necessary, may be safely performed in unprepared bowel (125).

**Dissection and Thermal Injury**
When mechanical bowel trauma is recognized during the dissection, treatment is the same as that described for trocar injury. **Should the injury involve radiofrequency electrical energy, it is important to recognize that the zone of desiccation and coagulation may exceed the area of visual damage.** This is especially true if the exact mechanism of the thermal injury is unknown or if injury results from contact with a relatively large surface area electrode that would be more likely to create a large coagulation injury. Conversely, **bowel injury created under direct vision with a radiofrequency needle or blade electrode is associated with little collateral coagulation effect and can be managed similar to a mechanically induced lesion.** Consequently, surgical repair should be implemented considering these factors, and should include, if necessary, resection of ample margins around the injury. **Thermal injury may be handled expectantly if the lesion seems superficial and confined,** such as when fulguration (noncontact arcing of high-voltage current) involves bowel. In such instances, the depth of injury is generally less than half a millimeter. In a study of 33 women with such injuries who were managed expectantly in the hospital, only 2 required laparotomy for repair of perforation (126).

**Urologic Injury**

Damage to the bladder or ureter may occur secondary to mechanical or thermal trauma incurred during laparoscopic procedures. Ideally, such injury should be prevented; otherwise, as is the case for most complications, it is preferable to identify the trauma intraoperatively.

**Bladder Injury**

Bladder injury can result from the perforation of the undrained bladder by an insufflation needle or trocar, or it may occur while the bladder is being dissected from adherent structures or from the anterior uterus (127,128). The frequency of injury is difficult to estimate and varies with the procedure. Estimates of the frequency of unintentional cystotomy associated with laparoscopic hysterectomy range from 0.4% to 3.2% and appear to be more frequent in the context of a previous cesarean section (129,130). The injury may be readily apparent by direct visualization. If an indwelling catheter is in place, hematuria or pneumaturia (CO$_2$ in the catheter drainage system) may be noticed. A bladder laceration can be confirmed by injecting sterile milk or a diluted methylene blue solution through a transurethral catheter. Thermal injury to the bladder, however, may not be apparent initially and, if missed, can present as peritonitis or a fistula. **Routine preoperative bladder drainage usually prevents trocar-related cystotomies.** Separation of the bladder from the uterus or other adherent structures requires good visualization, appropriate retraction, and excellent surgical technique. Sharp mechanical dissection is preferred, particularly when relatively dense adhesions are present.

**Very small-caliber injuries to the bladder (1 to 2 mm) may be treated with**
bladder catheterization for 3 to 7 days. If repair is undertaken immediately, catheterization is unnecessary. When a larger injury is identified, it can be repaired laparoscopically (127,128,131). If the laceration is near the trigone or involves the trigone, an open procedure should be used. The mechanism of injury should be taken into consideration in making this evaluation because electrical injuries often extend beyond the visible limits of the apparent defect. If a coagulation-induced thermal injury occurred, the coagulated portion should be excised.

For small lesions, closure may be performed with layers of absorbable 2-0 to 3-0 sutures. Postoperative catheterization with either a transurethral or suprapubic catheter should be maintained for 2 to 5 days for small fundal lacerations and for 10 to 14 days for injuries to the trigone. Cystography should be considered before the urinary catheter is removed.

Ureteral Injury

One of the most common causes of ureteral injury during laparoscopy is electrosurgical trauma (113,132,133). Ureteral injury can occur after mechanical dissection, including linear cutting and stapling devices (133–135). Although intraoperative recognition of ureteral injury is possible, the diagnosis is usually delayed (132,133). Ureteral lacerations may be confirmed intraoperatively, visually, or following the intravenous injection of indigo carmine. Thermal injury presents up to 14 days after surgery with fever, abdominal or flank pain, and peritonitis. Leukocytosis may be present, and intravenous pyelography shows extravasation of urine or urinoma. Mechanical obstruction from staples or a suture may be recognized intraoperatively by direct visualization. Cystoscopy following the intravenous injection of indigo carmine may be used to confirm failure of the dye to pass through the ureter. Abdominal ultrasound may be helpful, but a CT urogram can more precisely identify the site and degree of the obstruction. Unrecognized ureteral obstruction may present a few days to 1 week after surgery with flank pain and often fever (136).

Discharge or continuous incontinence is a delayed sign of ureterovaginal or vesicovaginal fistula. A vesicovaginal fistula can be confirmed by filling the bladder with methylene blue and then detecting dye on a tampon previously placed in the vagina. With a ureterovaginal fistula, the methylene blue will not pass into the vagina, but it can be detected with the intravenous injection of indigo carmine.

Knowledge of the course of the ureter through the pelvis is a prerequisite to reducing the risk of injury. The ureter can usually be seen through the peritoneum of the pelvic sidewall between the pelvic brim and the attachment of the broad ligament. Because of variation from one patient to another or the presence of disease, the location of the ureter can become obscured, making it necessary to enter the retroperitoneal space. The techniques used for retroperitoneal dissection are important factors in reducing the risk of ureteric injury. Blunt and sharp dissection with scissors is preferred, although hydrodissection can be used (137). The selective placement of ureteral stents may be helpful in preventing injury.
Ureteral injury can be treated immediately if it is diagnosed intraoperatively. Although limited damage may heal over a ureteral stent left in place for 10 to 21 days, repair is indicated in most patients. Laparoscopic repair of ureteric lacerations and transections is performed, but most injuries require laparotomy (132,138).

Incomplete or small obstructions and lacerations may be treated successfully with either a retrograde or anterograde ureteral stent. Urinomas may be drained percutaneously. If a stent cannot be placed successfully, a percutaneous nephrostomy should be performed before operative repair is undertaken. Repair may be accomplished by excision and reanastamosis, or, more commonly, ureteric reimplantation with or without facilitating procedures such as a psoas hitch or a Boarie flap.

**Neurologic Injury**

Peripheral nerve injury is usually related either to poor positioning of the patient or to excessive pressure exerted by the surgeons. Positioning the patient in lithotomy while she is awake may decrease this risk because the patient can determine whether any undue pressure or discomfort is felt (139). Nerve injury may occur as a result of the surgical dissection.

In the extremities, the trauma may be direct, such as when the common peroneal nerve is compressed against a stirrup. The femoral nerve or the sciatic nerve or its branches may be overstretched and damaged by excessive flexion or external rotation of the hips. The peroneal nerve may be injured by compression if the lateral head of the fibula rests against the stirrup (139–141). Brachial plexus injuries may occur secondary to the surgeon or assistants leaning against an abducted arm during the procedure. If the patient is placed in a steep Trendelenburg position, the brachial plexus may be damaged because of the pressure exerted on the shoulder joint. In most cases, sensory or motor deficits are found as the patient emerges from anesthesia. The likelihood of brachial plexus injury can be reduced with adequate padding and support of the arms and shoulders or by placing the patient’s arms in an adducted position.

Most injuries to peripheral nerves resolve spontaneously. The time to recovery depends on the site and severity of the lesion. For most peripheral injuries, full sensory nerve recovery occurs in 3 to 6 months. Recovery may be hastened by the use of physical therapy, appropriate braces, and electrical stimulation of the affected muscles. Open microsurgery should be performed for transection of major intrapelvic nerves.

**Incisional Hernia and Wound Dehiscence**

Incisional hernia after laparoscopy was reported in more than 900 cases (98,99). The most common defect is dehiscence that develops in the immediate postoperative period. Hernias may be asymptomatic or may cause pain, fever, periumbilical mass, obvious evisceration, and the symptoms and signs of mechanical bowel obstruction. Although no
incision is immune to the risk, defects that are larger than 10 mm in diameter are particularly vulnerable (99,142,143).

Richter’s hernias contain only a portion of the intestine in the defect, and the diagnosis is often delayed because the typical symptoms and findings of mechanical bowel obstruction may be absent. The initial symptom is usually pain. These hernias most often occur in incisions that are lateral to the midline where there is a greater amount of preperitoneal fat creating a potential space for incarceration. Fever can be present if incarceration occurs, and peritonitis may result from subsequent perforation. The condition is difficult to diagnose, requires a high index of suspicion, and may be confirmed with ultrasonography or CT (144).

In most cases, these occurrences can be prevented by using small-caliber cannulas, when possible, and with routine fascial and peritoneal closure of defects made by peritoneal access. The risk of inadvertent incorporation of the intestine into the wound can be reduced by viewing the closure with a smaller-caliber laparoscopy passed through a narrow caliber ancillary port. All ancillary cannulas should be removed under direct vision to ensure that bowel is not drawn into the incision and that there is an absence of active incisional bleeding.

The management of laparoscopic incisional defects depends on the time of presentation and the presence and condition of entrapped bowel. Evisceration always requires surgical intervention. If the condition is diagnosed immediately, the intestine is replaced in the peritoneal cavity (if there is no evidence of necrosis or intestinal defect), and the incision is repaired, usually with laparoscopic guidance. If the diagnosis is delayed or the bowel is incarcerated or at risk of perforation, laparotomy is necessary to repair or resect the intestine.

**Infection**

Wound infections after laparoscopy are uncommon; most are minor skin infections that can be treated successfully with expectant management, drainage, or antibiotics (145). Severe necrotizing fasciitis rarely occurs. Bladder infection, pelvic cellulitis, and pelvic abscess were reported (146).

Laparoscopy is associated with a much lower risk of infection than open abdominal or vaginal surgery. Prophylactic antibiotics should be offered to selected patients (e.g., those with enhanced risk for bacterial endocarditis and those for whom total hysterectomy is planned). Patients should be instructed to monitor their body temperature after discharge and to report immediately a temperature higher than 38°C.
Hysteroscopy

The hysteroscope is an endoluminal endoscope, adapted from the urological cystoscope that can be used to aid diagnosis or to direct the performance of a variety of intrauterine procedures. Hysteroscopic lysis of intrauterine adhesions was first described in 1973 (147). The technique of endoscopically guided electrosurgical resection was adapted from urology to gynecology for the removal of uterine leiomyomas (148). Hysteroscopic division of uterine septa was originally developed using a mechanical technique with specially designed scissors (149). Hysteroscopic destruction of the endometrium, generally termed endometrial ablation (EA), was originally reported using Nd:YAG laser vaporization, but subsequent innovators used the urological resectoscope to ablate the endometrium using electrosurgical coagulation, resection, or vaporization (150–152). Hysteroscopically guided thermal ablation with heated fluid was described, as the only endoscopically guided technique for nonresectoscopic EA. Developments in the design of endoscopes resulted in smaller-diameter instruments that retain the ability to provide a high-quality image and facilitate the use of hysteroscopy in an office or procedure room setting.
Diagnostic Hysteroscopy

The goal for evaluation of the uterine cavity is to obtain either a sample of the endometrium, usually for the detection of hyperplasia or neoplasia, or to identify structural abnormalities, typically a uterine septum or focal lesions, such as adhesions, polyps, or myomas. Blind endometrial sampling is the diagnostic mainstay for the detection of endometrial hyperplasia, whereas transvaginal ultrasonography, hysterography, MRI and hysteroscopy are options for the detection and characterization of structural anomalies. Hysteroscopic examination is probably superior to hysterography for evaluation of the endometrial cavity, but the diagnostic accuracy of transvaginal ultrasonography is comparable, especially when intrauterine saline is used as a contrast medium, a procedure called sonohysterography or saline infusion sonography (SIS) (153–156). MRI and ultrasound-based techniques have the advantage of allowing evaluation of the myometrium, whereas office-based hysteroscopy allows simultaneous removal of small polyps and even some myomas. Diagnostic hysteroscopy provides information not obtained by blind endometrial sampling, such as detection of endometrial polyps or submucous leiomyomas (157–163). Malignant or hyperplastic polyps or other localized lesions can be identified with hysteroscopy and removed via directed biopsy (160). Blind curettage remains an effective approach for the identification of global endometrial histopathology (157,162,164). Following are potential indications for diagnostic hysteroscopy:

- Unexplained abnormal uterine bleeding
  - Premenopausal
  - Postmenopausal
- Selected infertility cases
  - Abnormal hysterography or transvaginal ultrasonography
  - Unexplained infertility
- Recurrent spontaneous abortion

For many patients, diagnostic hysteroscopy can be performed in an office or procedure room setting with minimal discomfort and at a much lower cost than in a surgical center or a traditional operating room. For some, concerns about patient comfort or a preexisting medical condition may preclude office hysteroscopy. In many patients hysteroscopy can provide more information than blind curettage, but it should be used prudently. For most patients, other diagnostic or therapeutic measures can be undertaken before, or instead of, diagnostic hysteroscopy. For example, for women in the late reproductive years who have abnormal uterine bleeding (AUB) or for those with postmenopausal bleeding, transvaginal sonography or office endometrial biopsy or curettage is typically adequate to evaluate for neoplasia and provide enough information to support an initial management strategy. In the absence of a satisfactory diagnosis or if unexplained bleeding continues without response to treatment, further investigation is appropriate, using one or a combination of ultrasound, endometrial
sampling, SIS, or office hysteroscopy. For women in their earlier reproductive years who have AUB, medical or expectant management may be used initially, depending on the severity and inconvenience of the bleeding. For those who do not respond to medical treatments such as oral contraceptives, further diagnostic procedures such as transvaginal ultrasonography, SIS, or hysteroscopy with biopsy can be performed (165).

For women with infertility, hysterosalpingography is the best initial imaging step because it provides information about the patency of the oviducts. In the presence of a suspicious or identified abnormality in the endometrial cavity, hysteroscopy or sonohysterography can be performed to confirm the diagnosis, to better define the abnormality, and perhaps to direct the removal of a lesion. Some experts consider hysteroscopy or MRI mandatory for such patients because of the high occurrence of false-negative radiologic images in those with intrauterine anomalies (166). In women with previous in vitro fertilization failure, there is evidence that hysteroscopic identification and treatment of these “missed” anomalies improves pregnancy rates (167). Confirmation of patency of the oviduct is unnecessary in women who have recurrent abortions; therefore, these patients can be evaluated primarily with hysteroscopy.
Operative Hysteroscopy

A number of intrauterine procedures can be performed under endoscopic direction, including adhesiolysis, sterilization, division of a uterine septum, resection of myomas and polyps, removal of retained products of conception, and endometrial destruction through Nd:YAG laser vaporization or radiofrequency resection, desiccation, or vaporization. Hysteroscopy may be used to direct the removal of foreign bodies, including imbedded intrauterine contraceptive devices (IUDs).

Foreign Body

If the string of an IUD is absent, the device usually can be removed with a specially designed hook or a toothed curette (e.g., Novak). When removal is difficult or impossible, the location of the device may be confirmed by hysteroscopy, allowing removal with a grasping forceps. If the device is not seen or if only a portion is visible hysteroscopically and the remainder is imbedded in the myometrium, then individualized management is recommended, usually following appropriate imaging studies to identify the more precise location of the device.

Septum

When recurrent pregnancy loss is associated with a single corpus containing a uterine septum, hysteroscopic division of the septum improves reproductive outcome at a rate comparable to abdominal metroplasty, with reduced morbidity and cost (see Chapter 33) (168–173). There are fewer data regarding infertility but there is some evidence that metroplasty does improve fecundity (174). Confirmation of the external architecture of the corpus is important and can be achieved using either MRI or three-dimensional ultrasound. One group described an office method of “see and treat” where dissection is continued until attaining two of three criteria (pain, bleeding, the visualization of myometrial fibers) to determine the end point of septal transection (175). This procedure can be successfully performed in the office setting using local anesthesia protocols, with additional 0.05% lidocaine with 1/200,000 epinephrine directly injected into the septum. The procedure may be performed mechanically with scissors or with energy-based techniques such as the Nd:YAG laser or an electrosurgical knife, needle, or loop. Because most septa have few vessels, scissors can be used to avoid the minimal risk for thermal damage.

Endometrial Polyps

Endometrial polyps are associated with abnormal uterine bleeding and infertility. Although such polyps can be removed with blind curettage, many are missed (157,159,162,163). Therefore, known or suspected endometrial polyps are treated more successfully with hysteroscopic guidance, which usually can be performed as an office procedure. Hysteroscopy may be used either to evaluate the result of blind curettage, to determine if the polyp is avulsed, or to direct the use of grasping forceps or
small caliber scissors. Alternatively, for larger polyps, special polyp snares, electrosurgical needles, or a uterine resectoscope may be used to sever the stalk or morcellate the lesion. For patients with infertility and endometrial polyps, it is not clear whether or not polyp number and size are related to outcome (176). Consequently, removal of all accessible polyps should be attempted if the process can be completed with minimal trauma.

**Leiomyomas**

Hysteroscopy may be used to remove selected leiomyomas that involve the uterine cavity in women with heavy menstrual bleeding, infertility, or recurrent first trimester spontaneous pregnancy loss (155,177–183). This approach is limited based on the location, size, and number of the lesions. Preoperative administration of gonadotropin-releasing hormone (GnRH) agonists may help shrink submucous myomas, facilitating their complete removal, and more importantly, reduce operating time and systemic absorption of distension media (184–186).

To help document and evaluate the results of hysteroscopically directed myoma surgery, a classification system was developed that is based on the proportion of the myoma that is in the uterine cavity. **In patients with myomas that are 3 cm or less in diameter and entirely intracavitary (type 0), excision is feasible and in many instances relatively easy, whereas in large type II lesions an abdominal approach with laparoscopy or laparotomy is necessary.** Small type 0 leiomyomas may be removed following transection of the stalk with scissors or an electrode attached to a uterine resectoscope. For larger type 0 lesions, or for type I myomas, electrosurgical morcellation with a resectoscope is necessary before removal. For a limited number of type II myomas, careful dissection into the avascular plane interposed between the tumor and the myometrial pseudocapsule may be attempted, provided that satisfactory ultrasonography or MRI demonstrated an adequate margin of myometrium between the deepest aspect of the lesion and the uterine serosa. It may be preferable to undertake such procedures with laparoscopic monitoring to verify that bowel is not adjacent to the zone of dissection. Patients should be counseled that for some type I and many type II myomas, more than one procedure might be required to complete excision (178,187). The use of intrauterine prostaglandin $F_{2\alpha}$ was described to facilitate extrusion of type II myomas (188).
Endometrial Ablation

Heavy menstrual bleeding that does not respond to oral medical therapy may be managed by EA using coagulation, resection, or vaporization, provided the patient is willing to forgo future fertility (51). Alternatively, or if future fertility is desired, a levonorgestrel-releasing intrauterine contraceptive device can provide virtually equal clinical outcomes (189,190). Ablation may be performed with the laser, radiofrequency electrosurgical desiccation, resection, or vaporization using a uterine resectoscope, or by any of a number of nonresectoscopic techniques, including those employing thermal balloons, cryotherapy, heated free fluid, or microwave or bipolar radiofrequency energy (151,152,187,191–195). Many of these endometrial ablation devices can be used in an office setting using local anesthetic protocols.

Endometrial resection is an EA technique performed with an electrosurgical loop electrode to shave the endometrium and superficial myometrium (109,142,143,150,196,197). Vaporization utilizes specially designed electrodes that are attached to standard resectoscopes but which are capable of destroying large volumes of tissue without morcellation (187). Ablation is achieved using ball or barrel-shaped electrodes that coagulate the endometrial surface (51,152). Complications of these procedures include fluid overload, electrolyte imbalances (if nonelectrolytic or even isosmotic media are used), uterine perforation, bleeding, and intestinal and urinary tract injury (198,199). The risk of uterine perforation may be reduced by using a combination of resection or vaporization and electrosurgical ablation; the latter is most suitable for the thinner areas of the myometrium in the cornu (177). The preoperative use of GnRH analogues or danazol may reduce operating time. GnRH may reduce bleeding and the amount of fluid absorbed into the systemic circulation (186).

For many women, these procedures succeed in reducing or eliminating menses without hysterectomy or long-term medical therapy (51,200). Success rates vary and depend on the duration of follow-up and the definition of success. For many patients, amenorrhea is the goal, whereas for others, it is normalization of menses. About 75% to 95% of patients are satisfied with the surgical procedure after 1 year. Amenorrhea rates range from about 30% to 90% (depending in part upon the technique), but 40% to 50% of patients have amenorrhea, is a useful number to quote to patients considering the procedure. In comparative studies, there is no advantage of laser over electrosurgical techniques (198,201). The nonresectoscopic techniques have similar clinical outcomes, thus reducing the need for resectoscopic ablation. However, the nonresectoscopic approaches all have limitations defined by the size or configuration of the endometrial cavity. Consequently, for those women with heavy menstrual bleeding who are not suitable for nonresectoscopic techniques because of large uteri (>12 cm sounded length), resectoscopic endometrial ablation remains a viable option (161,202).

The long-term efficacy and impact of ablation or resection on women with adenomyosis is unknown. Because some endometrium inevitably cannot be ablated, there is the potential for endometrial cancer; therefore, postmenopausal women who underwent ablation or
Resection should take progestin as a part of hormonal therapy (203).

**Sterilization**

Sterilization can be performed under hysteroscopic guidance, an approach that eliminates the disadvantages and risks associated with abdominal or laparoscopic techniques (204). Two such techniques are available and others are under development. The Essure® system comprises a nickel-titanium coil with a Dacron filament that can be inserted relatively quickly in an office or procedure room setting (see Chapter 10). The Adiana® device uses a rice grain–sized porous silicon plug that is positioned in the proximal tube following the application of an aliquot of RC[MB1] current. It is designed for office use under local anesthesia. North American protocols require that hysterosalpingography be performed 3 months after the procedure to ensure that bilateral tubal occlusion took place.

**Synechiae**

**Asherman syndrome** is the presence of adhesions in the endometrial cavity resulting in infertility or recurrent spontaneous abortion with or without amenorrhea. These synechiae may be detected on a hystero gram or sonohysterogram, but are best shown with diagnostic hysteroscopy. Relatively thin, fragile synechiae may be divided with the tip of a rigid diagnostic hysteroscope (205). Thicker lesions may require division by semirigid or rigid scissors or energy-based instruments such as a resectoscope or an operative hysteroscope with either a radiofrequency electrode or an Nd:YAG laser. Reproductive outcome depends on the extent of the preoperative endometrial damage (206,207). This is another hysteroscopic procedure that is amenable to performance in the office, at least in selected cases without complete obliteration, but the surgeon must be careful to maintain orientation within the endometrial cavity.
Patient Preparation and Communication

Diagnostic hysteroscopy procedures traditionally were performed in the office or clinic settings, and operative hysteroscopy usually was performed in an operating room or hospital surgical center. Much is changing; in a number of centers, 90% of the operative hysteroscopies are performed in an office procedure room setting using local and verbal anesthesia. The patient should understand the rationale for the procedure, and the anticipated discomfort, the potential risks, and the expectant, medical, and surgical alternatives. The nature of the procedure and the chance of therapeutic success should be explained, and she should be given a realistic estimate of success based on the operator's experience.

Diagnostic Hysteroscopy: Risks

The risks of diagnostic hysteroscopy are few, and those complications that occur rarely have severe consequences (199). The uncommon adverse events that should be discussed with the patient include perforation, bleeding, and those related to anesthesia and the distention media. After diagnostic hysteroscopy, most patients have slight vaginal bleeding and occasionally, lower abdominal cramps. Severe cramps, dyspnea, and upper abdominal and right shoulder pain can develop if CO\textsubscript{2} is used as the distension media and it passes through the fallopian tubes into the peritoneal cavity. Consequently, even in an office environment, the patient should be encouraged to have a friend or relative escort her home.

Operative Hysteroscopy: Risks

Counseling before operative hysteroscopy varies depending on the planned procedure, the type of anesthesia, and the procedure location—office or operating room. Overall, the risks of operative hysteroscopy are higher than those of diagnostic hysteroscopy, but these increased risks are largely confined to procedures such as adhesiolysis of severe intrauterine synechiae or resection of leiomyomas that are either large or that extend deeply into the myometrium. These risks include those associated with anesthesia, which are intrinsic to all hysteroscopic procedures, and are related to the specific surgical procedure to be performed. With any hysteroscopic procedure, air embolus is a possibility, as are complications associated with the gaseous or fluid distention media used. Hypotonic distension media may not be tolerated in some patients if there is significant intravascular absorption, especially in patients with underlying cardiovascular disease. The patient must be aware of the risks associated with uterine perforation, which range from failure to complete the procedure, to hemorrhage, or damage to the intestines or the urinary tract. If such complications occur, laparotomy may be necessary to repair the injury.
Equipment and Technique

The equipment required for hysteroscopy depends on the reason for the procedure. The surgeon must be knowledgeable about the equipment, its mechanisms, and the technical specifications to facilitate efficiency, optimal clinical outcome, and a decreased probability of complications. A typical hysteroscopy setup for diagnostic and minor operative procedures is shown in Figures 23.24 and 23.25. Core competencies required for hysteroscopy are as follows:

- Patient positioning and cervical exposure
- Anesthesia
- Cervical dilation
- Uterine distention
- Visualization and imaging
- Intrauterine cutting and hemostasis
- Other instrumentation

Patient Positioning and Cervical Exposure

Hysteroscopy is performed in a modified dorsal lithotomy position; the patient is supine, and the legs are held in stirrups. For hysteroscopic procedures performed while the patient is conscious, comfort must be considered in conjunction with the need to gain good exposure of the perineum. Stirrups that hold and support the knees, calves, and ankles permit prolonged procedures. “Candy cane” stirrups are inappropriate for hysteroscopic surgery and for conscious patients.

The smallest speculum possible should be used to expose the cervix. A bivalve speculum hinged on only one side allows its removal without disturbing the position of the tenaculum and hysteroscope. The use of weighted specula should be avoided in conscious patients because of the discomfort involved.

Anesthesia

The anesthetic requirements for hysteroscopy vary greatly, depending on the patient’s level of anxiety, the status of her cervical canal, the procedure, and the outside diameter of the hysteroscope or sheath. In some patients, diagnostic hysteroscopy is possible without anesthesia, especially if the patient is parous or if narrow-caliber (<3 mm in outside diameter) hysteroscopes and sheaths are used (208). The pain of cervical dilation is avoided or minimized with the preprocedural use of oral or vaginal misoprostol (see below) or by inserting a laminaria “tent” in the cervix 3 to 8 hours before the procedure. Laminaria are thin rods of natural (slippery elm) or synthetic construction that, when passed through the internal os, expand over several hours thereby dilating the cervix. However, if laminaria are left in place too long (e.g., longer than 24 hours), the cervix may overdistend, which is counterproductive for CO₂ insufflation.
For most diagnostic and many operative procedures, effective cervical anesthesia is obtained using local anesthesia, allowing the hysteroscopy to be done in an office procedure room. Evidence suggests that the paracervical block may be the most effective (208,209). Following exposure of the cervix with a vaginal speculum, a spinal needle can be used to instill about 3 mL of 0.5% to 1% lidocaine into the anterior lip of the cervix to allow attachment of a tenaculum and manipulation of the exocervix. While the exact location and depth of the injection varies with providers and studies, the uterosacral ligament location (about 4 mm deep at approximately at the 4- and 8-o'clock positions as one looks at the cervix) was demonstrated successful (210). Care must be taken to avoid intravascular injection. An alternative technique is the use of an intracervical block where the anesthetic agent is injected evenly around the circumference of the cervix, attempting to reach the level of the internal os. The efficacy of this approach is unclear based on published studies (208).

Recognizing the complex innervation of the uterus, alternative or additional topical anesthesia may be applied to the cervical canal or to the endometrium, or both, using anesthetic spray, gel, or cream. It is unclear how effective these approaches are because many of the study protocols seemed to allow inadequate time between application and initiation of the procedure (211). A number of options were presented, including instillation of 5 mL of 2% mepivacaine into the endometrial cavity with a syringe, or the application of similar amounts of 2% lidocaine gel. Many operative procedures can be performed with these techniques combined, if deemed necessary, with the oral or intravenous use of anxiolytics or analgesics, although the use of such systemic agents mandates continuous monitoring of blood pressure and oxygenation and the availability of appropriate resuscitative staff and equipment. An important component of the optimal use of local anesthesia is allowing sufficient time from the injection or application of the agents before the commencement of the procedure. While injectable local anesthetic agents such as lidocaine and mepivacaine may have an onset of action in 2 to 3 minutes, it may take up to 15 to 20 minutes to obtain a maximal effect. If local anesthesia is not deemed appropriate, regional or general anesthesia may be used in the context of a surgical center or operating room.

Cervical Dilation

In many instances, and particularly in vaginally parous women, dilation of the cervix will be unnecessary, especially if narrow caliber hysteroscopic systems are used. Dilation will be necessary some of the time, and, although seemingly simple, cervical stenosis or suboptimal technique can result in perforation that compromises the entire procedure. If the objective lens of the endoscope cannot be placed in the endometrial cavity the hysteroscopy cannot be done. The process of dilation should be undertaken carefully, respecting the orientation of the cervix to the axis of the vaginal canal (version) and that of the corpus to the cervix (flexion). In difficult circumstances, simultaneous ultrasound may be valuable, and difficult dilation may be facilitated directly with the hysteroscope.

There are a number of options available to facilitate cervical dilation. There is evidence
that prostaglandin E\textsubscript{1} (misoprostol) administered 400 μg orally or 200 to 400 μg vaginally, approximately 12 to 24 hours before the procedure facilitates cervical dilation (212–215). Misoprostol alone may not be effective in postmenopausal women, but one well-designed randomized trial demonstrated that vaginal estrogen, administered daily for 2 weeks before the procedure facilitates the effect of the prostaglandin in this group of patients (215). Alternatively, there is evidence that intraoperatively administered intracervical vasopressin (0.05 U/mL, 4 cc at 4 and 8 o'clock) substantially reduces the force required for cervical dilation (216). Regardless of the circumstance, the cervix should be dilated asatraumatically as possible. It is best to avoid using a uterine sound because it can traumatize the canal or the endometrium, causing unnecessary bleeding and uterine perforation.

**Uterine Distention**

Distention of the endometrial cavity is necessary to create a viewing space. The choices include CO\textsubscript{2} gas, high-viscosity 32% dextran 70, and a number of low-viscosity fluids, including glycine, sorbitol, saline, and dextrose in water. **A pressure of 45 mm Hg or higher is generally required for adequate distention of the uterine cavity and to visualize the tubal ostia. To minimize extravasation, this pressure should not exceed the mean arterial pressure.** For each of the fluids, there are several methods used to create this pressure by infusion into the endometrial cavity.

**Sheaths**

A rigid hysteroscope is passed into the endometrial cavity through an external sheath. The design and diameter of the sheath reflect both the dimensions of the endoscope and the purpose of the instrument. Typical diagnostic hysteroscopes have a sheath slightly wider than the telescope, allowing infusion of the distention media. Operative sheaths have additional channels to permit the passage or efflux of distention media and the insertion of laser fibers, electrosurgical instruments or semirigid scissors, biopsy devices, or grasping forceps. These sheaths are usually 5 to 8 mm in diameter, and some allow continuous flow of distention media in and out of the endometrial cavity (Figs. 23.25 and 23.26).

*Figure 23.25 Office hysteroscopy instruments.* An assembled continuous flow operating hysteroscope with a 5.5-mm diameter external sheath is shown in (A). A 5-French semirigid scissors occupies the working channel. An additional biopsy forceps is shown in (B). Tubing transporting media to the system is shown in (C) going into a 3-mm external diameter flexible and steerable hysteroscope (D). A medical video camera is attached to the hysteroscope (F) and the light source is attached at (E). An open speculum (G) facilitates removal with instruments in place. A small dilator (H) or series of dilators will be necessary for a large number of patients. A tenaculum (I) attached to the cervix frequently facilitates both dilation and entry of the hysteroscope into the endometrial cavity.
Media

$\text{CO}_2$ provides an excellent view for diagnostic purposes, but it is unsuitable for operative hysteroscopy and for diagnostic procedures when the patient is bleeding because there is no effective way to remove blood and other debris from the endometrial cavity. To prevent $\text{CO}_2$ embolus, the gas must be instilled by an insufflator that is specially designed for the procedure—the intrauterine pressure is kept below 100 mm Hg and the flow rate is maintained at less than 100 mL per minute.

Normal saline is a useful and safe medium for procedures that do not require radiofrequency electricity from standard monopolar resectoscopes. Even if there is absorption of a substantial volume of solution, saline typically does not cause electrolyte imbalance. Therefore, saline is a good fluid for minor procedures performed in the office. The development of bipolar radiofrequency instrumentation for hysteroscopic surgery allowed the application of saline as a distending medium in even more advanced and complex procedures.

Dextran 70 is useful for patients who are bleeding because it does not mix with blood. However, it is expensive and tends to “caramelize” on instruments, which must be disassembled and thoroughly cleaned in warm water immediately after each use. Anaphylactic reactions, fluid overload, and electrolyte disturbances can occur.

For standard operative hysteroscopy with monopolar radiofrequency resectoscopes, low-viscosity, nonconductive fluids such as 1.5% glycine, 3% sorbitol, and 5.0% mannitol are used most often. These solutions can be used with standard, monopolar radiofrequency instrumentation because there are no electrolytes to disperse the current and impede the electrosurgical effect. Each of these media is inexpensive and readily available, usually in 3-L bags suitable for continuous-flow hysteroscopy. Because each fluid is electrolyte-free, extravasation into the systemic circulation can be associated with electrolyte disturbances. Compared with
1.5% glycine or 3.0% sorbitol, 5% mannitol is isomolar and it functions as a diuretic, both advantages when performing resectoscopic surgery. Regardless of the electrolyte content of the fluid distending media, systemic “absorption” must be monitored continuously or at least frequently (every 5 minutes) by collecting outflow from the sheath and subtracting it from the total infused volume. The fact that the manufacturer frequently fills the bags with more than the indicated 3 L makes accurate calculation of absorbed volume even more difficult (217). There are a number of machines designed to provide continuous feedback to the surgeon regarding the degree of negative fluid balance. Absorbed volumes greater than 1 L mandate the measurement of electrolyte levels. The risk of fluid overload is reduced by the judicious restriction of intravenous fluid by the anesthesiologist. The administration of an appropriate dose of furosemide should be considered, and the surgeon should plan for the expeditious completion of the procedure. If there is more than a preset limit (1.5 to 2 L of extravasated fluid), the procedure should be stopped. Excessive circulating sorbitol may cause hyperglycemia, and large volumes of glycine may elevate levels of ammonia in the blood (218).

Media Delivery Systems

Syringes can be used for office diagnostic procedures and are especially good for infusing dextran solution. The syringe can be operated by the surgeon and is either connected directly to the sheath or attached by connecting tubing. Because this technique is so tedious, it is suited only for simple operations.

Continuous hydrostatic pressure is effectively achieved by elevating the vehicle containing the distention media above the level of the patient’s uterus. The achieved pressure is the product of the width of the connecting tubing and the elevation—for operative hysteroscopy with 10-mm tubing, intrauterine pressure ranges from 70 to 100 mm Hg when the bag is between 1 to 1.5 m above the uterine cavity.

A pressure cuff may be placed around the infusion bag to elevate the pressure in the system. Caution must be exercised because this technique causes increasing extravasation if intrauterine pressure rises above the mean arterial pressure.

A variety of infusion pumps are available, ranging from simple devices to instruments that maintain a preset intrauterine pressure. Simple pump devices continue to press fluid into the uterine cavity regardless of resistance, whereas the pressure-sensitive pumps reduce the flow rate when the preset level is reached, thereby impeding the efflux of blood and debris and compromising the view.

Imaging

Endoscopes

Hysteroscopes are available in two basic types—flexible and rigid. Flexible hysteroscopes are self-contained in that they do not require a sheath; the single integrated channel is
used to transmit gas or fluid to the endometrial cavity for distention. As a result, these instruments are generally of smaller diameter than rigid systems. In addition, they can be designed to be “steerable,” allowing angled viewing. Flexible hysteroscopes utilize fiberoptic bundles rather than lenses to transmit the image to the observer and, consequently, have lower resolution than rigid instruments of a similar diameter and typically do not have a channel with a caliber suitable for most hand instruments. Rigid hysteroscopes are more durable and provide a superior image. The most commonly used hysteroscopes are 3 to 4 mm in diameter, although those using fibers can be smaller than 2 mm in diameter.

Rigid endoscopes require an angled (fore-oblique) lens to provide the angled view useful for operative hysteroscopy and are available in 0-degree, 12- to 15-degree, and 25- to 30-degree models (Fig. 23.26). The 0-degree telescope provides a panoramic view and is best for diagnostic procedures. Hysteroscopes with 25- to 30-degree angles are most often used for cannulation of the fallopian tubes or placement of sterilization devices, whereas 12- to 15-degree designs are a suitable compromise useful for diagnosis and ablation or resection. The utility of endoscopes with larger fore-oblique views may be offset by the tendency of resectoscopic electrodes to leave the visual field on full extension.

**Figure 23.26** Hysteroscope optics. Panoramic (0°) and oblique (15° and 30°) viewing angles.

**Light Sources and Cables**

Adequate illumination of the endometrial cavity is essential. Because it runs from a standard 110- or 220-volt wall outlet, the light source requires no special electrical connections. For most cameras and endoscopes, the element must have at least 150 watts of power for direct viewing and preferably 250 watts or more for video and operative procedures (219).

**Video Imaging**

Although diagnostic hysteroscopy may be performed with direct visualization, it is best to use video guidance for prolonged operations. Video imaging is important for teaching and recording pathology and procedures. The camera must be sensitive because of the
narrow diameter of the endoscope and the frequently dark background of the endometrial cavity, particularly when it is enlarged (Fig. 23.25).

**Image Documentation**

A small video camera can be used to teach and to coordinate the procedure with the operating room team. It allows the acquisition of still or video images for future reference or teaching. When a video recorder is used, the camera should be attached directly to the recorder to preserve the image quality. A number of video recording formats are available, each with inherent advantages and disadvantages. Some video printers provide images suitable for a medical record. Newer high-definition digital cameras provide high-quality video still images as well as high-resolution digital video, suitable for publication or teaching.

**Intrauterine Cutting and Hemostasis**

The instruments available for use through operative hysteroscopes include biopsy, grasping, cutting, and punch-biopsy devices. These tools are narrow and flexible enough to navigate the 1- to 2-mm diameter operating channel (Fig. 23.25). Although their value is limited by their small size and flimsy construction; the scissors can divide adhesions, the biopsy forceps can sample targeted lesions, and the grasping forceps can remove small polyps or intrauterine devices. Some operative hysteroscopes are designed to allow passage of fibers for the conduction of Nd:YAG laser energy, although this modality is generally superseded by electrosurgical electrodes.

The uterine resectoscope is similar to the one used in urology and is designed to apply radiofrequency electrical energy in the endometrial cavity (Fig. 23.27). An understanding of the principles of electrosurgery is mandatory for safe and effective use of this instrument. By sliding the “working element,” one of a variety of electrode tips can be manipulated back and forth within the cavity. Tissue can be divided with a pointed electrode, excised with a loop, or desiccated with a rolling ball or bar. An electrode with multiple tips or edges can vaporize tissue, provided high generator outputs are used. A clear operative field is maintained by the continuous flow of nonconductive distending media in and out of the cavity. Although basic design modifications made the resectoscope more useful in gynecology, extraction of resected fragments is time consuming. The most effective approach is the periodic use of a uterine curette or polyp forceps inserted after removal of the hysteroscope. Alternatively, much of the myoma or endometrium can be vaporized, thereby minimizing the need for periodic but time-consuming removal of tissue “chips.” If vaporization is used, it is important to obtain representative samples of the endometrium or myoma for pathological analysis.

*Figure 23.27  Resectoscope. The assembled resectoscope is shown, with two electrodes in the foreground. Manipulation of the electrode is via the white handle in the proximal portion of the device.*
Other Instrumentation

For any hysteroscopic procedure, it is necessary to have available a cervical tenaculum, dilators, uterine curette, and appropriate-sized vaginal specula. When using the resectoscope, it is helpful to have a solid-state, isolated circuit electrosurgical generator capable of delivering both modulated and nonmodulated radiofrequency current. Laparoscopy or laparotomy may be necessary for emergencies secondary to uterine perforation.
Complications

The potential risks of positioning a hysteroscopic system in the endometrial cavity solely for viewing ("diagnostic hysteroscopy") are largely limited to cervical trauma and uterine perforation. Other adverse events such as infection, excessive bleeding, and complications related to the distention media are extremely uncommon when the procedure is short and does not involve instrumentation of the myometrium (0% to 1%) (199). The risks of operative hysteroscopy are related to one of five aspects of the procedure performed: (i) anesthesia, (ii) the distention media, (iii) perforation, (iv) bleeding, and (v) thermal trauma (198,199).

Anesthesia

Local anesthetic protocols typically include the intracervical or paracervical injection of 0.5% to 2% lidocaine or mepivacaine solution, with or without a local vasoconstrictor such as adrenaline. Overdosage is prevented by ensuring that intravascular injection is avoided and by not exceeding the maximum recommended doses (lidocaine, 4 mg/kg; mepivacaine, 3 mg/kg). The use of a dilute vasoconstrictor such as epinephrine 1/200,000 reduces the amount of systemic absorption of the agent, virtually doubling the maximum dose that can be used and facilitates the onset of action of local anesthetic agents (220).

Complications of intravascular injection or anesthetic overdose include allergy, neurologic effects, and impaired myocardial conduction. Allergy is characterized by the typical symptoms of agitation, palpitations, pruritus, coughing, shortness of breath, urticaria, bronchospasm, shock, and convulsions. Treatment measures include administration of oxygen, isotonic intravenous fluids, intramuscular or subcutaneous adrenaline, and intravenous prednisolone and aminophylline. Cardiac effects related to impaired myocardial conduction include bradycardia, cardiac arrest, shock, and convulsions. Emergency treatment measures include the administration of oxygen, intravenous atropine (0.5 mg), and intravenous adrenaline and the initiation of appropriate cardiac resuscitation. The most common central nervous system manifestations are paresthesia of the tongue, drowsiness, tremor, and convulsions. Options for therapy include intravenous diazepam and respiratory support.

Distention Media

Carbon Dioxide

Carbon dioxide is highly soluble in blood; consequently such emboli as occur are usually clinically significant, and, in rare instances, CO₂ emboli may result in serious intraoperative morbidity and even death (221–223). These risks can be eliminated by avoiding the use of CO₂ with operative procedures, by ensuring that the insufflation pressure is always lower than 100 mm Hg, and that the flow rate is lower than 100 mL per minute. The insufflator used must be especially designed for
hysteroscopy; it is difficult to set laparoscopic insufflator flow rates below 1,000 mL per minute.

**Dextran 70**

Dextran 70 is a hyperosmolar medium that, rarely, can induce an allergic response or coagulopathy (224,225). Similar to other types of distention media, if sufficient volumes are infused, vascular overload and heart failure can occur (226,227). Because dextran is hydrophilic, it can draw six times its own volume into the systemic circulation. Consequently, the volume of this agent should be limited to less than 300 mL.

**Low-Viscosity Fluids**

The low-viscosity fluids—1.5% glycine, 3% sorbitol, and 5.0% mannitol—are used commonly because of their low cost, compatibility with standard electrosurgery, and availability in large-volume bags. However, should these electrolyte free and usually hypotonic media be absorbed to excess in the systemic circulation, they can create serious fluid and electrolyte disturbances, a potentially dangerous complication that can result in pulmonary edema, hyponatremia, heart failure, cerebral edema, and even death. There are a number of published guidelines describing the steps required to reduce the risk of fluid overload at the time of hysteroscopy (228).

**Before undertaking anything but simple operative procedures using these agents, baseline serum electrolyte levels should be measured.** Women with cardiopulmonary disease should be evaluated carefully. The selective preoperative use of agents such as GnRH agonists may reduce operating time and media absorption. Intracervical injection of 8 mL dilute in vasopressin (0.01 U/mL) immediately prior to surgery is effective at reducing the amount of systemic absorption of distending media (229). The duration of this effect may be limited to approximately 20 to 30 minutes, so repeat dosing may be useful for optimal effect.

**In the operating room, media infusion and collection should take place in a closed system to allow accurate measurement of the “absorbed” volume.** The volume should be measured continuously with a device specifically designed for the purpose or, if such a system is not available, calculated every 10 minutes by support staff who are trained in these calculations and unencumbered by duties that may interfere with this task.

**The lowest intrauterine pressure necessary for adequate distention should be used to complete the operation, preferably at a level that is below the mean arterial pressure.** A good range is 70 to 80 mm Hg, which can be achieved with a specially designed pump or by maintaining the meniscus of the infusion bag 1 m above the level of the patient’s uterus. If greater intrauterine pressure is needed for adequate distention, the anesthesiologist may temporarily raise the mean arterial pressure by administration of a vasoactive agent such as phenylephrine.

**Deficits of more than 1 L require repeat measurement of serum electrolyte levels and consideration of dose of intravenous furosemide appropriate to the**
patient’s renal function. When such a deficit exists, the procedure should be completed expeditiously. If the deficit reaches a preset limit (1.5 to 2 L), the procedure should be terminated, and a diuretic such as mannitol or furosemide should be used as needed. Patients with cardiovascular compromise will typically have a lower tolerance for fluid deficits, a circumstance that mandates setting a lower limit for systemic absorption and consequent termination of the procedure (230).

Perforation
Perforation may occur during dilation of the cervix, positioning of the hysteroscope, or as a consequence of the intrauterine procedure. With complete perforation, the endometrial cavity typically does not distend, and the visual field is generally lost. **When perforation occurs during dilation of the cervix, the procedure must be terminated, but, because of the blunt nature of the dilators, usually there are no other injuries.** If the uterus is perforated by the activated tip of a laser, or electrode, there is a risk for bleeding or injury to the adjacent viscera. Therefore, the operation must be stopped and **laparoscopy or laparotomy should be performed.** Injury to the uterus is relatively easy to detect with a laparoscope. However, mechanical or thermal injury to the bowel, ureter, or bladder is more difficult to detect and laparoscopy is frequently inadequate to make a complete evaluation. If the patient’s condition is managed expectantly, she should be advised of the situation and asked to report any symptoms of bleeding or visceral trauma such as fever, increasing pain, nausea, and vomiting.

Bleeding
Bleeding that occurs during or after hysteroscopy results from trauma to the vessels in the myometrium or injury to other vessels in the pelvis. Myometrial vessels are more susceptible to laceration. Resectoscopic procedures require myometrial dissection for procedures such as endometrial resection or type II myomectomy.

In planning operations that involve deep resection, autologous blood can be obtained before surgery. The risk for bleeding may be reduced by the preoperative injection of diluted vasopressin into the cervical stroma (229). The risk of injury to branches of the uterine artery can be lowered by limiting the depth of resection in the lateral endometrial cavity near the uterine isthmus, where ablative techniques should be considered. When bleeding is encountered during resectoscopic procedures, the ball electrode can be used to desiccate the vessel electrosurgically. Intractable bleeding may respond to the injection of diluted vasopressin or to the inflation of a 30-mL Foley catheter balloon or similar device in the endometrial cavity (177).

Thermal Trauma
Thermal injury to the intestine or ureter may be difficult to diagnose, and symptoms may not occur for several days to 2 weeks. Therefore, the patient should be advised of the symptoms that could indicate peritonitis.

Hysterectomy is one of the most commonly performed surgical procedures in the United States. Vaginal hysterectomy is the procedure of choice in parous women unless this route is contraindicated. Laparoscopic hysterectomy is associated with faster postoperative recovery and shorter hospital stay compared with abdominal hysterectomy. There are no randomized clinical trials demonstrating an advantage of robotic or single-port hysterectomy over conventional laparoscopic hysterectomy. There appears to be no advantage to the routine use of supracervical hysterectomy when compared with total hysterectomy. Salpingo-oophorectomy at the time of hysterectomy for benign disease in premenopausal women at average risk for ovarian malignancy is associated with an increase in long-term patient mortality from cardiovascular disease, and ovarian conservation should be strongly considered in these patients.

Hysterectomy is one of the most common surgical procedures performed. After cesarean delivery, it is the second most frequently performed major surgical procedure in the United States. According to the National Hospital Discharge survey, the rate of hysterectomy during the 5-year study period was 5.4 per 1,000 women per year in 2000 and declined to 5.1 per 1,000 per year in 2004. These data do not represent hysterectomies performed in ambulatory settings. **The highest rate of hysterectomy is between the ages of 40 and 49 years with an average age of 46.1 years.** The highest rates of hysterectomy are for women living in the southern United States and they occur at a younger age. The lowest rates are consistently in the northeastern portion of the United States. Lower socioeconomic status is associated with increased hysterectomy rates. Hysterectomy rates are higher for black women. Reports on the effect of physician gender conflict with recent data shows no overall impact.
Bilateral salpingo-oophorectomy decreased between 2000 and 2004 from 53.8% to 49.5% (1). The frequency was the highest with abdominal hysterectomy and the lowest with vaginal hysterectomy.
**Indications**

The indications for hysterectomy are listed in Table 24.1. **Uterine leiomyomas are consistently the leading indication for hysterectomy.** As expected, the **indications differ with the patient’s age** (1). Hospitalization rates for hysterectomy in women between the ages of 15 and 54 years decreased from 1998 to 2005 for all indications except for menstrual disorders (5).

Leiomyomas

The proportion of hysterectomies performed for leiomyomas decreased over time (1) (see Chapter 15). Fertility-preserving surgical management (myomectomy) is possible in most patients with leiomyomas. The decision to perform a hysterectomy for leiomyomas is usually based on the need to treat symptoms—abnormal uterine bleeding, pelvic pain, or pelvic pressure. Other indications for intervention have included “rapid” uterine enlargement, ureteral compression, or uterine growth after menopause. There is no clearly reproducible definition of rapid growth. The concept of rapid growth was challenged because these patients did not demonstrate clearly malignant conditions (6). Refuted reasons for hysterectomy in patients with leiomyomas are size greater than 12 weeks of gestation without symptoms, inability to palpate the ovaries on bimanual examination, and increased morbidity at hysterectomy with increased uterine size. If the procedures are performed abdominally, there is no difference in surgical morbidity between patients with a 12-week-sized uterus and those with a 20-week-sized uterus (7). Therefore, hysterectomy for leiomyomas should be considered only in symptomatic patients who do not desire future fertility (7).

To reduce uterine size before hysterectomy, patients with large leiomyomas may be pretreated with a gonadotropin-releasing hormone (GnRH) agonist (8,9). In many cases, the reduction of uterine size is sufficient to permit vaginal hysterectomy when an abdominal hysterectomy would otherwise be necessary. In one prospective trial, premenopausal patients with leiomyomas the size of 14 to 18 weeks' gestation were randomized to receive either 2 months of preoperative depot GnRH agonist or no GnRH agonist (8). Treatment with a short course (8 weeks) of leuprolide acetate before surgery enabled the procedures to be converted safely from an abdominal hysterectomy to a vaginal hysterectomy (9). This preoperative regimen was associated with a rise in hematocrit before surgery and a shorter hospital stay and convalescent period because patients were more likely to have a vaginal rather than an abdominal hysterectomy.
Dysfunctional Uterine Bleeding

Excessive uterine bleeding is the indication for about 20% of hysterectomies. Dysfunctional uterine bleeding assumes abnormal bleeding without an obvious anatomic cause (see Chapter 14). Anovulatory uterine bleeding is typically associated with polycystic ovary syndrome (PCOS), a condition in which anovulatory cycles are common. The bleeding can be controlled by medical intervention with progestin, estrogen, or a combination of progestin and estrogen given as oral contraceptives. Ovulatory abnormal uterine bleeding can be controlled by nonsteroidal anti-inflammatory agents, hormonal intervention, tranexamic acid, or the levonorgestrel intrauterine device. In these patients, endometrial sampling should be performed before hysterectomy (10). Dilation and curettage is not an effective means of controlling bleeding and is not necessary before hysterectomy. Hysterectomy should be reserved for patients who do not respond to or cannot tolerate medical therapy. Alternatives to hysterectomy (e.g., endometrial ablation or resection) should be considered in selected patients because these operations may be cost-effective and have a lower morbidity rate. However, in a clinical trial that randomized endometrial ablation to hysterectomy, 29% of patients assigned to the ablation underwent hysterectomy by 60 months (11).
Intractable Dysmenorrhea

About 10% of adult women are incapacitated for up to 3 days per month as a result of dysmenorrhea (see Chapter 16) (12). Dysmenorrhea can be treated with nonsteroidal anti-inflammatory agents used alone or in combination with oral contraceptives or other hormone agents to reduce or ablate menstrual flow (12). The levonorgestrel intrauterine device effectively reduces dysmenorrhea symptoms. Hysterectomy is rarely required for the treatment of primary dysmenorrhea. In patients with secondary dysmenorrhea, the underlying condition (e.g., leiomyomas, endometriosis) should be treated primarily. **Hysterectomy should be considered only if medical therapy fails or if the patient does not want to preserve fertility** (12).
Pelvic Pain
In a review of 418 women in whom hysterectomy was performed for a variety of nonmalignant conditions, 18% had chronic pelvic pain. Preoperative laparoscopy was performed in only 66% of these patients. After hysterectomy, there was a significant reduction in symptoms that was associated with an improvement in the patient’s quality of life (13). In a review of 104 patients who underwent hysterectomy for chronic pelvic pain that was believed to be of uterine origin, 78% experienced improvement in their pain after follow-up for a mean of 21.6 months (14). However, 22% of patients had no improvement in or exacerbation of their pain. Hysterectomy should be performed only in those patients whose pain is of gynecologic origin and does not respond to nonsurgical treatments (12) (see Chapter 16).
Cervical Intraepithelial Neoplasia
In the past, hysterectomy was performed as primary treatment of cervical intraepithelial neoplasia. More conservative treatments, such as laser or loop electrosurgical excision procedure (LEEP), can be effective in treating the disease, making hysterectomy unnecessary in most women with these conditions (see Chapter 19). For patients with recurrent high-grade dysplasia who do not desire to preserve fertility, hysterectomy may be an appropriate treatment option. After hysterectomy, these patients are at increased risk for vaginal intraepithelial neoplasia.
Genital Prolapse

Hysterectomy for symptomatic genital prolapse accounts for about 14.5% of hysterectomies performed in the United States (1). **Unless there is an associated condition requiring an abdominal incision, vaginal hysterectomy is the preferred approach for genital prolapse.** Uterine prolapse typically is not an isolated event and most often is associated with a variety of pelvic support defects. Each defect must be corrected to optimize the surgical outcome and decrease the risk of developing future pelvic support defects.
Obstetric Emergency
Most emergency hysterectomies are performed because of postpartum hemorrhage resulting from uterine atony. Other indications include uterine rupture that cannot be repaired or a pelvic abscess that does not respond to medical therapy. Hysterectomy may be required for patients with placenta accreta or placenta increta.
Pelvic Inflammatory Disease

Pelvic inflammatory disease can be treated successfully with antibiotics. The uterus, tubes, and ovaries should not be removed in a patient with pelvic inflammatory disease that is refractory to intravenous antibiotic therapy (see Chapter 18). Whether one proceeds with conservative surgical management, abscess drainage, or organ removal is a subjective decision that must be based on the individual. If accessible, some pelvic abscesses may be drained successfully by percutaneous catheter drainage guided by ultrasonography or computed tomography (CT) scanning. Surgical intervention is necessary if the patient has acute abdominal findings associated with peritonitis and signs of sepsis in the presence of a ruptured tubo-ovarian abscess. For the patient who desires future fertility, consideration should be given to unilateral salpingo-oophorectomy or partial bilateral salpingo-oophorectomy without hysterectomy. For the patient in whom bilateral salpingo-oophorectomy is required, the uterus can be left in place for possible ovum donation and in vitro fertilization.
Endometriosis

Medical and conservative surgical procedures are successful for treatment of endometriosis (15). **Bilateral salpingo-oophorectomy, with or without hysterectomy, should be performed only in patients who do not respond to conservative surgical (resection or ablation of endometriotic implants) or medical therapy (see Chapter 17).** Most patients with endometriosis who require hysterectomy have unrelenting pelvic pain or dysmenorrhea. Other less common situations include patients who do not desire future fertility and who have endometriosis involving other pelvic organs, such as the ureter or colon. Hysterectomy with or without salpingo-oophorectomy provides significant pain relief to the majority of patients. At the time of hysterectomy for endometriosis, consideration should be given to conserving normal ovaries (16).
Pelvic Mass or Benign Ovarian Tumor

If a pelvic mass is palpated on pelvic examination, a transvaginal ultrasound should be performed (see Chapter 14). If the mass is suspicious, appropriate consultation with a gynecologic oncologist is recommended. Benign ovarian tumors that are persistent or symptomatic require surgical treatment. If the patient desires fertility, the uterus should be conserved. If fertility is not an issue or if the patient is perimenopausal or postmenopausal, a decision must be made regarding whether the uterus should be removed. In one study, 100 patients who underwent bilateral salpingo-oophorectomy plus hysterectomy for benign adnexal disease were compared with a group of risk-matched women who underwent bilateral salpingo-oophorectomy without hysterectomy for the same indication (17). There was a significant increase in operative morbidity, estimated blood loss, and the length of hospital stay for patients in whom hysterectomy was performed.
Preoperative Considerations
The preoperative discussion should include an informed consent that documents the options, risks, benefits, outcome, and personnel involved with the procedure. The medical record should reflect the completion of childbearing and that adequate trial of medical or nonsurgical management was offered, attempted, or refused.
Health Assessment

An assessment of a patient’s health status is important in order to obtain an optimal outcome after hysterectomy for benign disease. There are no routinely recommended tests, although individual hospitals may have their own requirements. The patient should be evaluated for risk factors associated with venous thromboembolic events (18). Age, medical history, such as inherited or acquired thrombophilias, obesity, smoking, and hormonal medication, including contraceptives or hormone therapy, may increase the risk.

It is important to assess and correct underlying anemias before surgery. Blood product use can be minimized with preoperative iron supplementation or use of GnRH agonists.
Hysterectomy versus Supracervical Hysterectomy

There is a trend toward retention of the cervix at hysterectomy because of the perception that several outcome parameters, including sexual function and pelvic support, are better after a supracervical hysterectomy. Three prospective randomized clinical trials as summarized in a Cochrane review challenge this perception (19). There was no evidence to support the concept that leaving the cervix improves sexual function or lower rates of incontinence or constipation. All of these studies included hysterectomies that were performed by laparotomy. Surgical time was decreased by approximately 11 minutes. This decreased surgical time may be more significant for laparoscopic cases, as the most difficult part of the surgery is the detachment of the cervix from the lateral ligaments and from the vagina. This is where most ureteral injuries occur during laparoscopic hysterectomy. This advantage should be balanced with the potential risk of ongoing cyclic bleeding from the cervix that is reportedly between 5% to 20% from the randomized clinical trials and 19% from a prospective observational laparoscopic trial (20). With conservation of the cervix, the patient should be told there is a potential 1% to 2% risk for reoperation to remove the cervix and that trachelectomy is associated with a risk of intraoperative complications. Patients with suspected gynecologic cancers or cervical dysplasia are not candidates for supracervical hysterectomy.
Prophylactic Salpingo-oophorectomy

The decision to remove the ovaries and tubes should be based on assessment of risk and not the route of hysterectomy (21). Premenopausal women who are at average risk of ovarian cancer (approximate lifetime risk of 1.4%) should be considered for ovarian preservation when they are undergoing hysterectomy for benign conditions where the ovaries and fallopian tubes are healthy (22). Parous women who have used oral contraceptives may have a substantially lower risk (22). Elective removal of the ovaries and fallopian tubes has declined since 2002 (23).

Salpingo-oophorectomy is performed prophylactically to prevent ovarian cancer and to eliminate the potential for further surgery for either benign or malignant disease. Arguments against prophylactic salpingo-oophorectomy center on the need for earlier and more prolonged hormone therapy and the potential increase risk of cardiovascular disease and bone loss (24,25). There is no overall survival benefit of prophylactic salpingo-oophorectomy in women at average risk for ovarian cancer. In premenopausal women before age 50 years at average risk for ovarian cancer who underwent bilateral salpingo-oophorectomy, there was a significant increase in mortality from cardiovascular disease compared to women who had ovarian preservation (25). A Markov decision analysis model was used to estimate the best strategy for maximizing a woman’s survival when salpingo-oophorectomy is considered in women at average risk for ovarian cancer who are undergoing hysterectomy for benign disease, and in the women who had salpingo-oophorectomy before age 55 years, there was an 8.58% excess mortality by age 80 (26). Both the American College of Obstetricians and Gynecologists and the Society of Gynecologic Oncologists recommend carefully assessing risk, and consideration should be given to conservation of the ovaries in premenopausal women who are at average risk of ovarian cancer (21,22).

Although estrogen therapy is well tolerated and provides good short-term symptomatic relief, recent publications demonstrate that the increased risk of breast cancer in women taking estrogen after hysterectomy makes women reluctant to use it, and long-term compliance with posthysterectomy estrogen therapy is low (27).

In women at risk for ovarian or breast cancer, a formal evaluation with genetic counseling should be offered (see Chapter 37). Salpingo-oophorectomy is associated with a reduced risk of ovarian and breast cancer. Women with a strong family history of ovarian and breast cancer and those who carry germline mutations, BRCA1 or BRCA2 should undergo risk-reducing salpingo-oophorectomy as their lifetime risk is between 10% and 50% (21,22,28,29).

Based on the finding that many serous carcinomas arise in the fallopian tube rather than in the ovary, it was proposed that bilateral salpingectomy with ovarian conservation should be performed in patients with these high penetrance germline mutations while awaiting more definitive surgical intervention (30,31). One could consider this in women at average risk for these tumors when they undergo hysterectomy for benign disease. It
is unknown whether this would substantially decrease the risk of developing these malignancies.
Although salpingo-oophorectomy can be accomplished by laparoscopy or laparotomy in virtually 100% of cases, the success rate for vaginal hysterectomy ranges from 65% to 95% for experienced vaginal surgeons (32,33).
Concurrent Surgical Procedures

Appendectomy
Appendectomy may be performed concurrently with hysterectomy to prevent appendicitis and to remove disease that may be present. The former use is of limited value because the peak incidence of appendicitis is between 20 and 40 years of age, whereas the peak age for hysterectomy is 10 to 20 years later (34). **There is no increase in morbidity associated with appendectomy performed at the time of hysterectomy** (35). Incidental appendectomies in all abdominal hysterectomies could reduce the morbidity of appendicitis at a later time (35). Appendectomy is performed with vaginal hysterectomy without additional intraoperative or postoperative morbidity (36).

Cholecystectomy
Gallbladder disease is about four times more common in women than men, and its highest incidence occurs between 50 and 70 years of age, when hysterectomy is most often performed. Women may require both procedures. A combined procedure does not appear to result in increased febrile morbidity or length of hospital stay (37).

Abdominoplasty
Abdominoplasty performed at the time of hysterectomy is associated with a shorter hospital stay, a shorter operating time, and a lower intraoperative blood loss than when the two operations are performed separately (38,39). Liposuction can be performed safely at the time of vaginal hysterectomy (40).
Choice of Surgical Access: Vaginal, Abdominal, or Laparoscopic Hysterectomy

From 2000 to 2004, approximately 68% of all hysterectomies were performed abdominally and 32% were performed vaginally. One-third of the vaginal cases were performed with the assistance of the laparoscope (laparoscopically assisted vaginal hysterectomy) (1). There are no specific criteria that can be used to determine the route of hysterectomy. The route chosen should be based on the individual patient, but vaginal access is preferred. An alternative access is preferred if there is a narrow pubic arch (less than 90 degrees), and a narrow vagina (narrower than two fingerbreadths, especially at the apex), or if the there is an undescended immobile uterus. The presence of an adnexal mass, cul-de-sac disease, pelvic adhesions, or the assessment of chronic pain may require the addition of laparoscopy for assessment. A previous cesarean section or nulliparity does not contraindicate a vaginal approach (41).

A Cochrane review validated the perception that vaginal hysterectomy is the surgical route of choice for hysterectomy (42). This review included 3,643 patients from 27 randomized trials. It compared abdominal hysterectomy with vaginal hysterectomy and three types of laparoscopic hysterectomies. The main observations were the shorter length of hospital stay, faster postoperative recovery, and decreased febrile morbidity of vaginal and laparoscopic hysterectomy compared with abdominal hysterectomy. The report concludes that there are improved outcomes with vaginal hysterectomy, and, when vaginal access is not possible, laparoscopic hysterectomy appears to have advantages over abdominal hysterectomy. Cost-analysis trials demonstrate that laparoscopic hysterectomy can be cost-effective relative to abdominal procedure but not compared with vaginal hysterectomy (43,44). The main cost determinants are the length of hospital stay and the use of disposable surgical devices.

Risk of complication from each type of procedure provides insight into the proper options for the patient. The eVALuate study comprised two parallel randomized multicenter trials, with one comparing laparoscopic with abdominal hysterectomy and the other comparing laparoscopic with vaginal hysterectomy for nonmalignant disease (45). Patients with a uterine mass less than 12-week pregnancy were included. The primary end points were assessment of complications. A total of 1,380 patients were recruited. The trial included conversion to laparotomy for the laparoscopic and vaginal groups as a major complication. If you include conversion to laparotomy as a major complication, the number treated relative to those harmed was 20 for the laparoscopic group compared with the abdominal group. If you exclude conversion to laparotomy as a complication, then the complication rates are similar between all groups. All six ureter injuries reported in this series occurred in the laparoscopic group. The overall lower urinary tract complication rate is three times higher with the laparoscopic group compared with vaginal or abdominal procedures. A minor complication, mostly postoperative fever or infection, occurred in approximately 25% of each group.
Perioperative Checklist

It is important to systematically go through a checklist of perioperative measures to effectively reduce potential complications (Table 24.2). If excessive blood loss is expected, intraoperative blood salvage techniques should be considered. All patients undergoing hysterectomy for benign disorders are at moderate risk for venous thromboembolism and require prophylaxis (18). Unfractionated heparin (5,000 U every 12 hours) or low molecular weight heparin (e.g., Enoxaparin, 40 mg) or intermittent pneumatic compression device is recommended. Patients on oral contraceptives up to the time of hysterectomy should be considered for pharmacologic treatment. Mechanical bowel preparation for prevention of infection complications from bowel injury is no longer recommended (46).

Table 24.2 Perioperative Checklist

1. Is the informed consent signed?
2. Is there a recent Pap test documented in the chart?
3. Has pregnancy been ruled out?
4. Are blood products available if needed?
5. Will prophylactic antibiotics be initiated within 1 hour of incision?
6. Was the appropriate antibiotic selected according to American College of Obstetricians and Gynecologists guidelines?
7. Was the appropriate prophylaxis for venous thromboembolic events chosen?
8. Document that prophylactic antibiotics will be discontinued within 24 hours after surgery.
Technique
Abdominal Hysterectomy

General Preparation
To reduce the colony count of skin bacteria, the patient is asked to shower. Hair surrounding the incision area may be removed at the time of surgery or before surgery using a depilatory agent. Hair clipping is preferable to shaving because it decreases the incidence of incisional infection, and if shaving is done, it should be performed in the operating room just prior to the surgery (34).

Patient Positioning
For most abdominal cases, the patient is placed in the dorsal supine position for the operation. After the patient is anesthetized adequately, her legs are placed in the stirrups and a pelvic examination is performed to validate the in-office pelvic examination findings. A Foley catheter is placed in the bladder, and the vagina is cleansed with an iodine solution. The patient’s legs are straightened.

Skin Preparation
Several methods for skin cleaning can be recommended, including a 5-minute iodine solution scrub followed by application of iodine solution, iodine solution scrub followed by alcohol with application of an iodine-impregnated occlusive drape, or an iodine-alcohol combination with or without application of an iodine-impregnated occlusive drape.

Surgical Technique

Incision
The choice of incision should be determined by the following considerations:

- Simplicity of the incision
- Need for exposure
- Potential need for enlarging the incision
- Strength of the healed wound
- Cosmesis of the healed incision
- Location of previous surgical scars

The skin is opened with a scalpel, and the incision is carried down through the subcutaneous tissue and fascia. With traction applied to the lateral edges of the incision, the fascia is divided. The peritoneum is opened similarly. This technique minimizes the possibility of inadvertent enterotomy, entering the abdominal cavity.

Abdominal Exploration
Cytologic sampling of the peritoneal cavity, if needed, should be performed before abdominal exploration. The upper abdomen and the pelvis are explored systematically. The liver, gallbladder, stomach, kidneys, para-aortic lymph nodes, and large and small bowel should be examined and palpated.

Retractor Choice and Placement
A variety of retractors were designed for pelvic surgery. The Balfour and the O'Connor-O'Sullivan retractors are used most often. The Bookwalter retractor has a variety of adjustable blades that can be helpful, particularly in obese patients.

Elevation of the Uterus
The uterus is elevated by placing broad ligament clamps at each cornu so that it crosses the round ligament. The clamp tip may be placed close to the internal os. This placement provides uterine traction and prevents back bleeding (Fig. 24.1).

Figure 24.1 The uterus is elevated by placement of clamps across the broad ligament. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)

Round Ligament Ligation or Transection
The uterus is deviated to the patient’s left side, stretching the right round ligament. With the proximal portion held by the broad ligament clamp, the distal portion of the round ligament is ligated with a suture ligature or simply transected with Bovie cautery (Fig. 24.2). The distal portion can be grasped with forceps, and the round ligament is cut to separate the anterior and posterior leaves of the broad ligament. The anterior leaf of the broad ligament is incised with Metzenbaum scissors or electrocautery along the vesicouterine fold, separating the peritoneal reflection of the bladder from the lower
uterine segment (Fig. 24.3).

Figure 24.2 The round ligament is transected and the broad ligament is incised and opened. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)

Figure 24.3 The incision in the anterior broad ligament is extended along the vesicouterine fold. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)
Ureter Identification

The retroperitoneum is entered by extending the incision cephalad on the posterior leaf of the broad ligament. Care must be taken to remain lateral to both the infundibulopelvic ligament and iliac vessels. The external iliac artery courses along the medial aspect of the psoas muscle and is identified by bluntly dissecting the loose alveolar tissue overlying it. By following the artery cephalad to the bifurcation of the common iliac artery, the ureter is identified crossing the common iliac artery. The ureter should be left attached to the medial leaf of the broad ligament to protect its blood supply (Fig. 24.4).

Figure 24.4 Identification of the ureter in the retroperitoneal space on the medial leaf of the broad ligament. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)
If the ovaries are to be preserved, the uterus is retracted toward the pubic symphysis and deviated to one side, placing tension on the contralateral ovarian vessels (the so-called infundibulopelvic ligament), the tube, and the ovary. **With the ureter under direct visualization, a window is created in the peritoneum of the posterior leaf of the broad ligament under the utero-ovarian ligament and fallopian tube.** The tube and utero-ovarian ligament are clamped on each side with a curved Heaney or Ballantine clamp, cut, and ligated with both a free-tie and a suture ligature. The medial clamp at the uterine cornu should control back bleeding; if it does not, the clamp should be repositioned to do so (Fig. 24.5).

Figure 24.5 Ligation of the utero-ovarian ligament. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)
If the ovaries are to be removed, the peritoneal opening is enlarged and extended cephalad to the ovarian vessels (infundibulopelvic ligament) and caudad to the uterine artery. This opening allows proper exposure of the uterine artery, the ovarian vessels, and the ureter. In this manner, the ureter is released from its proximity to the uterine vessels and uterine vessels.

A curved Heaney or Ballantine clamp is placed lateral to the ovary (Fig. 24.6); care is taken to ensure that the entire ovary is included in the surgical specimen. The uterine vessels on each side are doubly ligated and cut (Fig. 24.7). Alternatively, free ties can be passed around the uterine vessels, two cephalad and one caudad, before they are cut.

Figure 24.6 Ligation of the infundibulopelvic ligament. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)
Bladder Mobilization

Using Metzenbaum scissors or Bovie, the bladder is dissected from the lower uterine segment and cervix. An avascular plane, which exists between the lower uterine segment and the bladder, allows for this mobilization. Tonsil clamps may be placed on the bladder edge to provide countertraction and easier dissection (Fig. 24.8).
Uterine Vessel Ligation

The uterus is retracted cephalad and deviated to one side of the pelvis, stretching the lower ligaments. The uterine vasculature is dissected or “skeletonized” from any remaining areolar tissue, and a curved Zeppelin or Heaney clamp is placed perpendicular to the uterine artery at the junction of the cervix and body of the uterus. Care is taken to place the tip of the clamp adjacent to the uterus at this anatomic narrowing. The vessels are cut, and the pedicle is ligated. The same procedure is repeated on the opposite side (Fig. 24.9).

Figure 24.9 Ligation of the uterine blood vessels. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)
Incision of Posterior Peritoneum

If the rectum is to be mobilized from the posterior cervix, the posterior peritoneum between the uterosacral ligaments just beneath the cervix and rectum may be incised (Fig. 24.10). A relatively avascular tissue plane exists in this area, allowing mobilization of the rectum inferiorly out of the operative field.

Figure 24.10 Incision of the rectouterine peritoneum and mobilization of the rectum from the posterior cervix. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)
Cardinal Ligament Ligation
The cardinal ligament is divided by placing a straight Zeppelin or Heaney clamp medial to the uterine vessel pedicle for a distance of 2 to 3 cm parallel to the uterus. The ligament is cut, and the pedicle is suture ligated. This step is repeated on each side until the junction of the cervix and vagina is reached (Fig. 24.11).

Figure 24.11 Ligation of the cardinal ligament. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)

Removal of the Uterus
The uterus is placed on traction cephalad, and the tip of the cervix is palpated. Curved Heaney clamps are placed bilaterally, incorporating the uterosacral ligament and upper vagina just below the cervix. Care should be taken to avoid foreshortening the vagina. The uterus is then removed with scalpel or curved scissors (Fig. 24.12).

Figure 24.12 Removal of the uterus by transection of the vagina. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996.)
Vaginal Cuff Closure

A figure-of-eight suture of 0 braided absorbable material is placed at the angle of the vagina for both traction and hemostasis. The pedicles are sutured with a Heaney stitch, incorporating the uterosacral and cardinal ligament at the angle of the vagina (Fig. 24.13). A running-locked suture can be used for hemostasis along the cuff edge (Fig. 24.14).

Figure 24.13 Vaginal cuff closure incorporating the uterosacral and cardinal ligaments. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)

Figure 24.14 A: Vaginal cuff left open with a running suture along the cuff. B: Peritoneum closed. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)
Irrigation and Hemostasis
The pelvis is thoroughly irrigated with saline. Meticulous hemostasis in the pelvis, particularly of the vascular pedicles, should be ensured. Ureteral position and integrity are checked to ensure that they are intact and do not appear dilated.

Peritoneal Closure
The pelvic peritoneum is not reapproximated. Research using animal models suggests that reapproximation may increase tissue trauma and promote adhesion formation (47).

Fascia Closure
The parietal peritoneum is not reapproximated as a separate layer. Fascia can be closed with an interrupted or continuous 0 or 1 monofilament absorbable suture. A prospective randomized trial did not show any advantage of interrupted versus continuous fascial closure (48). Bites should be taken about 1 cm from the cut edge of the fascia and about 1 cm apart to prevent wound dehiscence.

Skin Closure
The subcutaneous tissue should be irrigated, with careful hemostasis. Wound disruption seems to be decreased with closure of the subcutaneous fat layer in women with 2 cm or more fat (49). Skin staples or subcuticular sutures are used to reapproximate the skin edges. A dressing is applied and left in place for about 24 hours.

Intraoperative Complications
Every surgeon must be prepared to recognize and repair operative injuries, because despite a high level of attention to detail, injuries and complications, recognized and unrecognized, can still occur.

Ureteral Injuries
Injury to the pelvic ureter is one of the most formidable complications of hysterectomy (50). It is always essential to be aware of the proximity of the ureter to the other pelvic structures. Most ureteral injuries can be avoided by opening the retroperitoneum and directly identifying the ureter. The use of ureteral catheters as a substitute for direct visualization is often of little help in patients with extensive fibrosis or scarring resulting from endometriosis, pelvic inflammatory disease, or ovarian
cancer. In these instances, a false sense of security may increase an already high risk for ureteral injury. The use of ureteral catheters are associated with hematuria and acute urinary retention, although their complications are usually transitory in nature.

Direct visualization is accomplished by opening the retroperitoneum lateral to the external iliac artery. Blunt dissection of the loose areolar tissue is performed to visualize the artery directly. The artery may be traced cephalad to the bifurcation of the internal and external iliac arteries. The ureter crosses the common iliac artery at its bifurcation and may be followed throughout its course in the pelvis.

Despite these precautions, ureteral injuries may occur. Prompt consultation is necessary if the surgeon is not trained in ureteral repair. If a ureteral obstruction is suspected, confirmation may be obtained by intravenous injection of 1 ampule of indigo carmine dye and performance of a cystoscopic evaluation. The integrity of the ureters should be confirmed by the presence or absence of bilateral spill of tinted urine.

**Bladder Injury**

Because of the close anatomic relationship of the bladder, uterus, and upper vagina, the bladder is the segment of the lower urinary tract that is most vulnerable to injury. **Bladder injury may occur on opening the peritoneum or, more frequently, during the dissection of the bladder off the cervix and upper vagina.** Unless there is involvement of the bladder trigone, a bladder laceration is easily repaired. In the nonirradiated bladder, a one- or two-layer closure with a small-caliber braided absorbable suture such as a 3-0 polyglycolic acid is adequate. The bladder should be drained postoperatively. The length of time that drainage is required is controversial. If the bladder is not compromised, drainage should be continued at least until gross hematuria clears, which may occur as soon as 48 hours postoperatively. A more conservative practice is to continue drainage for 3 to 14 days depending on the type of injury (50). Elective incision into the dome of the bladder is performed in the same manner. If the trigone is involved, a surgeon trained in complicated urologic repair should be consulted, because reimplantation of the ureter may be necessary.

**Bowel Injury**

Small bowel injuries are the most common intestinal injuries in gynecologic surgery. Small defects of the serosa or muscularis may be repaired using a single layer of continuous or interrupted 3-0 braided absorbable suture. Although single-layer closure of the small bowel has proved adequate, it is safer to close defects involving the lumen in two layers using a 3-0 braided absorbable suture. **The defect should be closed in a direction perpendicular to the intestinal lumen.** If a large area is injured, resection with reanastomosis may be necessary. Because the bacterial flora of the ascending colon is similar to that of the small bowel, injuries can be repaired in a similar manner. The transverse colon rarely is injured in normal gynecologic procedures because it is well outside the operative field. However, the descending colon and the rectosigmoid colon
are intimately involved with the pelvic structures and are at significant risk for injury during gynecologic surgery. Injuries not involving the mucosa may be repaired with a single running layer of 2-0 or 3-0 braided absorbable suture. If the laceration involves the mucosa, it may be closed as with small bowel injuries.

Hemorrhage

**Significant arterial bleeding usually arises from the uterine arteries or the ovarian vessels near the insertion of the infundibulopelvic ligaments.** Blind clamping of these vessels presents a risk for ureteral injury; therefore, the ureters should be identified in the retroperitoneal space and traced to the area of bleeding to avoid inadvertent ligation. **It is best to apply a pressure pack to tamponade the bleeding and slowly remove the pack in an effort to visualize, isolate, and individually clamp the bleeding vessels.** Mass ligatures should be avoided. The use of surgical clips may be helpful. Venous bleeding is less dramatic but often is more difficult to manage, particularly in the presence of extensive adhesions and fibroids. This type of bleeding can be controlled with pressure alone or with suture ligation. Bleeding from peritoneal edges or denuded surfaces may be controlled with pressure, application of topical agents such as thrombin or collagen, or Bovie cautery. A variety of laser techniques are used to control bleeding, such as the use of the Argon beam laser.

**Postoperative Management**

**Bladder Drainage**

Overdistention of the bladder resulting from bladder trauma or the patient’s reluctance to initiate the voluntary phase of voiding is one of the most common complications after abdominal hysterectomy. An indwelling bladder catheter should be used for the first few postoperative hours until the patient is able to ambulate and urinate.

If retropubic urethropexy was performed, a suprapubic catheter, which allows postvoid residual levels to be checked without repetitive catheterizations, can be considered. This catheter may be removed when satisfactory postvoid residual levels of less than 100 mL are obtained.

**Diet**

As soon as the patient is alert, diet is resumed, offering solid foods as tolerated with return of appetite. This dietary regimen assumes minimal intraoperative bowel manipulation and dissection. **Early postoperative feeding was shown to be safe and to speed return of bowel function and recovery.** In patients who had pelvic and para-aortic lymphadenectomy, bowel surgery, or other extensive dissections, a slower return to normal bowel function may occur, so the diet is administered as tolerated when the patient’s appetite returns.

**Activity**
Early ambulation decreases the incidence of thrombophlebitis and pneumonia. Patients are encouraged to begin ambulation on their first postoperative day if possible and to increase their time out of bed progressively as their strength improves. **On discharge, the patient is instructed to avoid lifting more than 20 pounds for 6 weeks, thereby minimizing stress on fascia to allow full healing. Sexual intercourse is not recommended until 6 weeks after surgery, when the vaginal cuff is fully healed.** Patients are instructed to avoid driving until full mobility returns because postoperative pain and tenderness may hinder sudden braking or steering maneuvers in emergency situations. With these exceptions, the patient is encouraged to return to normal activities as soon as she feels comfortable doing so.

**Wound Care**

The abdominal incision normally requires little attention, except for ordinary hygienic measures. The wound is kept covered with a sterile dressing for the first 24 hours after surgery, by which time the incision has sealed. After the dressing is removed, the incision should be cleaned daily with mild soap and water and kept dry.
Vaginal Hysterectomy

Preoperative Evaluation

Evaluation of Pelvic Support
The most important observation in determining the feasibility of a vaginal hysterectomy is the demonstration of uterine mobility (51). A vaginal approach should be chosen only if the uterus is freely mobile. Pelvic support structures are elevated at the initial pelvic examination. In patients with no apparent prolapse, poor pelvic support can often be demonstrated by observing descent of the uterus with a series of Valsalva maneuvers. Although vaginal hysterectomy is easier to perform when the uterine supporting ligaments are lax, it is not an absolute requirement. The practice of applying traction to the cervix with a tenaculum to demonstrate descent of an apparently well-supported uterus is not recommended. Some gynecologists advocate the application of a tenaculum to the anterior cervical lip, with subsequent traction applied as the patient bears down. This exercise may give some indication of uterine mobility, but it is uncomfortable and not necessarily predictive of the success of vaginal hysterectomy.

Evaluation of the Pelvis
After assessment of pelvic support, the bony pelvis should be evaluated. Ideally, the angle of the pubic arch should be 90 degrees or greater, the vaginal canal should be ample, and the posterior vaginal fornix should be wide and deep. The surgeon may use a closed fist to approximate the bituberous diameter, which should exceed 10 cm. The size and shape of the female pelvis contributes to increased exposure. The importance of a wide pubic arch was underscored by the result of a study of 25 failed vaginal hysterectomies that were compared with 50 successful vaginal hysterectomies. Risk factors, such as age, parity, body weight, surgical indication, uterine size, presence of leiomyomata in the anterior lower uterine segment, previous pelvic surgeries, adhesions, location and length of the cervix, and narrow pubic arch (less than 90 degrees), were examined. In the study, only the presence of a narrow pubic arch increased the risk of vaginal hysterectomy (52).

Surgical Considerations

Patient Positioning
When the patient is in the dorsal lithotomy position, the buttocks should be positioned just over the table’s edge. Several stirrup types are available, including those that support the entire leg and those that suspend the legs in straps. To avoid nerve injury, adequate padding should be used; marked flexion of the thigh and pressure points should be avoided. Trendelenburg (10- to 15-degree) positioning aids in the intravaginal visualization needed during surgery.
Vaginal Preparation

A povidone-iodine solution is applied to the vagina, the bladder is drained, and the catheter is removed. Several methods for draping are proposed, including individual or single-piece drapes; the method chosen is at the surgeon's discretion. There is usually no need to shave or clip the pubic hair. Individual drapes with an adhesive barrier should be used to hold them in place and prevent the pubic hair from compromising the field.

Instruments

Instruments specific to and useful in performing a vaginal hysterectomy include right-angled retractors, narrow Deaver retractors, weighted specula, Heaney needle holders, and an assortment of Breisky–Navratil vaginal retractors. Heaney and Heaney–Ballantine hysterectomy clamps are preferable. Several other clamps are commonly used, including the Masterson clamp.

Lighting

Overhead high-intensity lamps should be used and positioned to direct light over the operator's shoulder. The surgeon may use a headlight, which can be worn to provide direct horizontal lighting. A fiberoptic-lighted irrigating suction system can provide additional light and transilluminate tissue planes.

Suture Material

Various suture materials are advocated for gynecologic surgery. The type of suture material chosen is based on the surgeon's preference. A synthetic delayed absorbable polyglactin or polyglycolic acid suture and atraumatic needles are preferable.

Procedure

The patient is examined while anesthetized to confirm prior findings and to assess uterine mobility and descent. The decision whether to proceed vaginally or abdominally is made.

Grasping and Circumscribing the Cervix

The anterior and posterior lips of the cervix are grasped with a single- or double-toothed tenaculum. With downward traction applied on the cervix, a circumferential incision is made in the vaginal epithelium at the junction of the cervix (Fig. 24.15).

Figure 24.15 Circumferential incision in the vagina to infiltrate a vaginal hysterectomy. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)
Dissection of Vaginal Mucosa

After the initial incision is made with a scalpel or a Bovie, the vaginal epithelium may be dissected sharply from the underlying tissue or pushed bluntly with an open sponge (Fig. 24.16). If the initial incision is made too close to the external cervical os, a greater amount of dissection is required and causes associated bleeding. This circumscribing incision should be made just below the bladder reflection. It is important to continue the dissection in the correct cleavage plane to minimize blood loss.

Figure 24.16 Dissection of the vaginal mucosa. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)
Posterior Cul-de-Sac Entry

The peritoneal reflection of the posterior cul-de-sac (cul-de-sac of Douglas) can be identified by stretching the vaginal mucosa and underlying connective tissue with forceps (Fig. 24.17). If difficulty is encountered (e.g., if the cervix is elongated and the peritoneum is not evident), the vaginal mucosa may be incised vertically to the point at which the cul-de-sac becomes more apparent.

Figure 24.17 Entry into the posterior cul-de-sac. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)

If the vaginal mucosa is dissected in the wrong plane, the hysterectomy may begin extraperitoneally by clamping and cutting the uterosacral and cardinal ligaments close to the cervix. The posterior cul-de-sac will be readily identifiable. If the peritoneal reflection of the posterior cul-de-sac cannot be identified, entry into the anterior peritoneum is attempted, and a finger is hooked into the posterior cul-de-sac to place tension on the peritoneum. The peritoneum is opened with Mayo scissors. An interrupted suture is placed to approximate the peritoneum and vaginal cuff and provide hemostasis (Fig. 24.18). The posterior pelvic cavity is examined for pathologic alterations of the uterus or adhesive disease of the cul-de-sac. The weighted speculum is placed into the posterior cul-de-sac.

Figure 24.18 Interrupted suture is placed on posterior vaginal cuff and peritoneum for hemostasis. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)
Uterosacral Ligament Ligation

With retraction of the lateral vaginal wall and countertraction on the cervix, the uterosacral ligaments are clamped with the tip of the clamp incorporating the lower portion of the cardinal ligaments (Fig. 24.19). The clamp is placed perpendicular to the uterine axis, and the pedicle is cut and sutured close to the clamp. A small pedicle (0.5 cm) distal to the clamp is optimal because a larger pedicle becomes necrotic and the tissue sloughs, which may become a culture medium for micro-organisms. The pedicle should be incised no more than one-half to three-fourths of the way around the tip of the clamp. Limiting the incision prevents the next pedicle, which may be vascular, from being cut.

Figure 24.19 Ligation of the uterosacral ligaments. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)
When suturing any pedicle, the needle point is placed at the tip of the clamp, and the needle is passed through the tissue by a rolling motion of the operator’s wrist. Once ligated, the uterosacral ligaments may be transfixed to the posterolateral vaginal mucosa (Fig. 24.20). This suture may lend additional support to the vagina and provide hemostasis at this point on the vaginal mucosa. This suture is held with a hemostat to facilitate location of any bleeding at the completion of the procedure and to aid in the closure of vaginal mucosa.

Figure 24.20 Transfixion of the uterosacral ligament to the posterolateral vaginal mucosa. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)

Entry versus Nonentry into the Vesicovaginal Space (Cul-de-Sac)

Downward traction is placed on the cervix. Using either Mayo scissors, with the points directed toward the uterus, or an open moistened 4 × 4 gauze sponge, the bladder is advanced. If the vesicovaginal peritoneal reflection is easily identified at this point, the vesicovaginal space may be entered. Otherwise, it may be preferable to delay entry. There is no danger in delaying entry so long as the operator ascertains that the bladder was advanced.

After the bladder is advanced, a curved Deaver or Heaney retractor is placed in the midline, holding the bladder out of the operative field. This process precedes each step of the vaginal hysterectomy until the vesicovaginal space is entered.

Cardinal Ligament Ligation

With traction on the cervix continued, the cardinal ligaments are identified, clamped, and
cut. The suture is ligated (Fig. 24.21).

Figure 24.21 Ligation of the cardinal ligament. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)

Advancement of Bladder
The bladder again is advanced out of the operative field. A blunt dissection technique may be used; sharp dissection may be helpful if the patient had previous surgery, such as cesarean delivery, which may have scarred the bladder reflection.

Uterine Artery Ligation
Contralateral and downward traction are placed on the cervix. With an effort to incorporate the anterior and posterior leaves of the visceral peritoneum, the uterine vessels are identified, clamped, and cut, and the pedicle is suture ligated (Fig. 24.22). A single suture and single clamp technique is adequate and decreases the potential risk for ureteral injury. When the uterus is large or when a fibroid distorts the anatomic relationships, a second suture may be required to ligate any remaining branches of the uterine artery.

Figure 24.22 Ligation of the uterine artery. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996.)
Entry into the Vesicovaginal Space

The anterior peritoneal fold can be identified just before or after clamping and suture ligation of the uterine arteries. The anterior peritoneal cavity should not be opened blindly because of the increased risk of bladder injury (Fig. 24.23). The peritoneum is grasped with forceps, tented, and opened using scissors with the tips pointed toward the uterus. A Heaney or Deaver retractor is placed, and the peritoneal contents are identified. This retractor serves to keep the bladder out of the operative field.

Figure 24.23 Entry into the vesicovaginal space. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)

Delivery of the Uterus
A tenaculum is placed onto the uterine fundus in a successive fashion to deliver the fundus posteriorly (Fig. 24.24). The operator’s index finger is used to identify the utero-ovarian ligament and aid in clamp placement.

Figure 24.24 Delivery of the uterine fundus posteriorly. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)

Utero-ovarian and Round Ligament Ligation

With the posterior and anterior peritoneum opened, the remainder of the broad ligament and utero-ovarian ligaments are clamped, cut, and ligated (Fig. 24.25). The utero-ovarian and round ligament complexes are double ligated with a suture tie followed by a ligature medial to the first suture. A hemostat is placed on the second suture to aid in the identification of any bleeding and to assist with peritoneal closure. A hemostat should not be placed on the first suture or any other vascular pedicle to avoid the risk for loosening the tie.

Figure 24.25 Ligation of the utero-ovarian and round ligaments. (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)
Removal of the Ovaries

During the removal of the adnexa, the round ligaments should be removed separately from the adnexal pedicles. Traction is placed on the utero-ovarian pedicle. The ovary is drawn into the operative field by grasping it with a Babcock clamp. A Heaney clamp is placed across the ovarian vessels (infundibulopelvic ligament), and the ovary and tube are excised (Fig. 24.26). A transfixion tie and suture ligature are placed on the ovarian vessels. The surgeon should not be reluctant to remove the fallopian tube separately from the ovary if taking them together risks loss of the tissue pedicle or injury to the ureter or nearby blood vessels.

Figure 24.26 Removal of the ovaries and fallopian tubes by clamping across the ovarian vessels (infundibulopelvic ligament). (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)

Hemostasis
A retractor or tagged sponge is placed into the peritoneal cavity, and each of the pedicles is visualized and inspected for hemostasis. If additional sutures are required, they should be placed precisely, with care to avoid the ureter or bladder.

**Peritoneal Closure**

**Because the pelvic peritoneum does not provide support and re-forms within 24 hours after surgery, the peritoneum need not be reapproximated routinely.** If it is important, the anterior peritoneal edge is identified and grasped with forceps. A continuous absorbable 0 suture is begun at the 12-o'clock position. The suture is continued in a purse-string fashion and incorporates the distal portion of the left upper pedicle and the left uterosacral ligament (Fig. 24.27). At the beginning of the procedure tension is applied to the suture that incorporates the posterior peritoneum and vaginal mucosa. This allows for high posterior reperitonealization, which shortens the cul-de-sac and helps prevent future enterocele formation. The right uterosacral ligament and the distal portion of the right upper pedicle are incorporated, and this continuous suture ends at the point on the anterior peritoneum where it began.

**Figure 24.27 Closure of the peritoneum.** (From Mann WA, Stovall TG. Gynecologic surgery. New York: Churchill Livingstone, 1996, with permission.)

**Vaginal Mucosa Closure**

The vaginal mucosa can be reapproximated in a vertical or horizontal manner, using either interrupted or continuous sutures (Fig. 24.28). The vaginal mucosa is, in this case, reapproximated horizontally with interrupted absorbable sutures. The sutures are placed through the entire thickness of the vaginal epithelium, with care taken to avoid entering the bladder anteriorly. These sutures will obliterate the underlying dead space and produce an anatomic approximation of the vaginal epithelium, thereby decreasing the postoperative formation of granulation tissue.
Bladder Drainage

After completion of the procedure, the bladder is drained. Unless an anterior or posterior colporrhaphy or other reconstructive procedure is performed, neither bladder catheter nor vaginal packing is mandatory.

Surgical Techniques for Selected Patients

Injection of Vaginal Mucosa

The use of paracervical and submucosal injection of 20 to 30 mL of 0.5% lidocaine with 1:200,000 epinephrine before incision of the vaginal mucosa may decrease postoperative pain and facilitate identification of surgical planes. There is no need to inject the cervix. Areas to be injected include the bladder pillars, lower portion of the cardinal ligament, uterosacral ligaments, and paracervical tissue. The incidence of cuff cellulitis and cuff abscess formation is increased when epinephrine is injected into the cervicovaginal mucosa.

Morcellation of the Large Uterus

Uterine morcellation is a well-known but underutilized surgical procedure whereby the uterus is removed piecemeal. Several methods of uterine morcellation were described, including hemisection or bivalving, wedge or “V” incisions, and intramyometrial coring (53). Before beginning any morcellation procedure, the uterine vessels must be ligated, and the peritoneal cavity must be entered. When uterine hemisection or bivalving is performed, the cervix is split at the midline, and the uterus is cut into halves, which are removed separately (53). This method seems best suited for fundal, midline leiomyomas. Wedge morcellation is best suited for anterior or posterior fibroids or for
fibroids in the other broad ligaments (i.e., when the fibroids are away from the midline). The cervix is amputated, and the myometrium is grasped with clamps. Wedge-shaped portions of myometrium are removed from the anterior or posterior uterine wall. The apex of the wedge is kept in the midline, thereby reducing the bulk of the myometrium. This process is repeated until the uterus can be removed or until a pseudocapsule of a fibroid can be grasped with a Leahy clamp or towel clip. Traction is applied, and a “myomectomy” is performed.

When the intramyometrial coring technique is used, the myometrium above the site of the ligated vessels is incised parallel to the axis of the uterine cavity and serosa of the uterus. This incision is continued around the full circumference of the myometrium in a symmetrical fashion beneath the uterine serosa. Traction is maintained on the cervix, and the avascular myometrium is cut to allow the undisturbed endometrial cavity, with a thick layer of myometrium, to be delivered with the cervix. As a result, the inside of the uterus with its unopened endometrial cavity is brought closer to the operator. Incision of the lateral portions of the myometrium medial to the remaining attachment of the broad ligament results in considerable additional descent of the uterus and greatly increases the mobility of the uterine fundus. The uterus is converted from a globular to an elongated tissue mass. The cored uterus is removed by clamping the utero-ovarian pedicle and fallopian tubes.

In a retrospective comparison of 383 patients undergoing abdominal hysterectomy or vaginal hysterectomy with uterine morcellation, length of stay and perioperative complications were significantly increased with abdominal hysterectomy. It appears that vaginal hysterectomy with uterine morcellation is safe and allows an increased number of women to undergo vaginal hysterectomy (54).

McCall Culdoplasty

Although McCall culdoplasty is thought to help decrease future enterocele formation, the accuracy of this belief remains open to debate. An absorbable suture is placed through the full thickness of the posterior vaginal wall at the point of the highest portion of the vaginal vault. The patient’s left uterosacral ligament pedicle is grasped and sutured. The suture incorporates the posterior peritoneum, between the uterosacral ligaments and the right uterosacral ligament. The suture is completed by passing the needle from the inside to the outside at the same point at which it was begun. The suture is tied, thereby approximating the uterosacral ligaments and the posterior peritoneum.

Schuchardt Incision

When vaginal exposure is difficult, the Schuchardt incision may be used. If the surgeon is right handed, the incision is made on the patient’s left side. To decrease blood loss, the area can be infiltrated with lidocaine-containing epinephrine. The incision follows a
curved line from the 4-o'clock position at the hymenal margin to a point halfway between the anus and the ischial tuberosity. The incision may be continued into the vaginal vault as high as necessary to gain exposure. The depth of the incision is the medial portion of the pubococcygeus muscle, which may be divided in extreme cases. The incision must be closed in layers at the completion of the procedure.

Intraoperative Complications

Bladder Injury
Injury to the urinary bladder is one of the most common intraoperative complications associated with hysterectomy. **If the bladder is inadvertently entered, repair should be performed when the injury is discovered and not delayed until completion of surgery.** When bladder injury is recognized, the edges of the wound should be mobilized to assess the full extent of the injury and allow repair without tension. This assessment should include visualization of the trigone to exclude injury to that area. The bladder may be repaired with a single- or double-layered closure with a small-caliber absorbable suture. Methylene blue, indigo carmine, or a dye of sterile milk formula can be instilled into the bladder to ensure that the repair is adequate.

Bowel Injury
Because patients with suspected pelvic adhesions or obvious pelvic disease are excluded as candidates for vaginal hysterectomy, bowel injuries do not occur often. Bowel injuries are associated with the performance of a posterior colporrhaphy and are usually confined to the rectum.

**If the rectum is entered, the injury is repaired with a single- or double-layer closure using a small-caliber absorbable suture, followed by copious irrigation.** Postoperatively, the patient should be given a stool softener and a low-residue diet.

Hemorrhage
Intraoperative hemorrhage invariably is the result of failure to ligate securely a significant blood vessel, bleeding from the vaginal cuff, slippage of a previously placed ligature, or avulsion of tissue before clamping. Most intraoperative bleeding can be avoided with adequate exposure and good surgical technique. **Using square knots with attention to proper knot-tying mechanisms will prevent bleeding in most cases.** The use of Heaney-type sutures may minimize ligature slippage and subsequent bleeding from bulky pedicles. When bleeding does occur, blind clamping, which may endanger the ureter, should be avoided. The bleeding vessel should be identified and precisely ligated, with visualization of the ureter if necessary. **If the location of the ureter is in question, it should be visualized before suturing a bleeding vessel.**

Perioperative Care
Bladder Drainage

Postoperative bladder drainage should be employed after any procedure in which spontaneous, complete voiding is not anticipated. Reasons to consider closed bladder drainage include significant local pain, additional vaginal reparative procedures, surgery for stress incontinence, the use of a vaginal pack, and patient anxiety.

After vaginal hysterectomy without additional repair, most patients can void spontaneously, and catheter drainage is not required. The relative amount of pain after a vaginal hysterectomy is less than with abdominal hysterectomy and, in the absence of additional repairs or a pack, no obstructive effect should be present.

If the patient does not tolerate pain well postoperatively or is extremely anxious, the transurethral insertion of a 16-Fr. catheter after completing surgery is warranted. This catheter may be inserted postoperatively if the patient is unable to void spontaneously on two attempts. Closed-catheter drainage after vaginal hysterectomy usually is not necessary for longer than 24 hours. The catheter is removed without clamping, and there is no need to obtain a urine specimen for culture and sensitivity.

Diet

Although little manipulation of the bowel occurs during vaginal hysterectomy, there is some slowing of gastrointestinal motility. This slowing rarely occurs to a degree that limits some form of oral intake soon after surgery. Most patients experience some degree of nausea after surgery, which, combined with drowsiness from analgesics, usually makes them disinterested in food on the evening after surgery. A clear liquid diet is suitable during the first night after surgery, and on the first full postoperative day, a regular diet can usually be consumed. The patient is often the best judge of what she can tolerate as her appetite returns.
Laparoscopic Hysterectomy

Preoperative Preparation
The main limitations to a laparoscopic approach are medical or anesthetic disorders that do not allow adequate pneumoperitoneum or proper ventilation (34). Extensive and dense pelvic abdominal adhesions from previous surgery and very large uterine size are relative contraindications, although this decision can be made after assessing the peritoneal cavity (see Chapter 23). If the uterine size limits access to the uterine vessels, laparoscopic hysterectomy may not be possible. Obesity is not a contraindication to laparoscopic hysterectomy. The increased morbidity from laparotomy in patients with high body mass (BMI) can be minimized with laparoscopy.

Different classifications were proposed for the types of laparoscopic hysterectomy. Laparoscopic hysterectomy is defined as a laparoscopic-assisted vaginal hysterectomy (LAVH) if the uterine vessels are occluded vaginally. The Cochrane review authors recommended that if the vessels are occluded laparoscopically, or if part of the operation is performed vaginally, the procedure be called laparoscopic hysterectomy, and, if no component is performed vaginally, the procedure should be called a total laparoscopic hysterectomy (41).

Patient Positioning
The patient is placed in dorsal lithotomy position with legs placed in Allen or Yellowfin stirrups (Allen Medical Systems, Acton, MA). Attention to proper leg placement will avoid nerve injury. Hyperflexion of the hips should be avoided because this may cause femoral nerve palsy. The patient should be placed on an egg crate mattress or beanbag cushion to limit patient movement in the Trendelenburg position. The arms are tucked on the patients' side and protected with egg crate–type material. No shaving or clipping is necessary. Shoulder braces should not be used as they are associated with brachial plexus injury.

The steps to follow before introducing the first trocar are:
- Perform an examination under anesthesia.
- Place a Foley catheter to drain the bladder.
- Introduce a uterine manipulator (e.g., Koh colpotomizer [Cooper Surgical Inc., Trumbull, CT] or VCare [Conmed Corp., Utica NY]).
- Place an oral gastric tube.

Instrumentation
The most important instrument is the one used to occlude blood vessels. A multitude of energy forms exist, including electrosurgery, lasers, and ultrasonic scalpel (see Chapter 23). Some surgeons use stapling devices, although the cost of these stapling devices is high, and an energy-occluding device is needed to access areas that a stapler cannot.
The versatility of the devices with energy makes them the method of choice to occlude vessels. There are no valid clinical data showing that one instrument is safer than another. The preferred one involves bipolar energy because gynecologists are experienced with this form of energy.

**Surgical Technique of Laparoscopic Hysterectomy**

**Peritoneal Access**

The most important technical consideration for all laparoscopic surgery is port placement (see Chapter 23). The umbilical site typically is used in patients without a previous history of surgery or intra-abdominal infection. In cases of previous surgery where there was a midline incision or a history of a pelvic-abdominal incision, an open laparoscopy is done or an alternative site is chosen to introduce the primary cannula. The open laparoscopy is essentially a mini-laparotomy at the umbilicus. The alternative site is the left upper quadrant. The standard closed technique involves the use of pneumoperitoneum needle (Verres needle), insufflation, and primary trocar insertion. An alternative technique is the direct trocar insertion (no insufflation prior to trocar insertion). A meta-analysis showed no advantage of one technique over the other (24). Gynecologists should use the approach with which they have most experience.

If the left upper quadrant is used, the surgeon should be aware of the closest anatomic structures to the left costal margin (see Chapter 23, Fig. 23.3). Typically the cannula is introduced below the left costal margin in the midclavicular line. The closest structures to this area are the stomach and the left lobe of the liver. Therefore, an oral gastric tube should be introduced to empty the stomach before starting the procedure.

The patient is kept in a horizontal (not Trendelenburg) position until proper peritoneal access is confirmed. The angle of insertion of the primary trocar will depend on the size of the patient. Typically for nonobese or overweight patients a 45-degree angle from the horizontal is used and with obese patients a 60- to 80-degree angle or open technique is used.

Proper placement of accessory ports is critical to allow the steps of a laparoscopic hysterectomy. The authors typically use three lateral accessory ports and do not use a suprapubic port. Lateral ports offer the surgeon an ergonomic approach in which both hands can be used comfortably. **The most important step when placing lateral ports is to avoid the inferior epigastric vessels, which are branches of the external iliac artery and vein.** (see Chapter 23, Fig. 23.3). Direct visualization is best. These vessels (typically two veins and an artery) are seen through the peritoneum medial to the insertion of the round ligament in the deep inguinal ring. They cannot be transilluminated. Ports are placed approximately 8 cm from the midline and 8 cm above the pubic symphysis.

Laparoscopic hysterectomy requires traction and countertraction to identify the vascular pedicles and the ureter, which is accomplished with the uterine manipulator. In the case
of a large uterus, a laparoscopic tenaculum is required. The procedure starts with coagulating and transecting the round ligament (Fig. 24.29). The incision is carried anteriorly to create a bladder peritoneal flap by sharp dissection of the loose areolar cervicovesical tissue. The retroperitoneal space is opened and the ureter identified on the medial leaf of the broad ligament (Fig. 24.30). The ovarian vessels (infundibulopelvic ligament) or the utero-ovarian ligaments are coagulated and transected, depending on whether the ovaries will be removed (Fig. 24.31). The surgeon can proceed vaginally (LAVH), but there will not be any improved uterine descent because the transected tissue has no major role in uterine support.

**Figure 24.29** The right round ligament is grasped and desiccated with a bipolar device.

![Image of the right round ligament grasped and desiccated with a bipolar device.](image)

**Figure 24.30** The round ligament has been transected and the right ureter is identified in the retroperitoneal space.

![Image of the round ligament transected and the right ureter identified.](image)
The uterus is then torqued away from the uterine artery to be occluded. The uterine artery is skeletonized by cutting the posterior peritoneum up to the uterosacral ligament, coagulated, and transected. The procedure is carried out on the other side. This area of occlusion is approximately the level of the internal os. If a supracervical hysterectomy was performed, the uterus can now be amputated. When this is done, the remaining endocervical canal should be cauterized.

The anterior dissection should be completed so that the bladder is completely off the anterior fornix area of the vagina (Fig. 24.32). Using a vaginal device such as the Koh, the surgeon can identify this area. Ensuring that no CO₂ escapes from the vagina, and an incision is made on the vagina circumferentially around the cervix (Fig. 24.33). The uterus can be pulled out through the vagina or can be morcellated first, and then removed either vaginally or laparoscopically, whichever is easier.

Figure 24.32 After the bladder peritoneum is sharply dissected down to the level of the cervix, the uterine vessels are grasped with the bipolar devise and desiccated.
The vaginal cuff is closed laparoscopically or vaginally with interrupted or continuous delayed absorbable suture (2-0 on CT-1 needle). To give added pelvic support, the uterosacral ligaments are reattached to the vagina (McCall’s culdoplasty) with delayed absorbable suture. Intravenous indigo carmine is given and the integrity of the bladder and ureters confirmed with cystoscopy, if desired, by the surgeon. At the end of the procedure, the secondary ports should be removed under direct
visualization to ensure that there is no bleeding. The fascia should be closed at port sites that are 8 mm or greater and smaller ports that have prolonged manipulation to avoid possible herniation.

The patient is kept in the short stay unit and discharged within 24 hours if there are no complications. A regular diet as tolerated is given on the same day as the surgery. Ambulation is encouraged as soon as possible. Median time to return to work is 3 to 4 weeks (42).

**Robotic-Assisted Laparoscopic Hysterectomy**

A surgical robot consists of a surgeon’s console with the instrument manipulators and view screen, a robot tower with telerobotic arms that are attached to the patient, and the computer interface equipment, which is housed in a separate tower (see Chapter 25 for a more complete discussion). Robotic assistance at laparoscopy has some advantages, including a three-dimensional view, instruments with articulating tips that offer seven[MB1] degrees of movement, scaling of movement, and more precise movements. The disadvantages are the bulky device around the patient that limits the assistant’s movements, the lack of haptic feedback, and the high cost of the robot. The robot device uses a 12-mm laparoscope and 8-mm instruments.

The robotic tower can be docked between the legs or on the patient’s side (side docked). Side docking allows access to the perineum and vagina so that the assistant can comfortably manipulate the uterus. A robot-assisted hysterectomy goes through the same steps as a laparoscopic hysterectomy. A right-handed surgeon should have the monopolar scissors or harmonic scalpel through a right robotic port and a vessel-sealing device such as a bipolar instrument through a left-sided robotic port. If a fourth robotic arm is used, the additional port is placed on the right side for right-handed surgeons.

Observational studies showed that outcomes for robotic-assisted hysterectomy can be similar to laparoscopic hysterectomy but with less blood loss and possibly fewer conversions to laparotomy (55,56). The learning curve to stabilize operative times for skilled laparoscopic surgeons is about 50 cases (57). Although these case series demonstrated equivalent operative times, an analysis of the Premier hospital database of over 36,000 laparoscopic or robotic hysterectomies demonstrated longer surgical times and higher costs with the robot-assisted procedures compared with conventional laparoscopy with little difference in perioperative and postoperative outcomes (58). Robotic-assisted laparoscopic hysterectomy is associated with delayed vaginal cuff dehiscence around 7 to 8 weeks after hysterectomy, although one case series showed an increased frequency with conventional laparoscopy (59,60). The frequency of other complications is similar to conventional laparoscopy. A more complete discussion of this subject is in Chapter 25.

**Laparoendoscopic Single-Site Surgery**

Another modification of laparoscopic hysterectomy is the introduction of laparoendoscopic
single-site surgery or single-port surgery. Because some surgeons use one of the multiple ports at one site, laparoendoscopic single-site surgery is probably the best term. The role of single-site access to hysterectomy is unclear, and there are only case reports (61). Specifically designed umbilical port systems that admit multiple instrument access have enabled the development of this technique. The availability of flexible instruments and flexible tip laparoscopes allows the surgeon to perform a hysterectomy by reducing instrument crowding and clashing at the umbilicus. The basic hysterectomy steps are the same.

**Intraoperative Complications: Laparoscopic Hysterectomy**

The intraoperative complications of a laparoscopic hysterectomy are similar to an open hysterectomy. These are injury to the ureter, bladder, and bowel and hemorrhage. Recognition and management are similar. **Because there is an increased frequency of injury to the ureter and bladder, a cystoscopic evaluation after injection of intravenous indigo carmine dye is recommended (62).**

Intraoperative bleeding during a laparoscopic procedure is handled by use of a bipolar instrument. The same principles apply as with an open case. Cautery should not be used without proper localization of the ureters. If it is not apparent where the bleeding is occurring, the procedure should be converted to an open one.

**Perioperative Care**

Many surgeons remove the bladder catheter at the end of the laparoscopic hysterectomy. Patients can resume a regular diet the same day as the surgery. Transition to oral analgesics can be made the same day.
Postoperative Complications of Hysterectomy

A comprehensive discussion of postoperative complications after gynecologic surgery is presented in Chapter 22.
Wound Infections

Wound infections occur after 4% to 6% of abdominal hysterectomies (33). Measures believed to reduce the incidence of wound infections include a preoperative shower, no removal of hair, or if hair removal is necessary, removal of hair with clippers in the operating room, use of adhesive drapes and prophylactic antibiotics, and delayed primary closure (see Chapter 22).
Incisional Pain

Incisional pain can occur at trocar sites, especially if located in the region of the ilioinguinal or iliohypogastric nerves. Pfannenstiel incisions can be a source of chronic pain at the incision site as a result of nerve entrapment (63).
Hemorrhage

Immediately after hysterectomy, hemorrhage may become apparent in one of two ways. Bleeding from the vagina may first be noted by the nursing staff or physician within the first few hours after surgery. Second, the patient may be noted to have little bleeding from the vagina but deteriorating vital signs manifested by low blood pressure and rapid pulse, falling hematocrit level, and flank or abdominal pain. The first presentation is in the form of bleeding from the vaginal cuff or one of the pedicles. The second presentation may be a retroperitoneal hemorrhage. Each situation is approached differently in its evaluation and treatment, but both involve the same general principles of rapid diagnosis, stabilization of vital signs, appropriate fluid and blood replacement, and constant surveillance of the patient’s overall condition.

After vital signs are assessed, attention should be directed to the amount of bleeding. A small amount of bleeding is expected after any vaginal hysterectomy. Steady bleeding 2 to 3 hours after surgery suggests lack of hemostasis. The patient should be taken promptly to the examining room, where the operative site is viewed using a large speculum and good lighting. If bleeding is not excessive, the vaginal cuff can be inspected, and in many instances, bleeding from the cuff edge will be found. Hemostasis can easily be achieved with one or two sutures placed through the mucosa.

If bleeding is excessive or appears to be coming from above the cuff, or if the patient is too uncomfortable to tolerate adequate examination, she should be taken to the operating room. General anesthesia should be administered and the vaginal operative site should be thoroughly explored. Any bleeding point may be sutured or ligated. Bleeding that is coming from above the cuff or is extremely heavy usually cannot be controlled through the vaginal route. An exploratory laparotomy is necessary to examine the pelvic floor, identify and isolate the bleeding vessel, and achieve hemostasis. The ovarian vessels and uterine arteries should be thoroughly inspected because they often are the source of excessive vaginal bleeding. If it is difficult to localize bleeding to a specific pelvic vessel, or if these maneuvers do not work, ligation of the hypogastric artery may be performed.

In the patient with little vaginal bleeding in whom vital signs have deteriorated, retroperitoneal hemorrhage should be suspected. Input and output should be monitored. Hematocrit assessment, along with cross-matching of packed red blood cells, should be performed immediately. Examination may reveal tenderness and dullness in the flank. In cases of intraperitoneal bleeding, abdominal distention may occur. Diagnostic radiologic studies can be used to confirm the presence of retroperitoneal or intra-abdominal bleeding. Ultrasonography is one option for viewing low pelvic hematomas; CT provides better visualization of retroperitoneal spaces and can delineate a hematoma.

If the patient’s condition stabilizes rapidly with intravenous fluids, one of two approaches may be used for continued care. The first is to give the patient a
transfusion and follow serial hematocrit assessments and vital signs. In many instances, retroperitoneal bleeding will tamponade and stop, forming a hematoma that may eventually be resorbed. The risk with this approach is that the hematoma will become infected, necessitating surgical drainage. In some instances when the patient’s condition is stable, radiologic embolization may be considered.

Another option is to perform abdominal exploratory surgery while the patient’s condition is stable. This approach adds the morbidity of a second procedure but avoids the possibility of the patient’s condition deteriorating with continued delay or the formation of a pelvic abscess. Once adequate exposure is obtained, the peritoneum over the hematoma should be opened and the blood evacuated. All bleeding vessels should be identified and ligated. If bleeding is difficult to control, consideration should be given to unilateral or bilateral ligation of the anterior division of the internal iliac artery. Once hemostasis is achieved, the pelvis should be drained using a closed system.
Urinary Tract Complications

Urinary Retention

Urinary retention after hysterectomy is an uncommon occurrence. If the urethra is unobstructed and retention occurs, it is usually the result of either pain or bladder atony resulting from anesthesia. Both are temporary effects.

If a catheter was not placed after surgery, retention can be relieved initially with the insertion of a Foley catheter for 12 to 24 hours. Most patients are able to void after the catheter is removed 1 day later. If the patient still has trouble voiding and urethral spasm is suspected, success can be achieved with a skeletal muscle relaxant such as diazepam (2 mg twice a day). In most cases, waiting is the best course, and voiding usually occurs spontaneously.

Ureteral Injury

In patients who develop flank pain soon after vaginal hysterectomy, ureteral obstruction should be suspected. The incidence of ureteral injury is lower with vaginal hysterectomy than with abdominal hysterectomy (41,44). One risk factor for its occurrence is total uterine prolapse, in which the ureters are drawn outside the bony pelvis.

In a patient with flank pain in whom ureteral obstruction is suspected, a CT urogram and a urinalysis should be performed. If obstruction is noted on CT scan, it is usually present near the ureterovesical junction. The immediate step is attempted passage of a catheter through the ureter under cystoscopic guidance. If a catheter can be passed through the ureter, it should be left in place for at least 4 to 6 weeks, allowing sutures to absorb and the obstruction or kinking to release. If the catheter cannot be passed through the ureter, the best course is to perform abdominal exploratory surgery and repair the ureter at the site of obstruction.

Vesicovaginal Fistula

Vesicovaginal fistulas occur most often after total abdominal hysterectomy for benign gynecologic disease (50). Intraoperative steps to avoid the formation of a vesicovaginal fistula include correct identification of the proper plane between the bladder and cervix, sharp rather than blunt dissection of the bladder, and care in clamping and suturing the vaginal cuff. The development of a postoperative vesicovaginal fistula after hysterectomy is rare; the incidence is as low as 0.2%.

Patients who have a postoperative vesicovaginal fistula develop a watery vaginal discharge 10 to 14 days after surgery. Some fistulas resulting from surgery are noted as early as the first 48 to 72 hours after surgery. After vaginal examination with a speculum, the diagnosis can usually be confirmed with the insertion of a cotton tampon into the vagina followed by the instillation of methylene blue or indigo carmine dye
through a transurethral catheter. If the tampon stains blue, a vesicovaginal fistula is present. If no staining occurs, the presence of a ureterovaginal fistula must be ruled out by the intravenous injection of 5 mL of indigo carmine dye. Within 20 minutes, the tampon should stain blue if a ureterovaginal fistula is present. A CT urogram should be performed to rule out ureteral obstruction.

If a vesicovaginal fistula is diagnosed, a Foley catheter should be inserted for prolonged drainage. Up to 15% of fistulas close spontaneously with 4 to 6 weeks of continuous bladder drainage. If closure has not occurred by 6 weeks, operative correction is necessary. Waiting 3 to 4 months from the time of diagnosis before operative repair is recommended to allow reduction of inflammation and to improve vascular supply. After vaginal hysterectomy, the fistula site is above the bladder trigone and away from the ureters. Vaginal repair can be anticipated in most patients. The surgical correction is undertaken in a four-layered closure: the bladder mucosa, the seromuscular layer, the endopelvic fascia, and the vaginal epithelium.

Incidental cystotomy at the time of hysterectomy is more common than vesicovaginal fistula. When identified and repaired correctly, cystotomy rarely results in the development of a fistula.

Prolapse of the Fallopian Tube

Posthysterectomy prolapse of the fallopian tube is a rare event and can be confused with granulation tissue at the vaginal apex. Predisposing factors for the development of fallopian tube prolapse include development of a hematoma and an abscess at the vaginal apex. Approximately one-half of patients undergoing vaginal hysterectomy form some granulation tissue at the vaginal vault. In patients in whom granulation tissue persists after attempts to cauterize it or pain is experienced with attempts to remove it, fallopian tube prolapse should be suspected. A biopsy of the area is warranted and usually reveals tubal epithelium if a fallopian tube is present. If fallopian tube prolapse is diagnosed, it should be repaired with surgery. The surrounding vaginal mucosa should be opened and undermined widely. The tube is ligated high and removed, followed by closure of the vaginal mucosa.
Discharge Instructions

Before discharging the patient, instructions should be reviewed. Printed postoperative instructions are helpful to the patient and a suggested set of instructions are as follows:

Avoid strenuous activity for the first 2 weeks, and increase activity level gradually.
Avoid heavy lifting, douching, or sexual intercourse until instructed by the physician.
Bathe as needed using shower or tub baths.
Follow a regular diet.
Avoid straining for a bowel movement or urination. For constipation, use Milk of Magnesia or Metamucil (1 tsp in juice).
Call the physician if excessive vaginal bleeding or fever occurs.
Schedule a return appointment at the time specified by the physician.

The physician should provide telephone numbers for emergencies both during and after office hours. Typically, the first postoperative visit is scheduled about 4 weeks after discharge from the hospital. At the time of that visit, the patient should be ambulating well, and vaginal discharge or bleeding should be minimal. Speculum examination of the cuff should be gentle and cursory, but the patient should be assured that the healing process is proceeding normally. Finally, the patient’s questions should be answered and advice given on increasing her activity level, including sexual activity, work, and normal household activity.
Patient satisfaction after hysterectomy is related to the initial indication for surgery and patient expectation. The Maine Women’s Health Study evaluated the effect of hysterectomy for nonmalignant disorders on quality of life (13). They documented a marked improvement in pelvic pain, urinary symptoms, and psychological and sexual symptoms at 1 year in the majority of patients. In the Maryland Women’s Health Study patients were followed for up to 2 years after hysterectomy for nonmalignant conditions (64). Symptoms related to the underlying indication for surgery, and associated symptoms of depression and anxiety and quality of life, improved after hysterectomy. Each study reported that about 8% of patients had new symptoms, such as depression and lack of interest in sex or lack of improvement in quality of life. Although women with pelvic pain and depression did not show the same level of improvement as other groups, there was significant improvement over baseline. Patient satisfaction is very high after hysterectomy (64).
Sexual Function

There is considerable debate in the lay literature about the effect of hysterectomy on sexual function, although evidence consistently suggests that the majority of women have unchanged or improved sexual function 1 to 2 years after hysterectomy (13,64). Few women who had a hysterectomy had a measurable worsening in sexual function during this time period. The long-term effects of hysterectomy on sexual function remain largely unknown. Studies have addressed the short-term effects of hysterectomy on dyspareunia, frequency of intercourse, orgasm, libido or sexual interest, vaginal dryness, and overall sexual function. The Maine Women’s Health Study demonstrated a significant decrease in the number of women who reported dyspareunia 12 and 24 months after hysterectomy compared to the preoperative period (13). Eighty-one percent of the women who experienced dyspareunia preoperatively had an improvement in this symptom at 24 months after hysterectomy, while only 1.9% of women without preoperative dyspareunia developed it by 24 months after surgery. In this study, 39% of women reported dyspareunia preoperatively, and only 8% had this complaint 12 months after hysterectomy. Women who were managed nonsurgically showed no decline in the mean frequency of dyspareunia (13).

Most studies report that hysterectomy has little impact on the frequency of intercourse, libido, and sexual interest. Orgasmic function before and after hysterectomy is somewhat more controversial, but the largest study by Carlson et al. reported a slight increase in the proportion of women who experienced orgasms after a hysterectomy (13). It is plausible that removal of the uterus and/or cervix (especially if the ovaries are also removed) may adversely affect sexual function in some women, but this may be offset by the improvement in sexual function that could result from cessation of abnormal or heavy vaginal bleeding, dysmenorrhea, or symptoms of prolapse. It is likely that vaginal dryness is not affected by hysterectomy and depends more on age and postoperative hormonal status. Body image and sexual function are improved after vaginal, abdominal, and laparoscopic hysterectomy, but no differences were found between the three routes (13,63).
References

Robotic surgery is a form of facilitated laparoscopy that utilizes robotic technology to enhance the performance of the operation by placing a computerized interface between patient and surgeon.

Two of the most important differences between conventional laparoscopic instruments and robotic instruments are articulation and intuitive movements. The robotic system offers advantages for the surgeon, but it is particularly useful in four circumstances: obese patients, long surgeries, and operations requiring extensive suturing or high precision.

High precision and absence of tremor are useful for retroperitoneal lymphadenectomy, adhesiolysis, parametrial ureteral dissection, and accurate suturing, in such procedures as ureteral anastomosis or reimplantation, and genitourinary fistula repair.

Applications of robotic technology include simple hysterectomy, myomectomy, appendectomy (in conjunction with other procedures), adnexectomy, excision of severe endometriosis, tubal anastomosis, and rectovaginal or vesicovaginal fistulas, especially those in the upper vagina.

Studies show the feasibility of robotics for the treatment of patients with cervical, endometrial, tubal, and ovarian cancer, with apparent similar or better perioperative outcomes compared to laparoscopy and with improved outcomes compared to laparotomy.

Robotic technology as applied to laparoscopy utilizes robotic technology to facilitate the performance of the operation by placing a computerized interface between patient and surgeon. Although originally designed for cardiovascular surgery and approved for that use by the U.S. Food and Drug Administration (FDA) in 2003, it has found applications in urology and gynecology, and more recently in otolaryngology and colorectal surgery.

There are studies showing that the use of robotic technology for the performance of preset laboratory exercises results in faster performance...
times, increased accuracy, enhanced dexterity, easier and faster suturing, and a lower number of errors when compared to conventional laparoscopic instrumentation (1–4). The physical stress for medical students learning robotics is significantly less than what they encounter when learning the same tasks by laparoscopy (5). The technological advantages of robotics can facilitate learning surgical techniques when compared to acquiring similar skills in laparoscopy, as demonstrated by a shorter learning curve for robotic surgery. There is a flattening of the operating time after 20 to 50 robotic hysterectomies, while for laparoscopically assisted vaginal hysterectomy (LAVH) a similar facility with the requisite skills does not occur until after 80 procedures (6–9). In gynecologic oncology, a flattening of the operating time was noted after 20 procedures for endometrial cancer when using the robotic technology (10).

Figure 25.1 Robotic column with robotic arms.
There is only one robotic system available, brand-named Da Vinci (Intuitive Inc, Sunnyvale, CA), which received FDA approval for the performance of hysterectomy in 2005. A second generation of the device, the Da Vinci S, was released in 2006, and the third generation of the Da Vinci robotic system, the SI model, was released in 2009 and incorporates a resident teaching console. A robotic system is composed primarily of a robotic column, which holds the robotic arms (Fig. 25.1) and a surgeon’s console (Fig. 25.2). The robotic arms that hold the robotic instruments (Fig. 25.3) are fastened to the robotic trocars (Fig. 25.4). Commonly used robotic instruments for gynecologic surgeries are shown in Figure 25.5A-F.

Figure 25.2 Robotic console with hand controls and foot switches.
Robotic Column

The robotic column has three or four robotic arms, depending on the selection at the time of purchase (Fig. 25.1). The fourth arm is extremely useful for assisting with tissue retraction. The robotic arms always function in the direction toward the robotic column and not away from it. For this reason the robotic column must be positioned strategically in response to the location of the surgery that will be performed.

For pelvic surgery the robotic column is commonly situated between the patient’s legs (Fig. 25.6), while for upper abdominal surgery it is positioned at the patient’s head. For procedures to the right or left of the abdomen, the robotic column is positioned at the opposite side of the patient. For instance, for extraperitoneal left aortic lymphadenectomy, the robotic column is at the patient’s right side. For procedures where easy access to the entrance of the vagina and rectum is necessary, the robotic column is positioned lateral to the right or to the left of the patient’s legs.

Figure 25.3 Robotic laparoscope and two robotic arms with robotic instruments inserted. The tip of the instruments can be appreciated in the insert.

Figure 25.4 The robotic trocars are metallic and can be seen to the right of the picture. The escape valve was added because the original trocars did not have it. The three types of available trocar obturators are on the left of the picture: blunt (left), tissue-spreading (middle) and cutting (right).
Figure 25.5 Robotic instruments commonly used in gynecologic surgeries. A: Monopolar curved scissors. B: Monopolar spatula. C: PK (plasma kinetic) dissecting forceps, bipolar. D: Prograsp forceps, bipolar. E: Tenaculum forceps used for myomectomy. F: Needle grasper used for suturing.
Figure 25.6 The robotic column is usually positioned between the patient legs for pelvic surgery. The assistant is seated to the left of the patient and is scrubbed for the procedure.
Robotic Console

The surgeon sits at the console (Fig. 25.2) away from the patient (Fig. 25.7) and the assistant sits next to the patient (Fig. 25.6). The surgeon has a stereoscopic image, which is different from the laparoscopic image, and controls the movements of the robotic arms using two hand controls and five foot switches: clutch, camera, focusing, monopolar (cutting and coagulating), and bipolar. The surgeon’s arms and hands can be maintained in a comfortable working position, because pressing the clutch foot switch disengages the robotic arms from the surgeon hands. This allows the surgeon to reposition the arms to an appropriate and comfortable position without moving the portion of the robotic arms connected to the patient.

Figure 25.7 The surgeon is seated at the console and is able to maintain a relaxed position for the arms and legs.

Because the surgeon is separated from the patient, there is a time delay that permits the performance of telesurgery, as long as the latency time does not exceed 150 milliseconds. The surgeon can control the movements of the robotic arms and instruments in a patient located at a different geographic location (11). Telementoring allows the mentor surgeon to guide another surgeon through a surgical procedure at a remote location by using superimposed electronic signals (telestration), direct voice commands, and control of the laparoscope via joystick and the electrosurgical instruments (12). Robotic movements are intuitive; the tip of the instrument mimics the movement of the surgeon’s hands, in contrast to the experience in laparoscopy when the movements of the tip of the instrument are counterintuitive, opposite to the movements of the surgeon’s hands.

Other technological advantages include downscaling of movements, absence of tremor, and stillness. In laparoscopy the amplitude of movement of the tip of the instrument is...
the same as the amplitude of the movement of the surgeon’s hands, whereas in robotics it can be downsized, resulting in increased precision. **The computerized interface between surgeon hands and robotic instruments eliminates unwanted tremor, increasing precision.** When placed in a specific position, such as for retracting bowel or uterus, the robotic instruments remain in place until repositioned, which can be a difference from human assistance.

**The lack of tactile feedback (haptics) is a drawback for the neophyte, but the stereoscopic view rapidly compensates for it.** There is a degree of resistance felt at the hand controls of the console, which, coupled with the stereoscopic view, allows the surgeon to determine the consistency of tissues, whether soft or hard, such as “to palpate” the rim of the cervical cup of a uterine manipulator, or “feel” a hard probe introduced in the rectum. The lack of tactile feedback is an advantage when operating in obese patients, because the surgeon cannot feel the resistance of the instruments being inserted through a thick abdominal wall, a difference from laparoscopy.

**Another potential advantage of the robotic laparoscopy technique compared to laparoscopy without the assistance of robotics is that it may decrease the number of injuries in surgeons.** There are multiple reports of laparoscopic-related surgeon morbidity syndromes, resulting from the unnatural forced position of wrists, fingers, elbows, and shoulders and the awkward standing position of the surgeon (13). A recent study revealed a lower number of surgeon injuries and lower perception of surgeon’s pain, numbness, and fatigue using robotics compared to conventional laparoscopy (14).
Instrumentation

Two of the most important differences between conventional laparoscopic instruments and robotic instruments are articulation and intuitive movements. The tip of a laparoscopic instrument is rigid and the instrument only has 4 degrees of freedom. The tip of robotic instruments are articulated with 7 degrees of freedom, reproducing the movements of the human wrist and fingers (Fig. 25.3) (EndoWrist instruments, Intuitive Surgery Inc, Sunnyvale, CA). The articulation allows the performance of complex maneuvers in small spaces; it accommodates the instrument to the correct plane of dissection (instead of forcing the tissue to the direction of the instrument as in laparoscopy), eliminates changing instruments from one port to another as in conventional laparoscopy, and facilitates suturing and intracorporeal knot tying. As indicated above, the movement of the robotic instruments is intuitive, following the movement of the surgeon hands.
Types of Instruments
Robotic instruments useful for gynecological surgery include ProGrasp forceps, PK dissecting forceps, tenaculum forceps, SutureCut needle driver, monopolar curved scissors, and monopolar cautery spatula (Fig. 25.5A-F).
Trocars

The robotic trocars are metallic and have three different types of obturators: blunt, tissue-spreading, and cutting (Fig. 25.4). **The robotic trocars are placed in a different configuration than conventional laparoscopy trocars because of technical limitations imposed by the robotic arms.** They are usually placed at the level of the umbilicus or higher for pelvic surgery and must be 10 cm apart from each other and from the laparoscope to prevent collision of the robotic arms (Fig. 25.8). At least one assistant trocar is necessary, which must be placed 3 to 5 cm away from any of the other trocars.

**Figure 25.8 Trocar position for robotic pelvic surgery.** The optical trocar is at the umbilicus. Two robotic trocars are placed 10 cm lateral to the right and left of the umbilicus, respectively. The assistant white trocar is 3 cm cranial and equidistant between the umbilical and left robotic trocar. An additional robotic trocar is 3 cm cranial and equidistant between the umbilical and the right robotic trocar.
Docking

Docking is a robotic term defined as the attachment of the robotic arms to the robotic trocars inserted in the patient. A mean docking time of about 3 minutes was reported in an initial study of 88 patients undergoing robotic hysterectomy (6). Docking times improved progressively after groups of 10 patients each.
Certification and Credentialing in Robotics

There is a mandatory training course of 2 days to obtain certification in robotics provided by the manufacturing company Intuitive, Inc (Sunnyvale, CA) in centers located in the United States, Europe, and Asia. The gynecologist learns the robotic system and logs about 8 hours of dry and animal laboratory tasks. Residents or fellows completing training programs with robotics must demonstrate proficiency with documented basic robotic training and successfully perform a minimum of 10 robotic surgeries, preferably of the same type, and obtain a letter from the program director attesting to their level of robotic proficiency. Credentialing is dependent on each hospital credentialing body and is different for each institution: while some require robotic practice in five animals and having a proctor for the first five robotic surgeries, others mandate having a proctor for only two to five robotic procedures prior to obtaining robotic privileges.
Assistant
An assistant is needed for docking, switching robotic instruments, solving robotic arm collision, retrieving small specimens, retracting tissue, and for the use of instruments not available with robotic technology, such as a vessel-sealing device and suction and irrigation. The assistant must be trained in robotics and be very knowledgeable about the procedure, because the surgeon is seated in a separate place and not scrubbed.
Teaching Robotics

The robotic teaching console allows the surgeon and the resident or fellow to each have his or her own console while having dual control. The surgeon is able to demonstrate the performance of a specific task to the trainee, or to assist the resident with one robotic arm, or prevent an imminent injury by disengaging the robotic arms from the resident’s hands, while both surgeon and resident are seated and viewing the stereoscopic image. The benefits of the teaching console were not compared to standard laparoscopic teaching to evaluate advantages. The half million dollar cost of the teaching console is a large disadvantage.

Previous laparoscopic experience was considered an advantage to learning robotics. Multiple reports show that transitioning from laparotomy to robotics is easier than transitioning from laparoscopy to robotics (15). A large number of gynecologic oncologists and gynecologists incorporated robotics into their daily practice without having incorporated laparoscopy into their practice or performing advanced laparoscopic procedures. In one study the initiation of robotics in a gynecologic oncology program reduced laparotomy from 78% to 35% in the first year of implementation and it increased the number of minimally invasive procedures from 22% performed by laparoscopy to 65% being robotic assisted (15). Thus, robotic technology is relatively easy to use, associated with a short learning curve, and comfortable for the surgeon (15–17). It is less stressful to learn robotics than laparoscopy. Reduced stress and ease of learning with robotics compared to laparoscopy was demonstrated when 16 medical students were exposed to both techniques (5).
Robotic Applications in Benign Gynecology

The robotic system offers advantages for the surgeon, but it is particularly useful in four circumstances: obese patients, long surgeries, and operations requiring extensive suturing or high precision. There is no resistance felt by the surgeon hands to the movement of the robotic instruments, regardless of the thickness of the patient’s abdominal wall. Suturing and intracorporeal knot tying are greatly facilitated by the articulation of the robotic instruments. Surgeon’s fatigue is decreased when seated for long operations. High precision and absence of tremor is useful for retroperitoneal lymphadenectomy, adhesiolysis, parametrial ureteral dissection, and accurate suturing, such as for ureteral anastomosis or reimplantation and genitourinary fistula repair. Applications of robotic technology include simple hysterectomy, myomectomy, appendectomy (in conjunction with other procedures), adnexectomy, excision of severe endometriosis, tubal anastomosis, and rectovaginal or vesicovaginal fistulas, especially those in the upper vagina (1,4). Robotic surgery is associated with a similar or shorter surgical time than conventional laparoscopy for the performance of simple hysterectomy and myomectomy, with a reduced blood loss, complication rates, and hospital stays (2,4).
Hysterectomy

Laparoscopic-assisted vaginal hysterectomy was introduced in 1989. By 2005, only 14% of hysterectomies in United States were laparoscopic (18). By contrast, 3 years after FDA approval of robotic hysterectomy in 2005, 10% of hysterectomies were performed robotically in 2008 (Intuitive, Inc).

A report on 91 patients undergoing a robotic simple hysterectomy demonstrated a mean surgical time of 127.8 minutes, blood loss of 78.6 mL, and hospital stay of 1.4 days. One enterotomy was repaired robotically. There were no conversions to laparoscopy or laparotomy. Postoperative complications included single instances of exacerbation of congestive heart failure, ileus, vaginal cuff abscess, and Clostridium difficile colitis (19). A retrospective comparison of robotic and laparoscopic hysterectomy showed a longer operating time for robotics (27 minutes) but a lower blood loss and shorter hospital stay (19). Postoperative complications were similar. The conversion rate was higher for laparoscopy compared to robotic operations (9% vs. 4%, respectively).
Laparoscopic myomectomy provides less morbidity and a shorter recovery time compared to open myomectomy in two prospective randomized studies (20,21). Similarly, robotic myomectomy morbidity and recovery times appear preferable to open myomectomy. In a comparison of both techniques, robotic patients experienced less blood loss, no blood transfusions, lower postoperative complications, and shorter hospital stays. The operating time and cost were increased in the robotic group (22). In an initial series of 35 patients undergoing robotic myomectomy, the mean operating time was 230.8 minutes, mean blood loss was 169 mL, and median hospital stay was 1 day (23). Two patients (8.6%) required conversion to laparotomy, resulting from inadequate robotic instrumentation for myomectomy.

Robotic myomectomy provided comparable perioperative results to laparoscopy in two retrospective studies of patients with symptomatic myomas (24,25). No significant differences were noted between both groups for blood loss, complications, and hospital stay. The robotic operating time was longer than laparoscopy in one of the studies and no different in the other (24,25). In our comparison study, we noted differences favorable to the robotic group relative to operating time (141 vs. 166 minutes), blood loss (100 vs. 250 mL), and hospital stay over 2 days (12% vs. 23%). There were no significant differences between groups when patients were adjusted for uterine size and myoma weight. There were no differences in intra- or postoperative complications. Postmyomectomy pregnancy rates, uterine rupture, and late operative complications using robotics remain undetermined.
Adnexectomy

Numerous studies show the benefits of laparoscopy over laparotomy for patients with an adnexal mass. Robotics provides similar perioperative outcomes when compared to laparoscopy for patients with an adnexal mass. Outcomes were improved with robotics for obese patients (body mass index [BMI] ≥30) with an adnexal mass. In a comparison series of 176 patients with an adnexal mass, 85 operations were by robotics and 91 by laparoscopy (26). The operating time was 12 minutes longer for the entire robotic group (83 vs. 71 minutes), but it was similar to laparoscopy when comparing only patients with a BMI 30 or more (80 vs. 71 minutes). Blood loss was similar for both groups (39.1 vs. 41.2 mL), but lower for the robotic group when comparing only obese patients (BMI ≥30) (39 vs. 60 mL). The length of hospital stay, as measured by the number of patients staying longer than 2 days (0 vs. 3) was similar for both groups.
**Tubal Reversal**

Robotic tubal reversal may be preferable to laparotomy. In a prospective study comparing both techniques on patients with a previous tubal ligation, the operating time was longer using robotics (201 vs. 155 minutes), but the hospital stay (4 hours vs. 1.3 days), and recovery time to normal activities (11.1 vs. 28.1 days) were improved for robotic patients (27). Both groups had similar pregnancy rates (62.5% vs. 50%). In another retrospective case-control study of outpatient tubal anastomosis performed by robotics or minilaparotomy, perioperative outcomes were similar except for a longer operating time, increased cost, and a shorter time to patient’s recovery with robotics (28).
Appendectomy

Reported results on 107 robotic appendectomies performed in conjunction with other pelvic procedures had a mean time for appendectomy of 3.4 minutes. No perioperative complications related to appendectomy were encountered. Increased abnormal pathological findings were observed in patients with pelvic pain compared to those without pain (37% vs. 15%, respectively). Appendiceal metastases were found in 43% of patients with ovarian malignancy (29).
Sacrocolpopexy

The robotic approach to sacrocolpopexy may be better than conventional laparoscopy because of the ease of suturing and of intracorporeal knot tying. A report of feasibility experience with 80 patients demonstrated total operating time of 197.9 minutes, and most patients underwent additional procedures at the same surgical setting (30). There was a 25.4% decrease of the operating time after the first 10 surgeries. Complications were minimal. Other reported operating times are 317 and 328 minutes (31,32).

Robotic sacrocolpopexy may be preferable to laparotomy because of improved perioperative outcomes and similar anatomical results. A comparison of 73 robotic with 105 laparotomy sacrocolpopexies for vaginal and uterine prolapse revealed a longer operating time (328 vs. 225 minutes) but reduced blood loss (103 vs. 255 mL) and shorter hospital stay (1.3 vs. 2.7 days) for the robotic group. Anatomical improvement was similar for both groups as determined by pelvic organ prolapse quantification (POP-Q) C point (−9 vs. −8) (see Chapter 27) (32). Late complications, such as erosion rate and long-term anatomical results of robotic sacrocolpopexy are unknown.
Gynecologic Oncology

Studies show the feasibility of robotics for the treatment of patients with cervical, endometrial, tubal, and ovarian cancer, with apparent similar or better perioperative outcomes, compared to conventional laparoscopy and with improved outcomes compared to laparotomy (33–39). A survey of Society of Gynecologic Oncologists members indicated 24% are regular users of robotics and 66% believed their use would increase (33).
Endometrial Cancer

Laparoscopy provides similar or longer operative times, less blood loss, fewer postoperative complications, shorter hospital stay and recovery times, with similar recurrence and survival rates compared to laparotomy (34–39). Robotic technology may be preferable to conventional laparoscopy in selected patients for surgery for endometrial cancer, especially in morbidly obese patients. In expert hands, the use of minimally invasive techniques—laparoscopy and robotics—may facilitate the operations.

**Studies comparing robotics to laparotomy suggest improved perioperative outcomes for robotics.** Operative times are similar or longer, blood loss and hospital stay are reduced, the number of lymph nodes is comparable or higher, and postoperative complications are similar or decreased with robotics (15–17,40–44). Studies comparing robotics with conventional laparoscopy for endometrial cancer show similar or superior results for robotics. Some showed reduced blood loss, shorter hospital stay, increased lymph node yield, and lower morbidity with robotics compared to conventional laparoscopy (41). Others reported longer operating time but reduced blood loss, lower transfusion rate, lower conversion rate to laparotomy, and reduced hospital stay, even though the robotic patients had a higher BMI compared to laparoscopy (44). Robotics, as with laparoscopy, resulted in a shorter recovery time for endometrial cancer patients compared to laparotomy (40,45).

In an initial review of 38 patients with robotics operations, the perioperative outcomes were similar to patients treated by laparoscopy (n = 22). Results were similar to patients treated by laparotomy (n = 16) other than a larger blood loss and longer hospital stay for this group of patients. The operating times were similar for the three groups, blood loss was lower for the robotic and laparoscopy groups (283, 222, and 517 mL), and length of hospital stay was shorter for the robotic and laparoscopy groups (2, 2.5, and 6 days). There was no difference relative to the number of lymph nodes removed (18.4, 26.3, and 18.4, for robotics, laparoscopy, and laparotomy, respectively), number of lymph node metastases, positive cytological findings, or tumor recurrence. Postoperative complications were comparable among the three groups.

Boggess et al. compared 103 robotic patients with 81 laparoscopy patients and 138 laparotomy patients (41). The operating times for robotic and laparoscopy procedures were similar, but longer than laparotomy (191.2 minutes, 213.4 minutes, and 146.5 minutes, respectively). The blood loss, hospital stay, and number of nodes were all improved for the robotic group. Bell et al. compared a group of 40 robotic patients with 30 patients operated by laparoscopy and 40 patients operated by laparotomy (40). Robotic and laparoscopy operating times were comparable (184 minutes and 171 minutes, respectively) and longer than laparotomy (108.6 minutes). Blood loss was similar to laparoscopy, and both were lower than the laparotomy group. The number of lymph nodes removed was similar among the three groups. Postoperative complications were lower in the robotic group compared to the other two groups (7.5%, 27.5%, and 20%, respectively).
Another study evaluated the results of robotics and conventional laparoscopy for obese and morbidly obese patients (BMI 30–60) with endometrial cancer (42). Robotics was found to be preferable to the laparoscopic approach because of a shorter operative time, reduced blood loss, increased number of lymph nodes removed, and shorter hospital stay. The benefits of robotics for obese patients was noted with simple robotic hysterectomy, where the operating time remained unchanged in spite of the patient’s increased BMI (6). This may result from the absent awareness of the resistance of the robotic instruments being inserted through a thick abdominal wall because of the lack of tactile feedback.

The application of robotics for endometrial cancer can result in improvements of the perioperative outcomes (43). The operating time decreased by 47 minutes, vaginal cuff delayed healing decreased from 16% to 0%, and the number of pelvic and aortic lymphadenectomies and number of nodes retrieved increased per quarter analyzed from the initiation of robotics.

**The increased costs of this technology is a criticism of robotics.** Because cost is tied to frequency of use, when used on a regular basis the cost becomes similar to laparoscopy and less expensive than laparotomy as a result of shorter hospital stay. A comparison study of costs for robotics, conventional laparoscopy, and laparotomy for endometrial cancer showed a significantly reduced cost for robotics and laparoscopy compared to laparotomy and comparable costs for robotics and laparoscopy (40).
Cervical Cancer

Early Cervical Cancer

Robotic and laparoscopic radical hysterectomy may provide patient benefits over a laparotomy approach relative to blood loss, blood transfusions, and length of hospital stay. Operating times and postoperative complications are lower or similar (46–52). Recurrence and survival rates remain unchanged when comparing the results of both techniques (46–48, 51, 52). A prospective randomized trial is under way comparing laparoscopic or robotic radical hysterectomy with laparotomy (53).

The surgical technique for robotic radical hysterectomy is described elsewhere (54). A rapid learning curve is noted with robotic radical hysterectomy, with a 44-minute reduction in operating time after the first 34 procedures in association with a low complication rate and high nodal count (55).

In several retrospective studies comparing laparotomy with robotic radical hysterectomy, there was a shorter, similar, or longer operating time; reduced blood loss; shorter hospital stay; lower, similar, or higher number of lymph nodes removed; and similar rate of postoperative complications (49, 56–58). In comparison with laparoscopy, robotics is associated with a shorter, similar, or longer operating time; reduced blood loss; shorter hospital stay; similar or lower postoperative complications; and comparable or higher number of nodes (49, 50, 57).

Tumor recurrence does not appear increased with robotics compared to laparoscopy. At a mean length of follow-up of 31.1 months (range, 10 to 50 months), none of the patients in the robotic group experienced recurrence, and there was no difference with the laparoscopy group (50).

Other Applications of Robotics for Cervical Cancer

Radical parametrectomy is a surgical option for patients with an undiagnosed invasive cervical carcinoma discovered on a simple hysterectomy specimen with negative margins and with no gross visible disease. The feasibility of robotic radical parametrectomy was reported by Ramirez et al. in five patients with acceptable complications (59). There are no comparison studies of robotic radical parametrectomy with laparoscopy or laparotomy.

Radical trachelectomy for cancer of the residual cervical stump is preferable to pelvic irradiation in some patients because of the increased risk of bowel complications from intestinal adhesions to the remaining cervix. The laparoscopic approach is previously reported (60). The use of robotic radical trachelectomy in a patient with a “cut-through” endometrial cancer discovered in the subtotal hysterectomy specimen was reported (61). Radical trachelectomy is an alternative to radical hysterectomy for cervical cancer in young patients desiring fertility and with a tumor size of 2 cm or less, no lymphatic invasion or nodal metastases, and potential for preservation of the upper portion of the cervix. The feasibility of robotic radical trachelectomy was demonstrated in two patients.
with early stage cervical cancer (62). The operative times were longer (387 and 358 minutes), because of the novelty of the procedure and the required waiting time for the frozen section. No intra- or postoperative complications were observed. There are no comparison studies of robotic radical trachelectomy with laparoscopy or laparotomy. A review of eight reported patients up to May 2009 showed a median operating time of 339 minutes, median blood loss of 62.5 mL, no intraoperative complications, no blood transfusions, no conversions to laparotomy, and a median length of hospital stay of 1.5 days (63). The median number of pelvic lymph nodes removed was 20.
The laparoscopic approach to pelvic and aortic lymphadenectomy prior to chemoirradiation for patients with advanced cervical cancer is well documented, both transperitoneal and extraperitoneal (64–69). There are many studies discussing robotic pelvic and aortic lymphadenectomy included in the treatment of patients with different types of gynecologic malignancies, including cervical, endometrial, and ovarian malignancies (16,49,50,55–58,70,71).

A novel technique and the results of robotic transperitoneal infrarenal aortic lymphadenectomy in 33 patients with different gynecologic cancers was reported (72). The requirement of this technique was the placement of the robotic column at the patient’s head, which mandated the rotation of the operating table 180 degrees after completion of the robotic pelvic operation and the insertion of additional trocars in the lower pelvis (72). The mean console time was 42 minutes, the mean number of nodes 12.9, and the mean number of positive nodes 2.6. There was one conversion to laparotomy caused by bleeding. These results are comparable to those reported with laparoscopic aortic lymphadenectomy. Placing the robotic column at the patient’s head and inserting additional trocars in the lower pelvis were requirements to remove the infrarenal aortic nodes with robotics. Previous attempts to remove the left infrarenal aortic lymph nodes in a frozen cadaver were unsuccessful when the robotic column was stationed at the level of the patient’s feet.

The feasibility of the extraperitoneal robotic approach to aortic lymphadenectomy was reported (73,74). The development of the robotic extraperitoneal technique in frozen cadavers, successfully applied to a patient with cervical cancer stage IB2 presenting with enlarged left aortic lymph nodes, is reported (73). It was noted that appropriate placement of the robotic trocars and the robotic column is necessary to prevent robotic arm collision and to reach the different aortic lymph nodal areas. The operating, docking, and console times were 103, 3.5, and 49 minutes, respectively. The blood loss was 30 mL. Selective removal of five enlarged aortic lymph nodes revealed no evidence of metastases.

Another study by Vergote et al. reported the development of their technique for inframesenteric aortic lymphadenectomy in five patients (74). All console times were less than 1 hour. The operating times and number of aortic lymph nodes in both studies are within the range of those reported with the laparoscopic approach. Both studies concluded that the robotic approach was technically easier than the conventional laparoscopy procedure (73,74).

Robotic Pelvic Exenteration for Recurrent Cervical Cancer

Robotic anterior pelvic exenteration was described in three patients with recurrent cervical cancer (75). The operating times (range, 480 to 600 minutes) are longer than for laparotomy, but blood loss (range, 200 to 500 mL) is markedly lower. The length of hospital stay was similar or longer than by laparotomy (range, 25 to 53 days). Patients
required a pararectal incision (10 cm) for the pouch construction, and one patient with vaginal reconstruction had a perineal phase. Whether the robotic approach to pelvic exenteration will become preferable to laparotomy is unknown.
Ovarian Cancer

Surgery for ovarian cancer requires access to all four abdominal quadrants. The ability to operate in all four quadrants using robotics can only be achieved by rotating the operating table and positioning the robotic column at the patient’s head. In this position it is possible to excise the aortic lymph nodes to the level of the renal vessels and to perform resection of upper abdominal metastases, including small bowel, diaphragm, liver, and supracolic omental disease. Initial experience with 21 patients with ovarian cancer who underwent operations by robotics was reported (76). Included were 12 primary, 4 interval, and 5 secondary cytoreductive surgeries for ovarian cancer. In addition to primary tumor excision, major procedures included modified posterior pelvic exenteration, rectosigmoid resection, small bowel resection, diaphragm resection, and resection of liver metastases. The operating times had a wide range (103 to 454 minutes) resulting from the extent of procedures. Blood loss was low (25 to 300 mL). Postoperative complications were low but increased with the number of procedures.

There are reports of robotics for ovarian cancer consisting of an occasional patient included within a series of patients with different types of gynecologic cancers and with no comparison to laparoscopy or laparotomy (77–81). Robotics may be useful for selected patients with ovarian cancer. Because of the need for operating table rotation and the insertion of additional trocars, it may not become widely accepted. The use of the surgical robotic system can be advocated in the case of isolated recurrences of ovarian cancer, such as in the pelvis, or in the upper abdomen, diaphragm, liver, and spleen. Isolated left liver metastases were removed successfully in three patients with recurrent ovarian cancer with no complications (82).

In conclusion, robotics and laparoscopy have advantages compared to laparotomy for selected patients with cervical, endometrial and early ovarian cancer. Although prospective randomized trials are desirable, the retrospective evidence supports the selected use of minimally invasive surgery for endometrial and cervical cancer patients and selected patients with primary or recurrent ovarian cancer.
Complications Unique to Robotics

Because there is no tactile feedback, the robotic arms can injure any organ not under visual control. The potential for injury is higher with the fourth retracting arm when out of the visual field and repositioned without visual control. Constant visual control of the robotic instrument position is mandatory for the prevention of injuries. Collision of the robotic arms is felt as an unwanted resistance, which is realized when the instruments are brought under view.

Constant pressure of the robotic arms on the patient thighs or arms may result in injury. This can be prevented during positioning of the trocars and robotic arms. A rapid move by the surgeon on any robotic instrument may result in hitting the assistant near the operating table with the robotic arm. Moving a robotic arm by anyone other than the surgeon may result in patient internal injury.

Because the robotic trocars are fastened to the robotic arms, and the arms are fixed to the robotic column, any sudden loss of the pneumoperitoneum may result in the instruments being pulled off the anterior abdominal wall as it becomes flattened. Similarly, any sliding of the patient on the operating table as a result of the Trendelenburg position will result in pressure at the trocars site and potential injury or increased postoperative trocar site pain. The robotic column must be positioned at the level of the patient’s feet or lateral to the legs in order to prevent access to the vagina, rectum, or urethra.
Disadvantages of Robotics

The present robotic system has limited surgical field reach. It allows for pelvic or abdominal surgery, but not both, unless the robotic column is repositioned from the patient's feet to the patient's head. This repositioning increases surgical time and requires the insertion of additional trocars.

The available robotic instrumentation is appropriate for gynecological surgery, but there is no vessel sealing cutting device or suction-irrigation device. An assistant is necessary, at the surgical site away from the surgeon, and therefore, all orders or corrections are verbal.

Although the grasping pressure of the robotic instruments is high and can damage tissue, tissue traction is not as efficient as with conventional laparoscopic instruments. Because there is no tactile feedback when grasping a tissue, there is only visual control of the traction exerted upon any structure. The lack of tactile feedback is an advantage in obese patients (see above technology), but can be a disadvantage when the instruments are not in the visual field.

Cost is a common reason why many institutions have delayed the initiation of robotic programs. The initial purchase of the robotic system is high, about $1.5 million, with an additional annual maintenance fee, and all robotic instruments become functionless after ten uses, so they are disposed.

The robotic column and its arms are bulky, with a total weight of 1,200 lb. An operating room must have adequate space, preferably about 600 square feet. There must be a dedicated team for robotic surgery and preferably a specific team for each surgical specialty. The surgical assistant must be versed in robotic technology and be able to provide the required maneuvers without direct interaction because the surgeon is away at a console and not in a surgical sterile condition.
References

Bladder storage and emptying depend on a complex interplay between the brain, spinal cord, bladder, urethra, and pelvic floor.

Urinary incontinence is common in women and generally is treated successfully with a range of nonsurgical and surgical treatments.

Stress urinary incontinence occurs with increases in abdominal pressure (such as coughing, running, lifting) and can be treated with pelvic muscle exercises, vaginal devices, lifestyle changes, and surgery.

Urgency urinary incontinence occurs with a sudden sense of urgency (such as on the way to the bathroom or when washing hands) and can be treated with bladder training, medications, lifestyle changes, and neuromodulation.

Bladder pain remains a challenging and poorly understood entity.
Physiology of Micturition

The bladder is a complex organ that has a relatively simple function: to store urine effortlessly, painlessly, and without leakage and to discharge urine voluntarily, effortlessly, completely, and painlessly. To meet these demands, the bladder must have normal anatomic support and normal neurophysiologic function.
Normal Urethral Closure

Normal urethral closure is maintained by a combination of intrinsic and extrinsic factors. The extrinsic factors include the levator ani muscles, the endopelvic fascia, and their attachments to the pelvic sidewalls and the urethra. This structure forms a hammock beneath the urethra that responds to increases in intra-abdominal pressure by tensing, allowing the urethra to be closed against the posterior supporting shelf (Fig. 26.1). When this supportive mechanism becomes faulty for some reason—the endopelvic fascia has detached from its normal points of fixation, muscular support has weakened, or a combination of these two processes—normal support is lost and anatomic hypermobility of the urethra and bladder neck develops. For many women, this loss of support is severe enough to cause loss of closure during periods of increased intra-abdominal pressure, resulting in stress incontinence. However, many women remain continent in spite of loss of urethral support (1).

The intrinsic factors contributing to urethral closure include the striated muscle of the urethral wall, vascular congestion of the submucosal venous plexus, the smooth muscle of the urethral wall and associated blood vessels, the epithelial coaptation of the folds of the urethral lining, urethral elasticity, and the tone of the urethra as mediated by α-adrenergic receptors of the sympathetic nervous system.

Effective urethral closure is maintained by the interaction of extrinsic urethral support and intrinsic urethral integrity, each of which is influenced by several
factors (muscle tone and strength, innervation, fascial integrity, urethral elasticity, coaptation of urothelial folds, urethral vascularity). In the clinical setting, damaged urethral support is manifested clinically by urethral hypermobility, which often results in incompetent urethral closure during physical activity and presents as stress urinary incontinence. Intrinsic urethral functioning is more complicated and is not understood nearly as well as incontinence related to loss of urethral support (2).

Clinical appreciation of the importance of extrinsic support and intrinsic urethral function led to the separation of stress incontinence into two broad types:

- Incontinence caused by anatomic hypermobility of the urethra
- Incontinence caused by intrinsic sphincteric weakness or deficiency

Surgical approaches are based on this arbitrary distinction, with a pubovaginal sling recommended for women with intrinsic sphincter deficiency and a colposuspension (also known as retropubic urethropexy) for those with hypermobility. This rationale was based initially on a small study in which women younger than age 50 years with urethral closure pressure less than 20 cm H2O had a higher failure rate after a Burch colposuspension than did women with a closure pressure greater than 20 cm H2O (3). No difference in outcome was seen in women older than 50 years. This dichotomy was called into question, based on the observation that all women with stress incontinence have some degree of sphincter weakness, regardless of whether they have hypermobility. Minimally invasive synthetic midurethral slings have largely replaced pubovaginal slings and retropubic urethropexy as the most commonly performed surgical procedures for stress urinary incontinence. The use of midurethral slings would seem to lessen the impact of a poorly functioning urethra; however, a similar debate is ongoing about the impact of poor urethral function with both retropubic and transobturator slings. It appears that women with poor urethral function are more likely to experience treatment failure irrespective of the type of procedure performed (4).
The Bladder
The bladder is a bag of smooth muscle that stores urine and contracts to expel urine under voluntary control. It is a low-pressure system that expands to accommodate increasing volumes of urine without an appreciable rise in pressure. This function appears to be mediated primarily by the sympathetic nervous system. During bladder filling, there is an accompanying increase in outlet resistance. The bladder muscle (the detrusor) should remain inactive during bladder filling, without involuntary contractions. When the bladder has filled to a certain volume, fullness is registered by tension-stretch receptors, which signal the brain to initiate a micturition reflex. This reflex is controlled by cortical control mechanisms, depending on the social circumstances and the state of the patient’s nervous system. Normal voiding is accomplished by voluntary relaxation of the pelvic floor and urethra, accompanied by sustained contraction of the detrusor muscle, leading to complete bladder emptying.
Innervation

The lower urinary tract receives its innervation from three sources: (i) the sympathetic and (ii) parasympathetic divisions of the autonomic nervous system, and (iii) the neurons of the somatic nervous system (external urethral sphincter). The autonomic nervous system consists of all efferent pathways with ganglionic synapses that lie outside the central nervous system. The sympathetic system primarily controls bladder storage, and the parasympathetic nervous system controls bladder emptying. The somatic nervous system plays only a peripheral role in neurologic control of the lower urinary tract through its innervation of the pelvic floor and external urethral sphincter.

The sympathetic nervous system originates in the thoracolumbar spinal cord, principally T11 through L2 or L3 (see Chapter 6). The ganglia of the sympathetic nervous system are located close to the spinal cord and use acetylcholine as the preganglionic neurotransmitter. The postganglionic neurotransmitter in the sympathetic nervous system is norepinephrine, and it acts on two types of receptors: α-receptors, located principally in the urethra and bladder neck, and β-receptors, located principally in the bladder body. Stimulation of α-receptors increases urethral tone and thus promotes closure, whereas α-adrenergic receptor blockers have the opposite effect. Stimulation of β-receptors decreases tone in the bladder body.

The parasympathetic nervous system controls bladder motor function—bladder contraction and bladder emptying. The parasympathetic nervous system originates in the sacral spinal cord, primarily in S2 to S4, as does the somatic innervation of the pelvic floor, urethra, and external anal sphincter. Sensation in the perineum is also controlled by sensory fibers that connect with the spinal cord at this level. For this reason, examination of perineal sensation, pelvic muscle reflexes, and pelvic muscle or anal sphincter tone is relevant to clinical evaluation of the lower urinary tract. The parasympathetic neurons have long preganglionic neurons and short postganglionic neurons, which are located in the end organ. Both the preganglionic and postganglionic synapses use acetylcholine as their neurotransmitter, acting on muscarinic receptors. Because acetylcholine is the main neurotransmitter used in bladder muscle contraction, virtually all drugs used to control detrusor muscle overactivity have anticholinergic properties.

Bladder storage and bladder emptying involve the interplay of the sympathetic and parasympathetic nervous systems. The modulation of these activities appears to be influenced by a variety of nonadrenergic, noncholinergic neurotransmitters and neuropeptides, which fine tune the system at various facilitative and inhibitory levels in the spinal cord and higher areas of the central nervous system (5–7). Neuropathology at almost any level of the neuourologic axis can have an adverse effect on lower urinary tract function.
Micturition

Micturition is triggered by the peripheral nervous system under the control of the central nervous system. It is useful to consider this event as occurring at a micturition threshold, a bladder volume at which reflex detrusor contractions occur. The threshold volume is not fixed; rather, it is variable and can be altered depending on the contributions made by sensory afferents from the perineum, bladder, colon, rectum, and input from the higher centers of the nervous system. The micturition threshold is, therefore, a floating threshold that can be altered or reset by various influences.

The spinal cord and higher centers of the nervous system have complex patterns of inhibition and facilitation. The most important facilitative center above the spinal cord is the pontine-mesencephalic gray matter of the brainstem, often called the pontine micturition center, which serves as the final common pathway for all bladder motor neurons. Transection of the tracts below this level leads to disturbed bladder emptying, whereas destruction of tracts above this level leads to detrusor overactivity. The cerebellum serves as a major center for coordinating pelvic floor relaxation and the rate, force, and range of detrusor contractions, and there are multiple interconnections between the cerebellum and the brainstem reflex centers. Above this level, the cerebral cortex and related structures exert inhibitory influences on the micturition reflex. Thus, the upper cortex exerts facilitative influences that release inhibition, permitting the anterior pontine micturition center to send efferent impulses down the complex pathways of the spinal cord, where a reflex contraction in the sacral micturition center generates a detrusor contraction that causes bladder emptying.

A normal lower urinary tract is one in which the bladder and urethra store urine without pain until a socially acceptable time and place arises, at which point voiding occurs in a coordinated and complete fashion. Lower urinary tract disorders include disorders of storage (such as urinary incontinence), emptying (such as urinary hesitancy and retention), and sensation (such as urgency or pain). Current definitions for these disorders are depicted in Table 26.1.

Table 26.1 Classification and Definition of Lower Urinary Symptoms in Women

I. Abnormal Storage
Incontinence (symptom) The complaint of any involuntary leakage of urine
Stress urinary incontinence (symptom) The complaint of involuntary leakage on effort or exertion, or on sneezing or coughing
Stress urinary incontinence (sign) Observation of involuntary leakage from the urethra, synchronous with exertion/effort, or sneezing or coughing
Urgency urinary incontinence (symptom) The complaint of involuntary loss of urine associated with urgency
Mixed incontinence Complaint of involuntary loss of urine associated with urgency and also with effort or physical exertion or on sneezing or coughing
Continuous urinary incontinence Complaint of continuous involuntary loss of urine
Frequency The number of voids per day, from waking in the morning until falling asleep at night
Increased daytime urinary frequency Complaint that micturition occurs more frequently during waking hours than previously deemed normal by women (traditionally defined as more than seven episodes)
Nocturia Complaint of interruption of sleep one or more times because of the need to micturate (each void is preceded and followed by sleep)
Nocturnal enuresis Complaint of involuntary loss of urine that occurs during sleep
Urgency Compliant of sudden, compelling desire to pass urine, which is difficult to defer
Postural urinary incontinence Compliant of involuntary loss of urine associated with change of body position, for example, rising from a seated or lying position
Insensible urinary incontinence Compliant of urinary incontinence where the women has been unaware of how it occurred
Coital incontinence Compliant of involuntary loss of urine with coitus. This symptoms might be further divided into that occurring with penetration or intromission and that occurring at organism.

Overactive bladder syndrome (OAB) Urinary urgency, usually accompanied by frequency and nocturia, with or without urgency urinary incontinence, in the absence of urinary tract infection or other obvious pathology

II. Abnormal Sensory Symptoms
Increased bladder sensation Complaint that the desire to void during bladder filling occurs earlier or is more persistent from that previous experienced (differs from urgency by the fact that micturition can be postpone despite the desire to void)
Reduced bladder sensation Complaint that the definite desire to void occurs later than that previously experienced, despite an awareness that the bladder is filling
Absent bladder sensation Complaint of both the absence of the sensation of bladder filling and a definite desire to void

III. Abnormal Emptying
Hesitancy Compliant of a delay in initiating micturition
Straining to void Complaint of the need to make an intensive effort (by abdominal straining, Valsalva or suprapubic pressure) to initiate, maintain, or improve urinary stream
Slow stream Complaint of a urinary stream perceived as slower compared to previous performance or in comparison with others
Intermittency Complaint of urine flow that stops and starts on one or more occasions during voiding
Feeling of incomplete bladder emptying Complaint that the bladder does not feel empty after micturition
Postmicturition leakage Complaint of a further involuntary passage of urine following the completion of micturition

Spraying of urinary stream Complaint that the urine passage is a spray or split rather than a single discrete stream

Position-dependent micturition Complaint of having to take specific positions to be able to micturate spontaneously or to improve bladder emptying, for example, leaning forward or backward on the toilet seat or voiding in a semistanding position

Urinary retention Complaint of the inability to pass urine despite persistent effort

Urinary Incontinence

Definitions
Defining urinary incontinence would seem an easy task: women who leak urine must be “incontinent.” A joint report from the International Urogynecological Association and the International Continence Society made recommendations on the terminology of female pelvic floor dysfunction in an attempt to update the definitions by a female-specific approach and clinically based consensus. This report defined incontinence as “the complaint of any involuntary leakage of urine” (8). This definition does not take into account the wide variation in this symptom and the disruption it causes. For example, half of young nulliparous women report occasional minor urine leakage; for most this is neither a bother nor a symptom for which they would seek treatment. At the other extreme, 5% to 10% of adult women have severe leakage daily. These women often dramatically alter their lives because of leakage, curtailing activities, social outings, and intimacy. Many suffer marked deterioration in self-esteem. In between these two extremes lies another one-third of adult women who report leakage at least weekly, but without the same degree of life-altering severity as the women previously noted.

Collectively, these women assume a substantial cost burden. The total annual cost to care for patients with incontinence in the United States is estimated at $11.2 billion in the community and $5.2 billion in nursing homes (9). In the United States, much of this cost is borne directly by women in the form of incontinence pads and excess laundry costs. Despite the burden imposed by leakage, many women do not discuss this symptom with a health care professional. For some women, this is because the leakage does not bother them, whereas others are embarrassed and suffer in silence. Still others do not raise this issue because they mistakenly believe the only treatment option is surgical. It is incumbent on the provider to ask women about leakage.

Studies show that there is little relationship between the volume of urine lost and the distress that it causes a patient (10). The degree to which women are bothered by leakage is influenced by various factors, including cultural values and expectations regarding urinary continence and incontinence. If the leakage is distressing to the patient, evaluation and treatment should be offered. Incontinence can almost always be improved and frequently can be cured, often using relatively simple, nonsurgical interventions.
Types of Disorders

Stress Urinary Incontinence

Stress urinary incontinence occurs during periods of increased intra-abdominal pressure (e.g., sneezing, coughing, or exercise) when the intravesical pressure rises higher than the pressure that the urethral closure mechanism can withstand. Some advocate the term “activity-related incontinence” in some languages to avoid the confusion with psychological stress (8). Stress urinary incontinence is the most common form of urinary incontinence in women and is particularly common in younger women. Active women are more likely to notice symptoms of stress urinary incontinence. In a survey of 144 collegiate female varsity athletes, 27% reported stress incontinence while participating in their sport (11). The activities most likely to produce urinary loss were jumping, high-impact landings, and running.

Stress incontinence is an interesting “disease” as the same symptoms have varying effects on different women. This condition is best considered in a biobehavioral model that examines the interaction of three variables: (i) the biologic strength of the urethral sphincteric mechanism, (ii) the level of physical stress placed on the closure mechanism, and (iii) the woman’s expectations about urinary control. This model explains the enormous variation that exists among the symptoms, the degree of demonstrable leakage, and a patient’s response to her stress incontinence. Modification of any one of these factors may influence the patient’s clinical status; for example, many patients give up certain physical activities (e.g., running, dancing, aerobics) when they experience stress incontinence. Limiting their activities may eliminate the incontinence problem, but it does so at a certain cost to their quality of life. Other women learn to cope with stress incontinence by adopting new body postures during physical activities that prevent them from leaking or by strengthening their pelvic muscles to compensate for increased exertion. Other women may be profoundly relieved to find out that the small amount of leakage they experience from time to time is not abnormal. In any case, the interaction of these three biopsychosocial factors opens up a variety of strategies for the management of stress incontinence. Surgical intervention is only one strategy, and it addresses only the biologic competence of the sphincteric mechanism rather than either of the other factors that interact to produce the clinical problem.

Urgency Urinary Incontinence and Overactive Bladder

Although stress incontinence is the most common type of urinary continence in all women, urgency incontinence is the most common form of incontinence in older women (12). Urgency urinary incontinence is the involuntary leakage of urine accompanied by or immediately preceded by urgency. The new joint report from the International Urogynecological Association and International Continence Society recommended this symptom be called urgency urinary
incontinence to differentiate between the normal urge experienced when the bladder is full from the abnormal response that may require treatment. This is a symptom-based diagnosis; the cause may or may not be detrusor overactivity, based on urodynamic observation characterized by involuntary detrusor contractions during the filling phase.

Women may have other related problems such as urgency, nocturia, and increased daytime frequency. The definition of nocturia is quantifiable: The woman wakes one or more times a night to void (8). Increased daytime frequency occurs when the patient considers that she voids too often. The term pollakisuria is used to describe this condition in many countries.

Urgency is the sudden compelling desire to pass urine that is difficult to defer. Most women have experienced these symptoms during times of voluntary delays in voiding or increased fluid intake. However, urinary urgency implies more than just the feeling that all normal women have if they voluntarily delay voiding beyond a reasonable time (8). When a woman presents for treatment, she generally reports an intrusive, bothersome, persistent need to urinate that takes her attention away from other activities. Increased daytime frequency is often brought up as an issue when a woman experiences a change in her own voiding pattern.

There is very little information about what is “normal” in terms of voiding frequency. Overactive bladder (OAB) is frequently defined in studies of pharmacologic agents as more than eight voids per 24 hours, a definition that was based on the 95th percentile of voids in a small sample of Scandinavian women (13). Data from a broader sample of women in the United States suggest that the median number of voids per day is eight, and 95% of so-called normal women void 12 or fewer times per day (14).

Overactive detrusor function is defined as a urodynamic diagnosis characterized by involuntary detrusor contractions during the filling phase, which may be spontaneous or provoked. It is divided into neurogenic detrusor overactivity, resulting from a relevant neurologic condition and idiopathic detrusor overactivity, when there is no clear cause (15).

The term overactive bladder syndrome is defined as urinary urgency, usually accompanied by frequency and nocturia, with or without urgency urinary incontinence, in the absence of urinary tract infection or other obvious pathology (8). It is often referred to as OAB-dry when women with these symptoms do not leak urine, and OAB-wet when it is accompanied by incontinence. It is important to note that a woman with severe urgency and a sense of impending leakage who remains dry may have the exact same bladder pathology as one with severe urgency and concomitant leakage. A woman with a strong urethral sphincteric mechanism may be able to avoid leakage during uninhibited bladder contractions, and although one with a strong sphincter may remain dry, she still may be disturbed by the urgency and impending sense of leakage.
Mixed Incontinence

As implied by the name, women with mixed incontinence have symptoms of both stress and urge urinary incontinence. Younger women are more likely to have stress incontinence alone, whereas in older women mixed and urge incontinence predominate. In a review of 15 population-based studies of women of all ages with urinary incontinence, a median of 49% (range 24% to 75%) had stress urinary incontinence, 21% (range 7% to 49%) had urge urinary incontinence, and 29% (range 11% to 61%) had mixed urinary incontinence (16).

Functional and Transient Incontinence

Functional incontinence is more common in elderly women and refers to incontinence that occurs because of factors unrelated to the physiologic voiding mechanism. A woman who cannot get to the bathroom quickly enough may often become incontinent. Functional incontinence can be related to such factors as decreased mobility, musculoskeletal pain, or poor vision. Factors leading to transient urinary incontinence are, as the name implies, medically reversible conditions. A useful mnemonic to help remember these factors is DIAPPERS (17,18) (Table 26.2). These factors argue strongly for the inclusion of a thorough medical evaluation as part of the workup of any patient with urinary incontinence.

Extraurethral Incontinence

Although most urinary incontinence represents unwanted urine loss through the urethra (transurethral incontinence), urine loss can also occur through abnormal openings. These openings can be created by congenital defects or some form of trauma. The congenital causes of urinary incontinence are not common and usually are easy to diagnose. The most extreme cases are caused by bladder extrophy, in which there is a congenital absence of the lower anterior abdominal wall and anterior portion of the bladder, resulting in the entire bladder opening directly to the outside (19). Such cases are
diagnosed at birth. Before the advent of modern reconstructive surgery, these infants usually died very early in life from sepsis.

Ectopic ureter, a subtle congenital anomaly causing extraurethral urine loss, generally is detected early in life, but occasionally may escape detection until adolescence or early adulthood (20). In infancy, an ectopic ureter should be suspected when a mother seeks care for her baby, whom she says is never dry. Normally, infants have periods of dryness interspersed with periods of wetness. Most commonly, the ectopic ureter drains into the vagina, but occasionally, it may drain into the urethra distal to the point of continence. This condition can be diagnosed by excretory urography.

A traumatic opening between the urinary tract and the outside is called a fistula. Vesicovaginal fistulas, located between the bladder and urethra, are most common, but fistulas may occur between the vagina, uterus, or bowel, and the urethra, ureter, or bladder.

Worldwide, the most common cause of vesicovaginal fistulas is obstructed labor. This was true in the Western world 150 years ago, but advances in the provision of basic obstetric services and advanced obstetric intervention have virtually eliminated this problem in developed countries.

Obstructed labor can occur in rural areas where girls are married young (sometimes as early as 9 to 10 years of age) and where transportation is poor and access to medical services is limited. In such circumstances, pregnancy often occurs shortly after menstruation begins and before maternal skeletal growth is complete. When labor begins, cephalopelvic disproportion is common and little can be done to correct fetal malpresentations. Women may be in labor as long as 5 to 6 days without intervention, and if they survive, they usually give birth to a stillborn infant. In such cases, the soft tissues of the pelvis are crushed by constant pressure from the fetal head, leading to an ischemic vascular injury and subsequent tissue necrosis. When this tissue sloughs, a genitourinary or rectovaginal fistula develops. Many of these patients have complex or multiple fistulas, involving total destruction of the urethra and sloughing of the entire bladder base (Fig. 26.2). Obstetric fistulas are frequently as large as 5 to 6 cm in diameter.

Figure 26.2 Moderate-sized obstetric vesicovaginal fistula. A metal probe has been placed through the urethra and is clearly visible through the bladder base. (Copyright Worldwide Fistula Fund, used by permission.)
After such fistulas develop, the lives of these young women (most of whom are younger than 20 years of age) are ruined unless they can gain access to curative surgical services. The constant, uncontrolled dribble of urine makes them offensive to their husbands and family members and they are often ostracized from their families. Most of them eventually become destitute social outcasts—and yet these are otherwise healthy young women. The social and economic costs of this problem are enormous, yet the world medical community largely ignores it. The morbidity associated with obstetric fistulas remains, along with the related maternal mortality, one of the single most neglected issues in international women’s health care.

In the industrialized world, the most common causes of genitourinary fistulas are surgery, malignancy, and radiation therapy, alone or in combination. Most often a vesicovaginal fistula develops after an otherwise uncomplicated vaginal or abdominal hysterectomy in which a small portion of the bladder was inadvertently trapped in a surgical clamp or was transfixed by a suture. These fistulas most often occur at the vaginal apex and are no larger than 1 to 2 mm. The amount of urine that can leak through a fistula of any size, however, is enormous. Figure 26.3 shows a cystoscopic view of three small vesicovaginal fistulae, lined up where the cuff suture line would have been. With traditional vaginal and abdominal hysterectomy, many surgeons recommend universal cystoscopy at the completion of the surgical case to assess for urinary tract injury and potentially decrease the incidence of urinary tract fistula. A review of 839 patients undergoing hysterectomy for benign disease followed by universal cystoscopy at completion of the procedure revealed lower urinary tract injury in 4.3%, including bladder injury in 2.9% and ureteral injury in 1.8% (21).

Figure 26.3 Posthysterectomy fistulas. Note three small fistulas in a row.
With the increase in minimally invasive techniques for pelvic surgery, including hysterectomy, the use of electrocautery devices is commonplace. This more frequent use of electrocautery for ligation of vessels and the resulting thermal spread increases concern about the possibility of ureteral damage that may lead to ureterovaginal fistula. **When significant urine leakage occurs, often 10 to 14 days following a laparoscopic hysterectomy, ureterovaginal fistula should be strongly considered in the differential diagnosis.** As with abdominal and vaginal surgery, careful attention to the location of the ureter, especially in proximity to the uterine arteries, must be a standard precaution. The incidence of ureterovaginal fistula after laparoscopic hysterectomy appears to be 1% to 4% (22).

Although rare, vesicouterine fistulas are increasing in incidence as the rate of cesarean deliveries increases. Such fistulas are almost always associated with repeat cesarean deliveries. **The classic triad of vaginal urinary leakage, cyclic hematuria, and amenorrhea is known as Youssef’s syndrome (23).**

**Nocturia**

Nocturia is the number of voids recorded during a night’s sleep; each void is preceded and followed by sleep. To sort out whether nocturia results from heightened urine production at night, the nocturnal urinary volume can be assessed from a bladder chart. Nocturnal urinary volume is defined as the total volume of urine passed between the time the woman goes to bed with the intention of sleeping and the time of waking with the intention of rising. Thus, it excludes the last void before going to bed but includes the first void after rising in the morning. Nocturia can be the result of nocturnal polyuria potentially related to delayed mobilization of fluid especially in the elderly, sleep problems (e.g., sleep apnea), or low volume voids. Nocturnal polyuria is present when an increased proportion of the 24-hour output occurs...
at night.
Risk Factors for Urinary Incontinence

Most of the data about risk factors for urinary incontinence come from clinical trials or cross-sectional studies using survey design. Some risk factors were more rigorously studied than others. Thus, the information available is limited in its general applicability and one cannot infer causality from it. Despite these limitations, there is some evidence that age, pregnancy, childbirth, obesity, functional impairment, and cognitive impairment are associated with increased rates of incontinence or incontinence severity (16). Some factors pertain more to certain age groups than others. For example, in studies of older women, childbirth no longer increases the risk of incontinence, possibly because of the presence of comorbidities and other factors that promote incontinence. Medical diagnoses that were associated with urinary incontinence include diabetes, strokes, and spinal cord injuries. Other factors about which less is known or findings are contradictory include hysterectomy, constipation, occupational stressors, smoking, and genetics.

Pregnancy and delivery predispose women to stress urinary incontinence, at least during their younger years. Of women who have not borne children, those who are pregnant leak more often than their nonpregnant counterparts; about half of women report symptoms of stress urinary incontinence during pregnancy, but in most, the symptom resolves after delivery. In a prospective study, 32% of 305 primiparas developed stress urinary incontinence during pregnancy and 7% after delivery. By 1 year, only 3% reported stress urinary incontinence (24). However, 5 years later, 19% of women with no symptoms after the first delivery had stress urinary incontinence. Of women reporting stress urinary incontinence 3 months postpartum (in most of whom it had resolved by 1 year), 92% had such leakage 5 years later. Transient postpartum leakage may be a marker for future incontinence.

Various changes happen after delivery that may predispose women to stress urinary incontinence. Levator ani muscle strength decreases (25). About 20% of women develop a visible defect in the levator ani muscles after vaginal delivery (26). The bladder neck descends, and the pelvic muscles undergo partial denervation with pudendal neuropathy (27). In most studies, parity is strongly associated with urinary incontinence in younger women (28). In studies of women 60 years and older, parity is no longer an independent risk factor for incontinence (29). The reason for this is not well elucidated, but it may be because the changes in muscle, nerve, connective tissue, and hormonal function that occur with aging make other women “catch up” to those who developed incontinence at a younger age because of delivery trauma. Alternately, it may be that medical problems more common in older women account for a larger proportion of incontinence risk as women age.

Obesity deserves special mention for its role in causing or exacerbating stress incontinence. Many researchers report an association (that remains after adjusting for age and parity) between increased weight and body mass index.
BMI and urinary incontinence. For example, a dose–response relationship between BMI and severe urinary incontinence was described (30). Compared with women with a BMI less than 25 kg/m², odds ratios (OR) for the following BMI groups were: 25 to 29, OR 2.0 (range 1.7–2.3); 30 to 34, OR 3.1 (2.6–3.7); 35 to 39, OR 4.2 (3.3–5.3); 40+ 5.0 (3.4–7.3). A prospective randomized study evaluating overweight and obese women with at least 10 urinary incontinence episodes per week undergoing an intensive 6-month weight-loss program versus structured education program found that women in the weight-loss program had a mean weight loss of 8.0% and decreased their leakage episodes by 47% compared to mean weight loss of 1.6% and 28% reduction in leakage episodes in the education program group (31).
Initial Evaluation

The initial evaluation of patients with incontinence requires a systematic approach to consider possible causes. The basic evaluation should include the following items: history (including assessment of quality of life and degree of bother from symptoms), physical examination, and simple primary care level tests. Most women can begin nonsurgical treatment after this basic evaluation.

History

A thorough medical history should be obtained from every incontinent patient. The history should include a review of symptoms, general medical history, review of past surgery, and current medications. The woman’s most troubling symptoms must be ascertained—how often she leaks urine, how much urine she leaks, what provokes urine loss, what improves or worsens the problem, and what treatment (if any) she had in the past. It is essential to keep the patient’s chief symptom at the forefront to avoid inappropriate management. Consider, for example, a woman whose chief concern is that once a month, while leading a business seminar, she has a sudden, overwhelming urge to void followed by complete bladder emptying. She finds this leakage devastating and is considering quitting her job because of her acute embarrassment. On occasion, she leaks a few drops of urine during exercise, but this minor leakage does not bother her. During the evaluation, urodynamics reveal minimal stress urinary incontinence at capacity during strong coughing. No detrusor overactivity is seen. The patient is offered, and undergoes, a surgical procedure for her documented urodynamic stress incontinence. Not surprisingly, her chief symptom is not improved and she is devastated.

The general medical history may reveal systemic illnesses that have a direct bearing on urinary incontinence, such as diabetes mellitus (which produces osmotic diuresis if glucose control is poor), vascular insufficiency (which can lead to incontinence at night when peripheral edema is mobilized into the vascular system, resulting in increased diuresis), chronic pulmonary disease (which can lead to stress incontinence from chronic coughing), or a wide variety of neurologic conditions that can affect the neurourologic axis at any point from the cerebral cortex to the peripheral nervous system. Medications that may affect the lower urinary tract are summarized in Table 26.3 (32–35).

Table 26.3 Medications that May Affect the Urinary Tract

1. Sedatives such as the benzodiazepines may cause confusion and secondary incontinence, particularly for elderly patients.
2. Alcohol may have similar effects to benzodiazepines and also impairs mobility and causes diuresis.
3. Anticholinergic drugs may impair detrusor contractility and may lead to voiding difficulty and overflow incontinence. Drugs with anticholinergic properties are widespread and include antihistamines, antidepressants, antipsychotics, opiates, antispasmodics, and drugs used to treat Parkinson’s disease.
α-Agonists, which are often found in over-the-counter cold remedies, increase outlet resistance and may lead to voiding difficulty.

α-Blockers, sometimes used to treat hypertension (e.g., prazosin, terazosin), may decrease urethral closure pressure and lead to stress incontinence.

Calcium-channel blockers may reduce bladder smooth muscle contractility and lead to voiding problems or incontinence; they may also cause peripheral edema, which may lead to nocturia or nighttime urine loss.

Angiotensin-converting enzyme inhibitors may result in a chronic and bothersome cough that can result in increasing stress urinary incontinence in an otherwise asymptomatic patient.

**Quality-of-Life Measures**

Physicians caring for incontinent women should ask them about the way the incontinence specifically affects their lives and to what degree the incontinence bothers them. There often is discord between the objective symptom severity and subjective bother. Only by understanding each woman’s situation can treatment be appropriately planned and response evaluated. Some women may be completely satisfied if they are able to sit through a movie without running to the bathroom, even if they leak urine at other times. Others may be satisfied only if they are 100% dry. Given that the latter is likely an unrealistic goal, knowing that the patient feels this way gives the provider the opportunity to educate her about the likely outcome of treatment.

Physicians may use one of several well-designed, validated quality-of-life measures. An expert summary of the literature in this area conducted for the International Consultation on Incontinence recommended the instruments summarized in Table 26.4. These instruments were found to be valid, reliable, and responsive to change following standard psychometric testing.

**Table 26.4 Questionnaires to Assess Urinary Incontinence**

The following questionnaires have been recommended by the International Consultation on Incontinence to assess symptoms of incontinence and impact of incontinence on quality of life in women.\(^a\)

**Symptoms**

Urogenital Distress Inventory (UDI)-6 (short form). **Uebersax JS, Wyman JF, Shumaker SA, et al.** Short forms to assess life quality and symptom distress for urinary incontinence in women: the incontinence impact questionnaire and the
Quality of Life

**Physical Examination**
The physical examination of the patient with incontinence should focus on general medical conditions that may affect the lower urinary tract and problems related to urinary incontinence. Such conditions include cardiovascular insufficiency, pulmonary disease, occult neurologic processes (e.g., multiple sclerosis, stroke, Parkinson’s disease, and anomalies of the spine and lower back), abdominal masses, and mobility. Key factors to assess during the physical examination are summarized in Table 26.5. A cotton swab test has poor predictive value for determining either stress urinary incontinence diagnosis or predicting treatment success (36). It is used by some clinicians to determine movement of the anterior vaginal wall with Valsalva. A woman with a fixed nonmobile urethra is a poor candidate for a surgery (such as a Burch colposuspension) designed to elevate the urethra. It is not possible to increase support
for an already well-supported urethra.

**Table 26.5 Physical Examination of a Woman with Lower Urinary Tract Dysfunction**

Anal sphincter function
Test of urethral mobility (e.g., cotton swab test)
Simple (Primary Care Level) Tests

It is important to realize that formal urodynamics tests are neither the only nor the most important tests of bladder function. Other simple tests that can be performed in the primary care setting provide useful information to guide patient care.

Voiding Diary

A frequency/volume bladder chart (often termed a “bladder diary”) is an invaluable aid in the evaluation of patients with urinary incontinence. A frequency/volume chart is a voiding record kept by the patient for several days. Patients are instructed to write down the time of every void on the chart and measure the amount of urine voided. The time of any incontinent episodes, and the specific activities associated with urine loss, should be recorded. If desired, the patient can be instructed to keep a record of fluid intake. Although the type of intake may guide management suggestions, in most cases volume of intake can be estimated with some accuracy from the amount of urine produced.

A frequency/volume bladder chart provides vital information about bladder function that is not provided by formal urodynamics studies: 24-hour urinary output, the total number of daily voids, number of nighttime voids, the average voided volume, and the functional bladder capacity (largest volume voided in normal daily life). This information allows the clinician to confirm reports of urinary frequency with objective data and to determine whether part of the patient’s problem is an abnormally high (or low) urinary output. The chart can be used to calculate the volume of urine generated in nighttime hours versus daytime hours. Nighttime volume is calculated by adding output from voids that occur after the woman has fallen asleep for the night and the first morning void on awakening for the day. Older women sometimes have a marked shift in urine production, with more than half of their urine output generated during sleeping hours (Fig. 26.4). Demonstrating this on the voiding diary may lead to further treatment options.

Figure 26.4 Voiding diary (also called bladder chart). Daytime frequency is seven. The patient has nocturia (gets up to void two times during sleeping hours) and also has nocturnal polyuria (an increased proportion of the 24-hour output occurs at night; note that nighttime urine output excludes the last void before sleep but includes the first void of the morning). She has urge incontinence, likely caused by the relatively larger bladder volumes voided at night, which in turn may be related to her greater fluid, caffeine, and alcohol consumption in the evening.
Urinalysis

Examination of the urine by dipstick testing and microscopy is done to exclude infection, hematuria, and metabolic abnormalities. **Hematuria cannot be diagnosed on the results of a dipstick test alone; confirmation by microscopic evaluation is mandatory.**

If a urinary tract infection is documented by microscopy or culture, it is reasonable to see whether urinary tract symptoms improved with eradication of bacteriuria. Occasionally, a simple urinary tract infection causes the onset or exacerbation of urinary incontinence. **Some women, particularly older ones, have asymptomatic bacteriuria that truly is asymptomatic; thus, if attempted treatment of a woman with bacteriuria but without classic urinary tract infection symptoms (such as dysuria, urgency, or frequency) does not improve incontinence, further antibacterial treatment is generally unnecessary.**

If hematuria and bacteriuria are found, the urine should be rechecked after eradication of the bacteriuria. **Hematuria found in the absence of bacteriuria may need further evaluation to rule out kidney or bladder tumors;** the necessity for and extent of the evaluation depends on concomitant risk factors and the clinical presentation. If malignancy is suspected, bladder biopsy should be performed by the surgeon who would treat the patient in the event a malignancy is discovered.

Routine urinary cytology is not helpful, but testing may be of value in women older than 50 years with irritative urinary tract symptoms, particularly if those symptoms are of sudden onset.

**Postvoid Residual Volume**

Incomplete bladder emptying may cause incontinence. Patients with a large
Postvoid residual (PVR) urine volume have a diminished functional bladder capacity because of the dead space occupied in the bladder by retained urine. This stagnant pool of urine is a source of urinary tract infections because the major defense of the bladder against infection is frequent, nearly complete emptying.

A large PVR volume can contribute to urinary incontinence in two ways. If the bladder is overdistended, increases in intra-abdominal pressure can force urine past the urethral sphincter, causing stress incontinence (sometimes termed “overflow incontinence” in the context of a large PVR volume). In some cases, bladder overdistention may provoke an uninhibited contraction of the detrusor muscle, leading to incontinence. These conditions may coexist, further complicating the problem.

The PVR volume can be assessed by either direct catheterization or ultrasonography. Although sufficiently accurate for clinical purposes, ultrasonography measurements of PVR volume have a standard error of 15% to 20%. It is reasonable to confirm an elevated PVR volume detected on ultrasound with a catheterized volume. It is important to perform this test within 10 minutes of a void to avoid an artificially elevated result because of diuresis. It is agreed that a PVR level less than 50 mL is normal and greater than 200 mL is abnormal, but there is much debate about values in the midrange. Because many women are unable to void well during an anxiety-ridden first visit, it is helpful to recheck the PVR volume at a future visit before embarking on further diagnostic tests. The value of assessing bladder emptying in neurologically normal women who do not have pelvic organ prolapse or symptoms of voiding dysfunction has not been demonstrated.

**Cough Stress Test**

Patients should be examined with a full bladder, particularly if stress incontinence is a consideration. Urine egress from the urethra at the time of a cough documents stress incontinence. If leakage is not observed when the woman is supine, she should stand with her feet separated and cough several times.

**Pad Tests**

Weighing menstrual or bladder pads before and after activity provides another objective way to measure urinary leakage. Such pad tests are widely used in patient-oriented research to assess treatment effectiveness, but rarely are they used in clinical practice. Pad tests can be divided into short-term tests, usually performed under standardized office conditions, and long-term tests, usually performed at home for 24 to 48 hours. Pad tests are generally performed with a symptomatically full bladder or with a certain volume of saline instilled into the bladder before beginning the series of exercises. A pad weight gain of 1 g or more is considered positive for a 1-hour test, and a pad weight gain greater than 4 g is positive for a 24-hour test.
Advanced Testing

Urodynamics

At its most basic level, a urodynamic study is anything that provides objective evidence about lower urinary tract function (38). In this sense, measurement of a patient’s voided urine volume and catheterization to determine her PVR volume are urodynamic studies. A frequency/volume chart is also a valuable urodynamic study. **Obtaining clinically valuable information does not always require the use of expensive, complex technology.** After basic testing, further testing is recommended in the following circumstances: the diagnosis is uncertain (for example, because of major discrepancies between the history, the voiding diary, and symptom scales); surgery is being considered; an elevated PVR volume, a neurologic condition that may complicate treatment (such as multiple sclerosis), marked pelvic organ prolapse, or numerous prior surgical attempts at correction. Bladder and kidney imaging should be considered if the patient has hematuria in the absence of an infection. Current urodynamic definitions are summarized in Table 26.6.

### III. Urethral function

| A. Normal urethral closure mechanism | Maintains a positive urethral closure pressure during bladder filling |
| B. Incompetent urethral closure mechanism | Allows leakage of urine in the absence of a detrusor contraction |
| C. Urethral relaxation incontinence | Leakage that is due to urethral relaxation in the absence of raised abdominal pressure or detrusor overactivity |
| D. Urodynamic stress incontinence | Involuntary leakage of urine during increased abdominal pressure, in the absence of detrusor contraction (replaces term genuine stress incontinence) |
| E. Urethral pressure ($P_{\text{ure}}$) | Fluid pressure needed to open closed urethra |
| 1. Pressure profile | Pressure along length of urethra |
| 2. Urethral closure pressure | $P_{\text{ure}} - P_{\text{ves}}$ |
| 3. Maximum urethral closure pressure (MUCP) | Maximum difference between $P_{\text{ure}}$ and $P_{\text{ves}}$ |
| 4. Pressure transmission ratio | Increment in urethral pressure on stress as percentage of simultaneously recorded increment in intravesical pressure |
**Uroflowmetry**

To assess voiding function, urodynamic testing usually begins with uroflowmetry, a study in which the volume of urine voided is plotted over time. Flow time, peak flow rate, and time to peak flow usually increase as the voided volume increases.

**Filling Cystometry**

Cystometry is done to assess bladder and urethral function during bladder filling. Simple (or single-channel) cystometry is performed when bladder pressure only is measured during filling. Because the bladder is an intra-abdominal organ, the pressure recorded in the bladder is a combination of several other pressures, most notably the pressure created by the activity of the detrusor muscle itself and the pressure exerted on the bladder by the weight of the surrounding intra-abdominal contents (e.g., uterus, intestines, straining, or exertion). For this reason, the technique of complex (also called multichannel or subtracted) cystometry is used to try to approximate the actual pressure exerted in the bladder by the activity of the detrusor muscle alone. The detrusor pressure ($P_{det}$) is obtained by measuring total intravesical pressure ($P_{ves}$) with a bladder pressure catheter, approximating intra-abdominal pressure ($P_{abd}$) with a rectal or vaginal catheter, and then electronically subtracting the latter from the former:

---

\[ P_{\text{det}} = P_{\text{ves}} - P_{\text{abd}}. \]

Measurements can be obtained using electronic microtip transducer pressure catheters, fluid-filled pressure lines, fiberoptic catheters, or air-charged catheters. All are acceptable for clinical use, but it is important to realize that when different types of catheters are used, the correlation between numbers is imperfect. Other technical factors that influence cystometry results include the choice of distending medium, filling rate, and patient position. The steps involved in a multichannel urodynamic study are outlined in Table 26.7. Normal cystometric values for women are shown in Table 26.8.

**Table 26.7 Steps in Conducting a Multichannel Urodynamic Study**

1. **Insert pressure and filling catheter into bladder** (may be two catheters or dual catheter) to measure intravesical pressure and to fill bladder. Insert pressure catheter into upper vagina or rectum to approximate abdominal pressure.
2. **Infuse fluid (usually sterile water or saline, sometimes radiographic contrast dye) at a rate of 50 to 100 mL/min.** Record the volume infused and the pressure measurements continuously. The patient’s bladder may be filled with her lying supine, in a modified lithotomy position, sitting, or standing. When possible, do cystometry in the standing position as most patients with incontinence report this problem more when they are erect.
3. **Note the point at which any leakage occurs.**
4. **During filling, record the first desire to void** (that is, the feeling that would lead her to void at the next convenient moment, but voiding can be delayed if necessary) and the strong desire to void (that is, the persistent desire to void without the fear of leakage). The maximum cystometric capacity, in women with normal sensation, is the volume at which the woman can no longer delay micturition; filling should not be continued to the point of pain or severe discomfort.
5. **If no detrusor overactivity is noted during filling, have the patient do provocative maneuvers at maximum capacity, such as coughing, heel-bouncing, and listening to the sound of running water to provoke uninhibited detrusor contractions,** which may be the cause of the patient’s symptoms.

**Table 26.8 Approximate Normal Values of Female Bladder Function**

- Residual urine <50 mL
- First desire to void occurs between 150 and 250 mL infused
- Strong desire to void does not occur until after 250 mL
- Cystometric capacity between 400 and 600 mL
- Bladder compliance between 20 and 100 mL/cm H₂O measured 60 sec after reaching
cystometric capacity
No uninhibited detrusor contractions during filling, despite provocation
No stress or urge incontinence demonstrated, despite provocation
Voiding occurs as a result of a voluntarily initiated and sustained detrusor contraction
Flow rate during voiding is >15 mL/sec with a detrusor pressure of <50 cm H2O

An example of detrusor overactivity seen during complex cystometry is shown in Figure 26.5. Surface or needle electromyography may be performed during filling and voiding to assess muscle activity of the urethral sphincter or pelvic floor. Electromyography as generally performed did not prove useful in neurologically intact women with symptoms of only stress urinary incontinence, and is not required in this patient population.

Figure 26.5 Detrusor overactivity on filling cystometrography. The patient begins to sense urgency, accompanied by an unstable bladder contraction, when 88 mL of water are instilled into the bladder. The detrusor pressure rises, and when 96 mL of water are instilled, she leaks. P_{abd}, abdominal pressure; P_{ves}, vesical pressure; P_{det}, detrusor pressure.

Both false-positive and false-negative results can occur with urodynamic studies. False-positive results occur in patients with asymptomatic detrusor overactivity, detrusor overactivity that is irrelevant to the symptom, or detrusor overactivity that is situational (e.g., caused by test anxiety). False-negative results can occur because a 20- to 40-minute cystometrogram is not always an accurate measure of 24-hour bladder activity. Looking for detrusor overactivity with such a test is like looking for an episodic
cardiac arrhythmia using 12-lead electrocardiography, as opposed to looking for the arrhythmia using a 24-hour Holter monitor. The sensitivity of the latter test is far greater than that of the former. Ambulatory urodynamics can be performed and are more likely to detect detrusor overactivity than office-based studies.

Tests of Urethral Function

Several tests of urethral function, including urethral pressure profilometry, Valsalva leak-point pressures, and the fluoroscopic and cystoscopic assessment of the bladder neck, are used in attempts to guide therapy in women with stress urinary incontinence. **Women with poor urethral function, evidenced by low Valsalva leak-point pressures, low maximal urethral closure pressures, or a visualized open bladder neck, are thought to be at higher risk of treatment failure using standard retropubic urethropexy** (Fig. 26.6). Cutoff values for these tests are poorly defined and remain controversial. Although women with stress urinary incontinence have, on average, significantly lower maximal urethral closure pressures than those without incontinence, there is wide overlap in the values between such women, and no lower limit of urethral closure pressure or leak point pressure is established that diagnoses stress urinary incontinence.

**Figure 26.6** Open and scarred bladder neck in an elderly woman who has undergone three anterior colporrhaphies for stress urinary incontinence in the past.

The urethral pressure profile is a test designed to measure urethral closure. Because continence requires the pressure in the urethra to be higher than the pressure in the bladder, it was believed that measuring the pressure differential between the two would
provide useful clinical information. The urethral pressure profile is determined by slowly pulling a pressure-sensitive catheter through the urethra from the bladder.

The urethral closure pressure ($P_{\text{close}}$) is the difference between the urethral pressure ($P_{\text{ure}}$) and the bladder pressure:

\[(P_{\text{ves}}): P_{\text{close}} = P_{\text{ure}} - P_{\text{ves}}.\]

It was suggested that women with stress incontinence with low urethral closure pressure (<20 cm H$_2$O) have a poorer prognosis for surgical outcome than women who do not have this condition; however, this area is the subject of considerable debate (3,39,40). Because stress incontinence, by definition, occurs during increases in intra-abdominal pressure that are generated by some kind of physical activity, it is not obvious why measurement of resting urethral pressure should be relevant to stress-related leakage, which is a dynamic event. One review concluded that urethral pressure profilometry is not a useful diagnostic test for stress incontinence in women and that its use in clinical management is unsupported by current evidence (41).

Leak-point pressure (LPP) is a urodynamic measure of the minimum intra-abdominal or intravesical pressure required to cause incontinence during abdominal strain or cough. There is no consensus about whether it should be measured from the resting supine baseline (generally near 0) or from the standing resting baseline (which increases depending on body mass). Other factors that may affect the results include the catheter’s type, caliber, and placement (vaginal, rectal, or intravesical), the bladder volume at which the measurement is obtained, the mechanism by which intra-abdominal pressure is increased (coughing versus straining), and patient position (42).

Leak point pressure measurements often are performed at a bladder volume of 200 or 300 mL. Patients are asked to cough with gradually increasing force (cough leak-point pressure) and finally to strain slowly (Valsalva) to increase intravesical pressure gradually. The lowest pressure at which leakage occurs is recorded as the cough or the Valsalva leak-point pressure (Fig. 26.7). If leakage is not demonstrated, the highest pressure that was obtained can be recorded with the notation “no leakage” to the specified pressure as measured in centimeters of water pressure. Many clinicians use a cutoff point of 60 cm water pressure to separate women who have intrinsic sphincter deficiency from those who do not. This is problematic for two reasons: (i) the marked variability of results that depend on all the aforementioned factors and (ii) the lack of prospective studies that demonstrate the predictive value of leak point pressure values on surgical outcomes. Results from this and other urodynamics tests must be evaluated as one piece of the patient’s puzzle, along with the history, physical examination, voiding diary, and other tests. Medicare guidelines require that when bulking agents, such as collagen, are considered to treat stress incontinence, the intra-abdominal leak point pressure when the bladder has been filled with at least 150 mL of fluid must be less than 100 cm H$_2$O.
Fluoroscopy and cystourethroscopy were used to visualize the bladder neck because many clinicians and investigators believe that a closed bladder neck is important in maintaining continence. However, studies of continent women reveal that many individuals with normal urethral function show evidence of bladder neck opening with physical stress (43). Neither test is recommended in the routine evaluation of women with straightforward incontinence.

**Voiding Cystometrogram**

Urodynamic testing usually concludes with an instrumented voiding study (also known as a pressure-flow study or voiding cystometrogram), in which the vesical, abdominal, and urethral pressures are measured simultaneously during bladder emptying (Fig. 26.8). Various studies identified Valsalva voiding, low preoperative flow rate, and high preoperative detrusor pressures during voiding as risk factors for postoperative voiding dysfunction; however, findings often are contradictory.

Figure 26.8 Voiding cystometrogram. This patient voids in an uninterrupted flow pattern by means of a prolonged bladder contraction. She does not strain to void, with the exception of minimal straining toward the end of the flow.
Imaging Tests
The role of imaging techniques in studying female urinary incontinence is not yet established. Researchers are evaluating the potential roles of ultrasonography, fluoroscopy, functional neuroimaging, and magnetic resonance imaging (MRI). These tests should not be done routinely but are useful in certain conditions. If the patient’s symptoms (easily remembered by the three Ds: dysuria, dribbling, and dyspareunia) or examination suggests a urethral diverticulum, MRI is the test of choice (44).

Neurophysiologic Tests
The neuromuscular function of the pelvic floor is dependent on the integrity of the nervous system. Injury can theoretically occur anywhere along these nerves, from the cell body located in Onuf’s nucleus in the ventral part of the spinal cord, along its axon, to the neuromuscular junction. Pelvic floor neurophysiology utilizes techniques applied to nerves and skeletal muscles elsewhere in the body to document neuromuscular integrity or evidence of injury. These tests are not routinely used in the clinical evaluation of most incontinent women.

Pudendal Nerve Terminal Motor Latency
The pudendal nerve terminal motor latency (PNTML) indirectly assesses the integrity and patency of the terminal portion of the pudendal nerve, its neuromuscular junction, and the muscle it serves. Using a specialized electrode affixed over the index finger, the pudendal nerve is electrically stimulated near the ischial spine (either transrectally or transvaginally), and the resulting muscular response is measured. The response, termed
a compound muscle action potential (CMAP), is detected at the anal sphincter. The interval between the stimulation and the onset of the CMAP is measured. A prolonged latency is noted with injury to large and heavily myelinated axons. The latency time may be within the normal range when only smaller nerve fibers are affected; thus, neurologic dysfunction may exist in the presence of a normal latency time.

Sacral Reflexes
Only the distal efferent arm of the pudendal nerve is analyzed in the PNTML. Similar to the clinically obtained anal wink or bulbocavernosus reflex, electrically induced sacral reflexes can gather information about both the afferent and efferent arc in the pelvic nerves. A short train of dual impulses delivered next to the clitoris and measured at the anal sphincter is termed the clitoroanal reflex and provides information about the integrity of the afferent and efferent arm of the somatic pudendal nerve. A stimulating electrode placed in the bladder sends these signals along the visceral, autonomic fibers to the spinal cord, and a reflex signal will return along the pudendal nerve to the anal sphincter.

Somatosensory Evoked Potentials
Normal pelvic floor and pelvic organ function ultimately is controlled by higher centers in the central nervous system, including the cerebral cortex. Recording electrodes located on the scalp near the motor cortex allow the signal transmission speed between a skeletal muscle and the brain to be measured. Repeated electrical stimuli, called somatosensory evoked potentials, at a muscle of interest are used to assess the integrity of the central afferent limb. In a reverse fashion, electrical or magnetically induced stimuli can be delivered at the motor cortex (or along the spine), and the induced muscle action potentials can be detected. Prolonged latencies not attributable to the peripherally studied nerves (such as with a PNTML or sacral reflex) are evidence of a central nervous system conduction flaw.

Electromyography
Electromyography (EMG) assesses the inherent electrical potentials generated during neuronal activation of skeletal muscle. It can be performed using surface electrodes or needle electrodes. Surface EMG measures the summation of muscle activity in the general area of the applied electrode. It is best used for simply describing the pattern and coordination of muscle activity but is less useful in providing more specific assessments. Needle EMG of the pelvic floor can “map” the anatomic location of muscles but is mostly replaced by ultrasonography. The major value of needle EMG is its ability to assess nerve injury and determine whether the injury is acute and ongoing or chronic. Single-fiber EMG can quantify the ratio of muscle fibers to nerve fibers (the so-called fiber density). An increase in fiber density is evidence of previous nerve injury with successful reinnervation. Concentric needle EMG is more widely available and allows for further neurophysiologic evaluation. Abnormal electrical activity associated with acute injury may be seen, and
motor unit action potentials (MUAPs) can be assessed and quantified. Following nerve injury and reinnervation, MUAP parameters—such as duration, amplitude, number of phases, and turns—are typically larger.

**Emerging Technologies**

Positron emission tomography and functional magnetic resonance imaging studies are yielding preliminary insights into the neural control of continence; these technologies are used in the research setting only.
Nonsurgical Treatment

Treatment of urinary incontinence can be either nonsurgical or surgical. The approach to treatment is based on the clinical findings and the degree of discomfort experienced by the patient, who should be fully informed of the risks and expected outcome.

Lifestyle Changes

Lifestyle interventions can decrease stress urinary incontinence in many women (45). There is good level 1 evidence that weight loss in both morbidly and moderately obese women decreases both stress and urge urinary incontinence (31). Postural changes (such as crossing the legs during periods of increased intra-abdominal pressure) often prevent stress urinary incontinence. There is some evidence that decreasing caffeine intake improves continence; however, fluid intake in general seems to play a minor role in the pathogenesis of incontinence. Although smokers are at greater risk for incontinence, no data were reported on whether smoking cessation resolves incontinence.

Physical Therapy

Medical evidence from well-designed randomized clinical trials shows that supervised pelvic floor muscle training (Kegel exercises) is an effective treatment for stress urinary incontinence. The Cochrane Incontinence Group concluded that pelvic floor muscle training is consistently better than no treatment or placebo treatment for stress incontinence and should be offered as first-line conservative management to women. Intensive training sessions that include personal contact with a health care professional to teach and supervise pelvic floor muscle training may be more beneficial than standard care. Biofeedback provides no added benefit over pelvic floor muscle training alone in women with stress urinary incontinence (46).

Several factors improve the likelihood that pelvic muscle training will relieve stress urinary incontinence. The woman must do the exercises correctly, regularly, and for an adequate duration. Based on exercise training of skeletal muscles elsewhere in the body, many physical therapists recommend training sessions three to four times per week, with three repetitions of eight to ten sustained contractions each time.

Electrical stimulation therapy was used to treat incontinence by delivering low levels of current via a probe placed in the vagina or rectum. When compared with sham devices and pelvic floor exercises, electrostimulation produced mixed results in the treatment of stress urinary incontinence but may be more helpful in women with overactive bladders (47–50). Further research is needed to determine what niche this treatment may fill for women with urinary incontinence.

Behavioral Therapy and Bladder Training
Bladder training focuses on modifying bladder function by changing voiding habits. Behavioral therapy focuses on improving voluntary control rather than bladder function (51). The key component to bladder training is a scheduled toileting program. After reviewing the patient’s voiding diary, an initial voiding interval is chosen that represents the longest interval between voiding that is comfortable. She is instructed to empty her bladder when she awakes, and then every time during the day that the interval is reached (for example, every 30 to 60 minutes). When the patient feels the urge to void during that interval, she is instructed to use urge-suppression strategies, such as distraction or relaxation techniques, until she gets to the stated interval. Effective distraction strategies include mental exercises (such as mathematical problems), deep breathing, or “singing” the words to a song silently. The main goal is to avoid running to the bathroom at the moment of severe urgency. Another strategy is to quickly contract the pelvic muscle several times in a row (“freeze and squeeze”), which often lessens urgency. Gradually, the interval is increased (usually weekly) until the patient voids every 2 to 3 hours. Bladder training is most effective when women record every void and check in (by telephone or in person) with a health care provider weekly. This program lasts for about 6 weeks. Bladder training is effective; in a trial in which bladder training was compared with treatment with oxybutynin, 73% of women in the bladder training group were clinically cured (52).

The primary technique of behavioral training is pelvic floor muscle training, as described previously, but with a focus on urge inhibition. Mastering voluntary pelvic floor muscle contractions helps to strengthen the outlet (decreasing leakage) and inhibit detrusor contractions. Other components of therapy may include voiding schedules, urge-inhibitions strategies, and fluid management.

Patients with neurogenic detrusor overactivity, rather than idiopathic detrusor overactivity, do not respond as well to behavioral therapy because the problem is actually one of neural pathway destruction rather than the need to reestablish cortical control mechanisms. Frequently, these patients have a trigger volume of urine that sets off a contraction that they cannot control voluntarily. They may benefit from a timed schedule in which they void at regular intervals (such as every 2 hours) to keep their bladder volume below the trigger point. Attempting to lengthen the interval between voids often does not work well.

Less-intensive treatments also decrease incontinence episodes. In a randomized trial, the guidance of a simple self-help booklet was only somewhat less effective in reducing leakage (mean reduction in leakage episodes 43%) than behavioral training (mean reduction 69%) or behavioral training plus electrical stimulation (mean reduction 72%) (53).

Vaginal and Urethral Devices

Vaginal devices (pessaries) and urethral inserts are available for treating stress urinary incontinence. In a tertiary care population, approximately two-thirds of
women with stress urinary incontinence offered a trial of vaginal devices chose to undergo pessary fitting (54). Most (89%) achieved a successful fit. Of those who took a pessary home to manage their stress urinary incontinence, approximately one-half used it for more than 6 months. Women who stopped using the pessary generally did so within the first month. In an intent-to-treat analysis of a recent large multisite randomized trial, 3 months after beginning either pessary or behavioral therapy, 40% of those randomized to pessary and 49% of those doing behavioral therapy were “very much” or “much” better. By 12 months there were no group differences in outcomes and patient satisfaction was greater than 50% for each group (55). Some women are pleased to be able to avoid surgery or to use a “crutch” while waiting for the effect of pelvic muscle training; others prefer a treatment option (like surgery) that does not require daily intervention. Examples of some vaginal devices are shown in Figure 26.9.

Figure 26.9 Vaginal incontinence pessaries: (clockwise from top): A: Suarez ring (Cook Urological, Spencer, IN), B: PelvX ring (DesChutes Medical Products, Bend, OR), C: Incontinence dish (Milex Inc., Chicago, IL), D: Incontinence dish with support (Mentor Corp., Santa Barbara, CA), E: Introl prosthesis (was Johnson and Johnson; currently not available), F: Incontinence ring with support (Milex Inc., Chicago, IL), (middle): G: Incontinence dish with support (Milex Inc., Chicago, IL).

Urethral inserts are sterile inserts placed into the urethra by the patient and removed before a void, after which a new sterile insert is placed. Such inserts are appropriate for women with relatively pure stress incontinence, no history of recurrent urinary tract infections, and no serious contraindications to bacteriuria (e.g., artificial heart valves). The FemSoft device was U.S. Food and Drug Administration (FDA) approved in 1997 and is the only urethral insert that is available in the United States. Several other urethral inserts and urethral occlusion devices were marketed with good effectiveness but were withdrawn from the market. In a 5-year, multicenter trial involving 150 women with a mean follow-up of 15 months, a statistically significant reduction in incontinence episodes and pad weight were observed with 93% of the women having a
negative pad test at 12 months. However, urinary tract infections were common and found in 31.3% of the subjects (56). Urethral inserts have not developed a widespread acceptance but may offer a viable treatment option for some select patients.

Medications

Stress Incontinence

The tone of the urethra and bladder neck is maintained in large part by α-adrenergic activity from the sympathetic nervous system. For this reason, many pharmacologic agents are used with varying degrees of success to treat stress incontinence. These drugs include imipramine (which has a concomitant relaxing effect on the detrusor), ephedrine, pseudoephedrine, phenylpropanolamine, and norepinephrine. Many of these compounds increase vascular tone and may, therefore, lead to problems with hypertension, a condition that afflicts many postmenopausal women with stress incontinence. There is an increased risk for hemorrhagic cerebral vascular accident in women taking phenylpropanolamine, and while the risk is very low, it is not possible to predict who is at risk for this complication (57). The use of these agents in the treatment of stress urinary incontinence appears to be more limited than originally thought (58). No drugs are cleared by the FDA to treat stress incontinence.

Based on a biologic rationale, it was thought that estrogen could effectively treat urinary incontinence, given the presence of estrogen receptors in the bladder, urethra, and levator muscles. In early uncontrolled case series, women using various estrogen preparations experienced less incontinence. However, in several large randomized trials, women assigned to receive estrogen and progesterone did not have less leakage, and were more likely to experience the onset of incontinence or worsening of baseline symptoms (59). In over 23,000 women enrolled in the Women’s Health Initiative double-blind, placebo-controlled, randomized clinical trial, use of menopausal hormone therapy (conjugated estrogen alone in women with a prior hysterectomy, conjugated estrogen and medroxyprogesterone acetate in women with a uterus) increased the incidence of all types of urinary incontinence at 1 year among women who were continent at baseline (60). Among women who reported urinary incontinence at baseline, both frequency and severity of incontinence worsened at 1 year in women taking either hormone preparation compared with those in the placebo group. Thus, conjugated estrogen with or without progestin should not be prescribed for the prevention or relief of urinary incontinence.

Urge Incontinence and Overactive Bladder

The drugs used for treating detrusor overactivity can be grouped into different categories according to their pharmacologic characteristics; these drugs are anticholinergic agents that exert their effects on the bladder by blocking the activity of acetylcholine at muscarinic receptor sites. All of these drugs have side effects, the
Most common of which are dry mouth resulting from decreased saliva production, increased heart rate because of vagal blockade, feelings of constipation resulting from decreased gastrointestinal motility, and occasionally, blurred vision caused by blockade of the sphincter of the iris and the ciliary muscle of the lens of the eye.

Medications commonly used to treat these conditions are listed in Table 26.9. The introduction of several new drugs for overactive bladder resulted in significant attention being given to urinary incontinence in the media.

The newer drugs have some advantages over oxybutynin, which was available for decades. These advantages include once- (or sometimes twice-) daily dosing, rather than three to four times per day and, to some degree, a less severe side-effect profile. The latter results from changes in the delivery system and to more selectivity of muscarinic receptors (so that, for example, the bladder may be targeted more than the salivary glands). In addition, quaternary amines (such as trospium chloride) are not distributed into the central nervous system because of their large molecular size and hydrophilicity. The primary disadvantage of the newer agents is cost.

In 2009, the Agency for Healthcare Research and Quality carried out an evidence-based review of the large body of literature on pharmacologic therapies for urinary urgency incontinence and overactive bladder (61). Estimates from their meta-analysis models suggest that immediate-release forms of medications (oxybutynin, short-acting tolterodine) decreased incontinence episodes and voids by 1.46 and 2.16 per day, respectively. Extended-release forms of medications (tolterodine, trospium chloride, solifenacin, oxybutynin) decreased incontinence episodes and voids by 1.78 and 2.24 per day, respectively. However, placebo also impacted continence, decreasing incontinence episodes and voids by 1.08 and 1.48 per day, respectively. Whether or not the improvements observed with medication are clinically significant depends on patients' perceptions and initial level of severity. In the randomized trials reviewed, baseline episodes of incontinence ranged from 1.6 to 5.3; decreasing this by one or two may or may not constitute a successful outcome for a given patient.

When initiating therapy with generic oxybutynin, it is best to start with a lower dose (particularly for elderly patients) and increase it as needed to a higher, more frequent dosage. Patients should be encouraged to titrate their medication to their symptoms and to vary the dosage (within acceptable limits) according to their needs. If this is not effective, the next step is to move to one of the other anticholinergic agents. Some women may respond better to one agent than another. A 2-week trial is sufficient to determine effectiveness. It is helpful to ask patients to record daily episodes of incontinence or urgency before and during therapy so effectiveness can be more accurately determined.

Patients should be warned of the side effects of anticholinergic agents. Patients should be particularly advised about the symptom of a dry mouth and told that this is not caused by thirst. Some patients increase their fluid intake to combat this problem, with a subsequent worsening of their incontinence. If dry mouth is a problem, patients should relieve it by chewing gum, sucking on a piece of hard candy, or eating a piece of moist fruit.

Nocturia and Nocturnal Enuresis

Medications that treat nocturia and nocturnal enuresis have one of three aims: (i) to reduce urine output, (ii) to increase bladder capacity and reduce
unstable bladder contractions, and (iii) to act centrally on sleep and micturition centers.

An analogue of arginine vasopressin, DDAVP, is used extensively to treat children with nocturnal enuresis. Some studies suggest that it may be useful in adults (62,63). It is available as a nasal spray and as an oral preparation. When taken orally, the dose required is approximately 10 times greater because of the increased availability of the nasal preparation. Complications associated with the DDAVP include hyponatremia, particularly in patients with excessive fluid intake; therefore, it is essential in higher-risk patients to measure serum sodium levels periodically.

There are few clinical trials that specifically investigate the use of anticholinergic medications to treat nocturia or nocturnal enuresis. Anecdotal evidence supports a trial of a long-acting or extended-release form of an anticholinergic, taken approximately 1 hour before bedtime.

The most extensively studied medications for the treatment of nocturnal enuresis are tricyclic antidepressants, particularly imipramine. These agents may work by altering the sleep mechanism, by providing anticholinergic or antidepressant effects, or by affecting antidiuretic hormone excretion. The typical starting dose of imipramine is 25 mg at bedtime, which may be increased to as high as 75 mg. In the elderly, imipramine should be used cautiously because it increases the risk of hip fracture, presumably related to the potential side effect of orthostatic hypertension (64).

In a randomized, placebo-controlled study comparing nighttime doses of placebo and 1 mg of bumetanide (a loop diuretic), bumetanide decreased nocturia episodes by 25% compared with placebo (65). Patients who produce half of their total urine at night often benefit from the use of a diuretic (e.g., 20 mg furosemide) in the late afternoon to move fluid through the system and decrease their nighttime urine production.
Surgical Treatment for Stress Incontinence

Historically, the body of literature concerning surgical therapy for stress urinary incontinence, while large, is hampered by poor methods, short follow-up, biased outcome observations, and little attention paid to the patients' perceptions of symptoms and quality of life (66). Over the past decade, scientific research in this area evolved; while much of the literature continues to reflect small short-term case series, randomized trials with rigorous follow-up are becoming more common.

Several shifts occurred in recommendations regarding surgical therapy in the past generation. In 1997, the American Urological Association convened a clinical guidelines panel to analyze published outcomes data on surgical procedures to treat female stress urinary incontinence and to produce practice recommendations to guide surgical decision making (67). The panel concluded that colposuspension (e.g., Burch, Marshall-Marchetti-Krantz [MMK]) and slings were more effective than transvaginal needle suspensions or anterior repairs for long-term success (48-month cure/dry rates). The median probability estimates for cure/dry rates at 48 months and longer were 84% (95% confidence interval [CI], 79%–88%) for colposuspension and 83% (95% CI, 75%–88%) for sling procedures, compared with 67% (95% CI, 53%–79%) for transvaginal needle suspensions and 61% (95% CI, 47%–72%) for anterior repairs. Thus, the latter two procedures are no longer recommended as adequate treatments for stress urinary incontinence.

Historical Perspective

Anterior vaginal repair (also termed anterior colporrhaphy) was described by Howard Kelly in 1914, and this operation remained the standard first approach to stress incontinence until the middle of the 20th century (68). Many different operations are lumped together under the term anterior colporrhaphy, including simple plication of the bladder neck, elevation of the bladder neck by plicating the fascia under the urethra, and elevation and fixation of the bladder neck by passing sutures lateral to the urethra and driving the needles anteriorly into the back of the pubic symphysis for fixation. As noted previously, the problem with most techniques of anterior colporrhaphy is that they do not hold up well over time (69–71). In essence, this operation attempts to take weak support from below and push it back up from below, with hope that these structures will maintain their strength and position over time. Although there were excellent long-term results shown with anterior colporrhaphy, most of these cases involve specific techniques requiring skillful dissection of the endopelvic fascia, deep bold bites of suture, and fixation of permanent sutures to the pubic bone from below: in essence, a transvaginal retropubic bladder neck suspension (72,73). Most surgical series that evaluated techniques of anterior colporrhaphy for stress incontinence show long-term success rates of only 35% to 65%, a figure that most would regard as unacceptably low. Anterior colporrhaphy should be reserved primarily for patients requiring cystocele repair who do not have significant stress incontinence.
Needle suspension procedures are so named because they suspend the urethra and bladder neck through a technique that involves passage of sutures between the vagina and anterior abdominal wall using a specially designed long needle carrier. Although initial cure rates are between 70% to 90%, rates decrease significantly over time in many series, with 5-year success rates of 50% or less (67,74–77). Therefore, these operations are no longer recommended.

**Retropubic Urethropexy (Colposuspension)**

The modern era of retropubic surgery for stress incontinence began in 1949, when Marshall et al. described their technique for urethral suspension in a man with postprostatectomy incontinence (78). A variety of modifications of this operation were described, all of which share at least two characteristics: They are performed through an open low abdominal incision or with laparoscopically assisted exposure of the space of Retzius, and they all involve attachment of the periurethral or perivesical endopelvic fascia to some other supporting structure in the anterior pelvis (Fig. 26.10). In the MMK operation, the periurethral fascia is attached to the back of the pubic symphysis. Another approach, the Burch colposuspension, involves the attachment of the fascia at the level of the bladder neck to the iliopectineal ligament (Cooper's ligament) (79,80). With the paravaginal repair, the lateral endopelvic fascia along the urethra and bladder is reattached to the arcus tendineus fascia pelvis (81,82). In the Turner-Warwick vagino-obturator shelf procedure, the endopelvic fascia, vagina, or both are attached to the fascia of the obturator internus muscle (83,84).

![Figure 26.10 Points of reattachment of the endopelvic fascia during retropubic bladder neck suspensions.](image)

A 2009 Cochrane review found that 69% to 88% of women treated with Burch colposuspension were largely continent, and 5 years after surgery the continence rate remained high at 70%. Twelve trials were available that compared colposuspension with various forms of suburethral slings; there were no significant differences in failure rates between slings and colposuspension at any time interval studied (85).
The long-term success of laparoscopic colposuspension is unclear, but there is limited evidence to suggest the results are less favorable than with open colposuspension, although this may reflect a learning effect and be unreliable in isolation (86).

**Traditional Pubovaginal Sling**

Sling operations traditionally were performed using a combined vaginal and abdominal approach (Fig. 26.11). The anterior vagina is opened, the space of Retzius is dissected on each side of the bladder neck, and a sling is passed around the bladder neck and urethra and then attached to the anterior rectus fascia or some other structure to cradle the urethra in a supporting hammock. This supports the urethra and allows it to be compressed during periods of increased intra-abdominal pressure (87–97). The sling can be made of organic or inorganic materials. Organic materials can be autologous tissues harvested from the patient (e.g., fascia lata, rectus fascia, tendon, round ligament, rectus muscle, vagina), processed allografts from human donors (e.g., fascia lata, dermis), or heterologous tissues harvested from another species and processed for surgical use (e.g., ox dura mater, porcine dermis). Synthetic materials (e.g., Silastic, Gore-Tex, Marlex) are popular because of their consistent strength and availability, but historically these substances were plagued by problems with erosion and infection when used around the urethra (67,98,99).

Figure 26.11 A completed traditional suburethral sling procedure with the fascia located at the bladder neck with the ends of the sling tied to or above the rectus fascia. The classic procedure uses autologous fascia; however, some surgeons use allograft or xenograft tissue performed in a similar fashion. (Redrawn from original by Jasmine Tan.)
The multicenter Urinary Incontinence Treatment Network conducted a randomized clinical trial comparing Burch colposuspension and fascial pubovaginal sling in 655 women with stress urinary incontinence (100). The primary outcome, success, was rigorously defined as a negative pad test, no urinary incontinence (as recorded in a 3-day diary), a negative cough and Valsalva stress test, no self-reported symptoms, and no retreatment for the condition. At 24 months, success rates were higher for women who underwent the sling procedure than for those who underwent the Burch procedure for the overall category of success (47% vs. 38%; \( p = .01 \)). However, more women who underwent the sling procedure later had urinary tract infections, difficulty voiding, and postoperative urge incontinence. This study highlights the wide range in success depending on how it is defined: for example, based on a cough stress test, success rates were 71% in the Burch group and 87% in the sling group, while based on a pad test, rates were 84% and 85%, respectively.

**Minimally Invasive Sling**

In the 1990s, various orthopedic bone anchors were marketed to implant into the pubic bone to suspend the urethra with sutures or slings. Despite a lack of medical evidence to support either the bone anchor or the allograft use, bone anchor systems became the quick and minimally invasive method to suspend allograft slings (101). Although bone anchors were not superior to standard fixation techniques, their use led to increased complications in several series.

In 1996, Falconer et al. described the tension-free vaginal tape (TVT) for correcting stress urinary incontinence (102). In this technique, polypropylene mesh is placed under the midurethra with minimal tension (Fig. 26.12 A). To perform this operation, a small midurethral incision is made in the vaginal epithelium mucosa. A 40- by 1-cm mesh tape covered by a plastic sheath and attached to two 5-mm curved trocars is passed lateral to the urethra and through the endopelvic fascia into the retropubic space. The trocar is passed along the back of the pubic bone, through the rectus fascia, and into two small suprapubic skin incisions. The tension on the tape is adjusted, the sheath is removed, and the remaining tape is cut off at the level of the skin. This technique has the advantage of being performed quickly using limited anesthesia (fewer than 30 minutes in experienced hands). The procedure requires the use of a catheter guide to deviate the urethra and cystoscopy to ensure that bladder or urethral perforations are recognized immediately because the trocar is passed blindly.

Numerous modifications of the TVT were proposed and marketed. Such devices generally circumvent the stringent regulatory control provided by the FDA by gaining approval through a Premarket Notification 510(k). This mechanism is a submission to the FDA demonstrating that a new device is substantially equivalent either to a legally marketed or “predicate” device introduced before 1976 in the United States or to one approved by the FDA through the 510(k) process itself. Substantial equivalence means the new device has the same intended use as the predicate device and has the same technological characteristics or different technological characteristics, but it is as safe and effective as
Surgeons should be aware that most new devices for urinary incontinence are not tested in clinical trials before they are marketed. Since its introduction, there were scores of articles published suggesting that TVT is effective and safe and similar in effectiveness to colposuspension. Larger, multicenter trials provide the most realistic look at outcomes of a surgical procedure performed by many surgeons with varying experience on a wide array of patients. A report of the 2-year follow-up of 344 women with urodynamic stress incontinence enrolled from 14 centers in a multicenter randomized clinical trial compared TVT and open Burch colposuspension. The objective cure rates (defined as a negative 1-hour pad test) ranged from 63% to 85% for the TVT procedure and 51% to 87% for open colposuspension, depending on how missing data were handled, leading the authors to conclude that “TVT may be better, worse, or the same as open colposuspension in the cure of stress incontinence” (103). Subjectively, only 43% of women in the TVT group and 37% of women in the open colposuspension group reported cure of their stress leakage. Women undergoing the TVT were more likely to have a cystocele after surgery, whereas those undergoing the Burch colposuspension were more likely to have apical prolapse. Two years after the index procedure, seven women (4.8%) in the Burch colposuspension group underwent surgery for pelvic organ prolapse, compared with no women in the TVT group. There was no difference in the number of women that underwent repeat surgery for stress incontinence (1.8% in the TVT group and 3.4% in the Burch group). Women who underwent TVT were less likely to have voiding disorders requiring intermittent self-catheterization than those who underwent colposuspension (0% vs. 2.7%).

Another form of minimally invasive sling is the transobturator tape procedure (also known as a TOT) or transobturator suburethral tape. This modification was designed to reduce complications associated with retropubic needle passage. Inserting the trocar through the obturator space theoretically lessens the risk of bladder, bowel, or vascular injury because the procedure involves passing the polypropylene midurethral sling through the obturator membrane along its ischiorectal fossa path, bypassing the pelvic cavity altogether (104,105). In a multicenter trial, 183 women from seven sites underwent a transobturator tape procedure for stress and mixed urinary incontinence. At 1-year follow-up 80.5% patients were cured (defined as absence of subjective report of stress urine leakage and negative cough stress test). Perioperative complications included one bladder perforation, two urethral perforations, and one lateral vaginal perforation. Tape erosion necessitating removal occurred in five cases (three vaginal and two urethral) (106).

A 2009 Cochrane review identified 62 trials with over 7,000 women in which minimally invasive sling was studied in at least one arm (107). Most were of poor to moderate quality with short follow-up. Minimally invasive synthetic suburethral sling operations appeared to be as effective as traditional suburethral slings but with shorter operating time and less postoperative voiding dysfunction and de novo urgency symptoms. Similarly, minimally invasive synthetic suburethral slings were as effective as open retropubic colposuspension with fewer perioperative complications, less postoperative
voiding dysfunction, shorter operative time and hospital stay, but significantly more bladder perforations (6% vs. 1%). A retropubic bottom-to-top route was more effective than top-to-bottom route and was associated with significantly less voiding dysfunction, fewer bladder perforations, and tape erosions. At the time of this review, 17 trials comprising 2,434 women compared the transobturator route with the retropubic route of sling placement. The transobturator route had a slightly lower objective cure rate (84% vs. 88%) but had less voiding dysfunction, blood loss, bladder perforation, and shorter operating time.

After the publication of this Cochrane review, the largest (597 women) randomized equivalence trial to date comparing retropubic and transobturator sling approaches was published by the Urinary Incontinence Treatment Network (108). Women were randomized in the operating room and were followed for 1 year. The primary outcome was treatment success at 12 months according to both objective criteria (a negative stress test, a negative pad test, and no retreatment) and subjective criteria (self-reported absence of symptoms, no leakage episodes recorded, and no retreatment). Objective success rates were 80.8% and 77.7% and subjective success rates were 62.2% and 55.8%, in the retropubic and transobturator groups, respectively. Women in the retropubic group had more voiding dysfunction (2.7% vs. 0%), while those in the transobturator group had a higher rate of neurologic symptoms (9.4% vs. 4.0%). There were no significant differences between groups in postoperative urge incontinence, satisfaction with the results of the procedure, or quality of life.

A third generation of minimally invasive slings was developed, the so-called minislings. Insertion of the minisling requires only a single vaginal incision, less dissection, and the potential to be placed in a clinic setting. Data are mixed, with some finding equivalent success rates and others up to eightfold higher failure rates in the minisling group than in the full-length synthetic sling (109,110).

**Bulking Agents**

Injectable (so-called bulking) agents are less invasive than surgery, and although they are less likely than surgery to result in cure, they relieve symptoms in many women. In the United States, glutaraldehyde cross-linked bovine collagen (Contigen), carbon beads (Durasphere), cross-linked polydimethylsiloxane (Macroplastique), and calcium hydroxylapatite (Coaptite) are approved for use to treat stress urinary incontinence and can be injected either peri- or transurethrally. The newer agents were studied primarily by transurethral injection. Injecting a material around the periurethral tissues facilitates coaptation of the urethra under conditions of increased intra-abdominal pressure (111–116). In a 15-article review, the short-term cure or improvement rate was 75% (117). Contigen can be passed easily through small-bore needles under local anesthesia but requires preoperative skin testing to check for possible allergic reactions (3%). Durasphere is nonantigenic (thus no skin testing is required) and does not migrate. As compared with collagen, Durasphere appears to have similar reduction in leakage episodes and is more likely to require only a single injection (112).
This bulking agent does require a larger-gauge needle for injection and is somewhat more difficult to inject than collagen. Macroplastique is approved for use in the United States. This material appears to offer better outcomes as defined by improvement and cure rates than Contigen at 12 months (113). A follow-up 24-month study revealed that 84% of patients maintained improvement from the 12-month assessment (114). A recent prospective randomized trial of Coaptite versus Contigen revealed similar improvement and safety profile at 12 months when compared Contigen. Coaptite required less material per injection (4 mL vs. 6.6 mL) and was more likely to require only a single injection (115). These techniques may require several injections to achieve continence, and the long-term success of these operations remains poorly studied.

Complications

In choosing surgical management, surgeons must weigh the chance of cure against the chance of severe complications. In the aforementioned randomized trial comparing TVT and Burch, women undergoing TVT were more likely to experience a bladder perforation than those undergoing the Burch procedure (9% vs. 2%, respectively) but less likely to have a fever (1% vs. 5%) or prolonged catheterization more than 29 days (3% vs. 13%) (118). Less common complications require a large sample size to detect differences. Severe complications reported on the FDA manufacturer and user facility device experience (MAUDE) database include vascular injuries, bowel injuries, and patient deaths after retropubic midurethral slings and groin and leg pain, visceral injuries, and severe infections from transobturator approaches (119). Even though these serious life-threatening complications are rare, surgeons must be cognizant of the risks and use intraoperative safety measures to prevent their occurrence.

Actual complication rates are often difficult to discern because denominators often are not available. In a nationwide analysis of 367 complications associated with 1,455 TVT procedures performed in Finland, there was a 1.9% rate (95% CI, 1.2–2.7) of blood loss over 200 mL, a 1.9% rate (95% CI, 1.2–2.7) of retropubic hematoma, a 0.5% rate (95% CI, 0.2–1.0) of hematoma outside the retropubic area, a 0.1% rate (95% CI, 0.0–0.4) of injury to the epigastric vessel, a 0.1% rate (95% CI, 0.0–0.4) of injury to the obturator nerve, and a 3.8% rate (95% CI, 2.9–5.0) of bladder perforation (120).

A prospective, randomized trial of retropubic versus transobturator slings (the TOMUS trial) involving 597 patients revealed more bladder perforations in the retropubic group (15 vs. 0), more patients with elevated PVR volume (>100 mL at time of discharge), and higher rate of sling release or catheterization for voiding dysfunction after 6 weeks (8 vs. 0). The transobturator group had more vaginal perforations (13 vs. 6) and neurologic symptoms including lower extremity weakness and numbness found immediately following surgery to 6 weeks (31 vs. 15). Otherwise, serious adverse events were similar in both groups (108).

Erosion is unique to surgeries in which a graft is placed, and the rate depends largely on the type of graft used. Tension-free vaginal tape is associated with a low rate of
Graft erosion, compared with a much higher rate of erosion with certain synthetics previously used for pubovaginal slings. Most midurethral synthetic slings used at this time are made of polypropylene; the main differences in the character of the mesh involve elasticity and rigidity and not the material itself. In the randomized trial comparing TVT to TOT described above, of the 597 women who underwent a sling procedure, 1.8% of the patients were noted to have a mesh erosion or exposure (108).

The most common adverse events (5% to 10% rate for each) after all surgeries for stress urinary incontinence include urinary tract infection, failure to cure, new onset detrusor overactivity, voiding dysfunction, genital prolapse, and bladder perforation. When new onset detrusor overactivity occurs after surgery for incontinence, cystoscopy should be considered to rule out a foreign body in the bladder (Fig. 26.13). Less common events (2% to 5% for each) include excessive blood loss, wound infection, pain, or nerve injury. Events such as sinus tracts and fistulae are rare. Erosion rates depend on the material implanted and, as noted previously, are rare for the midurethral slings. In addition, medical events, such as thromboembolic, cardiac, or pulmonary events, are rare.

Figure 26.12 Midurethral synthetic slings involve the use of large pore, monofilament polypropylene mesh placed after minimal dissection at the midurethra followed by placement of a trocar through the retropubic route. Some surgeons prefer placing the trocar by a suprapubic route beginning with a small abdominal incision. A: The trocar is guided into the previously performed midurethral incision with care to place the trocar against the pubic bone to avoid entry into the peritoneal cavity. The trocar handle has been removed in this view after perforation through the abdominal incision. B: The synthetic sling should rest in the midurethra location and is brought through two stab incisions above the pubic symphysis. (Redrawn from original by Jasmine Tan.)

Figure 26.13 Cystoscopic view of encrusted suture penetrating bladder wall following sling urethropexy.
As midurethral slings largely replace pubovaginal slings and retropubic urethropexies as the primary procedure for stress urinary incontinence, the comparison of complications of these procedures becomes more important. Given the debate on the effectiveness of the different approaches for midurethral slings, the severity and incidence of complications for midurethral slings will become more important when determining the best primary procedure for stress urinary incontinence. Likewise, the uncommon occurrence of intraoperative and long-term complications of these procedures and underreporting of complications demonstrates the need for reliable large registries for midurethral slings and other promising procedures to assess the safety of these procedures.
Procedures for Urgency Urinary Incontinence

Neuromodulation

Even with the development of newer anticholinergic medications with fewer side effects, there continues to be a select group of patients with overactive bladders who remain refractory to standard medical and behavioral treatment. Surgical treatment of this condition traditionally involved substantial morbidity and major urinary denervation, reconstruction, or both to achieve therapeutic benefits. The development of implantable sacral nerve root stimulators led to FDA approval of sacral root neuromodulation in patients with refractory urinary urgency and frequency, urge incontinence, and voiding dysfunction. This therapy offers patients with severe symptoms an alternative to urinary augmentation or diversion. Sacral nerve stimulation therapy is performed in two phases. In the first phase, a percutaneous nerve evaluation test is performed to determine which patients respond to this type of therapy. Those who respond are implanted with a permanent electrode lead adjacent to the third sacral nerve root connected to a pulse generator.

A multicenter prospective study demonstrated that 63% of test patients responded to the initial procedure. After implantation, 47% of patients became completely dry, and 77% were successful in eliminating “heavy” leakage episodes. Despite substantial success in nearly 80% of patients who received implants, 30% of patients required further surgical revision because of pain or other complications at the generator or implant site. No permanent injuries or nerve damage was reported in the initial trials (121, 122).

In a group of 96 patients with implants (who responded favorably during the test stimulation period), reductions in urge incontinence episodes and severity were still seen at an average of 31 months after implantation. The device was removed in 11 of the 96 patients because of lack of efficacy, pain, or bowel dysfunction. There were no permanent injuries (123). The technique for this procedure evolved to include the location of a generation implant site on the back and the performance of the procedure in two stages with initial percutaneous implantation of a quadpolar instead of a unipolar stimulator. These modifications may improve success rates and decrease the morbidity associated with these procedures. A recent systematic review evaluating eight randomized trials concluded that continuous sacral neural stimulation offers benefits for carefully selected patients with overactive bladder and urinary retention in the absence of obstruction, but many implants did not work or required revisions. The review recommended trials to assess effectiveness directly compared to other treatment options (124).

Percutaneous Tibial Nerve Stimulation

Percutaneous tibial nerve stimulation (PTNS) was first described in 1987 to treat lower urinary tract symptoms and FDA approved in 2000 for overactive bladder. This therapy uses peripheral neurostimulation technique with small (34-gauge) needle electrode inserted at a 60-degree angle approximately 5 cm cephalad to the medial malleolus and
slightly posterior to the tibia. The treatment course typically consists of a weekly 30-
minute session for 12 weeks. A multicenter, double-blind, randomized control trial
involved 220 women with overactive bladder symptoms randomized 1:1 to 12 weeks of
treatment with weekly PTNS or sham therapy. The PTNS treatment group achieved
statistically significant improvement in bladder symptoms, with 55% reporting moderate
to marked improvement compared to 21% in the sham arm compared to baseline (125).
The OrBIT (Overactive Bladder Innovative Therapy) trial compared PTNS to extended-
release tolterodine in the treatment of OAB and found similar improvements in both
groups (126). A large portion of responders in this trial (96%) had sustained
improvement in OAB symptoms at 12-month follow-up when receiving periodic
treatments (127,128). PTNS may represent a viable treatment option for patients who
cannot tolerate side effects from anticholinergic medications, who do not responded to
behavioral therapy, or who decline implantable neurostimulators.

Botox Injections
Botulinum toxin A (BtxA), a neurotoxin produced by the anaerobic bacteria Clostridium
botulinum, acts on peripheral cholinergic nerve endings to inhibit calcium-mediated
release of acetylcholine vesicles at the presynaptic neuromuscular junctions. In a report
from a multicenter study, a 73% continence rate occurred in 180 patients with neurogenic
detrusor overactivity incontinence who underwent cystoscopic Botox injections (129). A
recent prospective placebo-controlled trial in patients with refractory idiopathic urge
incontinence demonstrated a 60% clinical response using the Patient Global Impression
of Improvement score of 4 or greater with a median duration of response of 373 days.
The Botox group did experience an increase in postvoid residual in 75% of the subjects
(130). The off-label use of Botulinum A cystoscopic detrusor injections to treat refractory
urge incontinence in women with and without neurologic impairment is gaining
popularity. The procedure is done via cystoscopy and involves injecting 15 to 30 different
detrusor muscle sites under direct visualization, sparing the bladder trigone and ureteral
orifices.

Augmentation Cystoplasty and Urinary Diversion
Surgery to replace the function of a diseased bladder has been done for more than a
century and over the past several decades has gained some popularity in treating people
with intractable detrusor overactivity not responsive to any other form of management.
These surgical options include (i) conduit diversion (creation of various
intestinal conduits to the skin) or continent diversion (which includes a rectal
reservoir or continent cutaneous diversion), (ii) bladder reconstruction, or (iii)
replacement of the bladder with various intestinal segments. For a discussion of
these techniques, both historical and current, the interested reader is referred to a review
by Greenwell et al. (131). A Cochrane review found only two randomized trials that were
of sufficient quality to include and concluded that there were no major differences in
outcomes between the techniques and that higher quality research was needed (132).
With the advent of sacral neuromodulation and cystoscopic injection with Botulinum A, these procedures are done much less often to treat women with detrusor overactivity.
Surgical Treatment of Fistulae

A wide variety of techniques are available for fistula repair (133,134). Traditionally, fistula repair was performed after a waiting period to allow the resolution of inflammation and formation of scar tissue. This is particularly important in the case of obstetric fistulas, in which the extent of the vascular injury to the soft tissues of the pelvis may not be apparent for many weeks. However, there is a recent trend toward early closure of small gynecologic fistulas (135). The keys to closure of a vesicovaginal fistula include wide mobilization of tissue planes so that the fistula edges can be approximated without any tension, close approximation of tissue edges, closure of the fistula in several layers, and meticulous attention to postoperative bladder drainage for 10 to 14 days. The closure of large fistulas will be enhanced by the use of tissue grafts (e.g., Martius labial fat-pad grafts, gracilis muscle flaps) that provide an additional blood supply to nourish an area that has sustained vascular injury. The Latzko procedure used to close a vesicovaginal fistula is shown in Figure 26.14.

**Figure 26.14 Repair of apical vesicovaginal fistula.** A: The fistula at the vaginal apex is exposed with adequate retraction. A pediatric foley can be placed into the fistula tract to aid in traction and dissection. B: The vaginal epithelium is dissected from the fistula to mobilize the tissue to allow for tension-free closure. In the classic Latzko procedure, the vaginal epithelium 2 cm around the opening of the fistula is removed. C: The fistula tract may either be completely excised, or in the Latzko procedure, the fistula edge may freshened up slightly but is not excised. D: Interrupted absorbable sutures are placed in an extramucosal location in an interrupted fashion. An additional layer of interrupted sutures is often placed to invert the initial suture line. The vaginal epithelium is then closed over the repair. In the classic Latzko procedure, the initial layer involves closure of the vagina over the fistula tract, then two additional layers with the vaginal epithelium result in an apical colpocleisis. (Redrawn from original by Jasmine Tan.)
Cystoscopy

Scientific evidence does not support routine cystoscopy in women with stress urinary incontinence in the absence of other pathologies (136). Cystoscopy cannot be used to predict intrinsic sphincteric deficiency, stress incontinence, or detrusor overactivity. Cystoscopy can be considered in the following circumstances: (i) in women with urge incontinence to rule out other disorders, especially in women with microscopic hematuria, (ii) in the evaluation of vesicovaginal fistulae, and (iii) intraoperatively to evaluate possible ureteral or vesical injury.

Urologists often use flexible cystoscopy in men; however, women tolerate a rigid cystoscope well, given their short urethras and absence of prostate glands. The view afforded by a rigid cystoscope is clearer than that obtained with a flexible scope, and less technical skill is required to view the entire bladder using a rigid scope. However, with advancement in technology, the efficacy divide between rigid and flexible cystoscopes continues to narrow. Cystoscopes are available with several viewing angles: 0 degree (straight), 30 degrees (forward-oblique), 70 degrees (lateral), and 120 degrees (retroview). The last scope is rarely used in women. Zero-degree lenses are essential for viewing the urethra, whereas a 30-degree lens provides the best view of the bladder base and posterior wall, and the 70-degree lens generally provides the best view of the anterior and lateral walls. For diagnostic cystoscopy, sterile water is an ideal medium because it is readily available and inexpensive.

To evaluate the urethra, the cystoscope, typically with a 0-degree or 30-degree lens, should be advanced with distension medium flowing, keeping the center of the urethral lumen in the center of the visual field. The mucosa is normally pink and smooth and the urethral folds close.

After insertion of the cystoscope into the bladder with a 70-degree lens, an air bubble will be present at the bladder dome, which may assist in proper orientation. Then the remainder of the bladder is examined systematically by making a series of sweeps, slowly rotating the cystoscope between the dome and urethrovesical junction. To view the trigone, the light cord should be oriented toward the ceiling (keeping the camera in an upright position). The scope is pulled back until it is almost in the urethra and the base of the bladder is viewed. Because the trigone is a zone of metaplasia, it looks different from the rest of the urothelium (Fig. 26.15).

Figure 26.15 Cystoscopic view of normal-appearing trigone with left ureteral orifice visible.
Vaginal and abdominal hysterectomies are associated with a 0.02% to 0.85% incidence of ureteral injury (137). The injury rate increases in reconstructive pelvic surgeries, reaching as high as 11% after uterosacral ligament suspension (138). In a study of 46 women who underwent proximal uterosacral ligament vaginal vault suspension, three of the five women with cystoscopic evidence of obstruction were treated successfully by removing and replacing the sutures. This finding emphasizes the importance of confirming ureteral integrity at surgery. The value of cystoscopy to evaluate ureteral injury after minimally invasive hysterectomy is unknown because this injury is often thought to occur in association with thermal injury, and it is unclear whether obstruction or decreased flow will be apparent intraoperatively.

Administering indigo carmine dye intravenously 5 minutes before cystoscopy aides in the assessment of ureteral patency. Quick efflux of stained urine should be seen bilaterally. Sluggish efflux should prompt further investigation. However, preexisting ureteral obstruction may be responsible for lack of flow. In 157 women who underwent complex urogynecologic procedures, 5 cases (3.2%) of unsuspected ureteral obstruction were identified with intraoperative cystoscopy (139). One was caused by ureteral ligation, and the remaining four represented chronic ureteral obstruction resulting from pelvic organ prolapse (two cases), ureteropelvic junction obstruction (one case), and ureterovesical junction stenosis after prior transurethral resection of bladder cancer (one case).
Voiding Dysfunction and Bladder Pain Syndromes

Voiding Dysfunction

Women are afflicted less commonly than men with voiding difficulties, but these disorders do occur in women and can be defined as emptying dysfunction resulting from relaxation of the pelvic floor musculature or failure of the detrusor muscle to contract appropriately. True outflow obstruction (defined as a detrusor pressure of more than 50 cm H$_2$O in association with a urine flow rate of less than 15 mL/sec) is rare in women and, when seen, is usually found in those who underwent obstructive bladder neck surgery for stress incontinence (140,141). For normal voiding to occur, the pelvic floor and urethral sphincter must relax, which should happen in conjunction with a coordinated contraction of the detrusor muscle that leads to complete bladder emptying. The bladder may be emptied by other mechanisms, such as by abdominal straining in the absence of a detrusor contraction or simply by relaxation of the pelvic floor. Complete bladder emptying is not the same as normal voiding. Some women may empty their bladders completely but only by expending great effort over several minutes. In such cases, voiding is clearly abnormal, even though the bladder is empty when voiding ceases. In the worst cases, voiding is both difficult and incomplete.

Causes

Neurologic diseases, such as multiple sclerosis, may cause voiding difficulty as a result of detrusor-sphincter dyssynergia, in which the urethral sphincter contracts at the same time as the detrusor (143). Great effort is required to overcome urethral resistance; the patient voids with an interrupted stop-and-start stream and usually has a significant amount of residual urine.

Other causes of voiding difficulty include medications (such as antihistamines and anticholinergic agents), infections (in particular, herpes simplex virus, and urinary tract infections), obstruction (following bladder neck surgery, or in women with advanced pelvic organ prolapse), overdistension, severe constipation (particularly in the elderly), and, rarely, psychogenic factors. Fowler’s syndrome refers to unexplained urinary retention occurring as an isolated phenomenon (144). Such women usually are between 20 and 35 years of age. Commonly the first retention episode will be triggered by an event such as surgery or childbirth. Retention rarely resolves but is not associated with the development of other disorders.

Evaluation

Evaluation of a woman with voiding difficulty begins with a careful physical examination. Advanced pelvic organ prolapse may contribute to urinary retention, but it is unlikely that prolapse above the level of the vaginal introitus will be the sole cause of retention. When in doubt, the woman can wear a pessary for a week to see
whether elevating the prolapse reduces the voiding difficulty. Occasionally pelvic masses—in particular, low anterior myomas—may cause urinary retention. Abnormal findings detected during neurologic examination of the perineum and lower extremities may suggest the need to focus on the spine. Urodynamic evaluation will help determine whether the woman has an obstruction (manifested by high detrusor pressures during voiding or by no urethral relaxation during voiding) or whether the detrusor muscle is not contracting. The latter is not necessarily indicative of a neurogenic disorder in women, because a large minority of normal healthy women void by urethral and pelvic floor muscle relaxation alone, with no detrusor contraction. Cystourethroscopy may reveal an obstructing lesion, such as a polyp, tumor, ureterocele, or ball-valve stone. Usually, the evaluation reveals no obvious source, and treatment can commence.

Treatment

The mainstay in the treatment of voiding difficulty is clean, intermittent self-catheterization (145). The most important protection against urinary tract infection is frequent and complete bladder emptying rather than avoiding the introduction of a foreign body into the bladder. Self-catheterization allows the patient to accomplish this task using a small (14-Fr) plastic catheter that she inserts through the urethra into the bladder, draining its contents. The catheter is then removed, washed with soap and water, dried, and stored in a clean, dry place. Elaborate sterile procedures are not necessary. Bacteria are introduced into the bladder in this process, and the urine of women after self-catheterization regimens will always be colonized with bacteria; however, this condition should not be treated unless symptomatic infection occurs.

In addition to decreasing urinary urgency and incontinence caused by detrusor overactivity, neuromodulation of the sacral nerve roots may help women with nonobstructive urinary retention (122). In a trial of 177 patients with idiopathic urinary retention, those who had greater than 50% improvement in baseline voiding symptoms during a test stimulation period qualified for surgical implantation of InterStim. Of these, 37 were randomly assigned to early implantation, whereas 31 in the control group delayed implantation for 6 months. Improved voiding occurred in 83% of the implant group compared with 9% of the control group at 6 months (146). It appears that the long-term success rates of InterStim for urinary retention remain high. In a trial following patients for 5-years after implantation, 71% of the patients with urinary retention had successful outcomes (147). Although this technology requires a surgical procedure, many women favor this therapy over lifelong self-catheterization.

Mild sedatives are sometimes helpful in this process, as are α-blockers (e.g., prazosin, phenoxybenzamine, tamsulosin), which reduce urethral tone. Although cholinergic medications such as bethanechol chloride are successful in making strips of bladder muscle contract in a laboratory, there is little evidence that such drugs are helpful clinically (148).
Bladder Pain Syndromes

Most patients with disorders of bladder sensation experience pain rather than lack of bladder sensation. As with the treatment of most chronic pain disorders, the cause of most painful bladder conditions is unknown, and the therapies used are only partially successful. As a result, disorders of bladder sensation are among the most frustrating urogynecologic conditions to manage.

Terminology and Prevalence

Bladder pain syndrome, often termed interstitial cystitis, is a poorly defined heterogeneous syndrome, and diagnostic criteria are changing continuously. The International Continence Society standardization report recommends adapting the term bladder pain syndrome, rather than interstitial cystitis, and defines painful bladder syndrome as “an unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder associated with lower urinary tract symptom(s) of more than 6 weeks duration, in the absence of infection or other identifiable causes” (15). Urgency and pain are the defining characteristics of bladder pain syndrome (149). Several factors have inhibited advances in the understanding of interstitial cystitis, including the lack of specific diagnostic criteria, the lack of specific histopathologic changes, the unpredictable fluctuation in symptoms, and the marked variability among patients in terms of symptoms, objective findings, and treatment responses (150).

The National Institute of Diabetes, Digestive, and Kidney Diseases (NIDDK) developed a research definition for interstitial cystitis that requires objective findings of glomerulations or a classic Hunner’s ulcer during hydrodistention of the bladder and subjective symptoms of bladder pain or urinary urgency in the absence of other urogenital pathology (151). Strict application of NIDDK criteria in one study would have misdiagnosed more than 60% of patients thought to definitely or possibly have interstitial cystitis (152). Many clinicians have challenged the clinical utility of the NIDDK research criteria, and most conceptualize interstitial cystitis as the end point on the spectrum of painful bladder disorders (153).

The prevalence of bladder pain syndrome varies widely depending on the diagnostic criteria utilized. When mild and moderately severe cases are considered, the syndrome is not rare (154). Estimates of prevalence in the United States range from 52 per 100,000 women in the population-based Nurses Health Study to as high as 1 in 4.5 women “with accurate diagnostic records” (155,156). The prevalence appears to be 6 to 15 times more common among women than men (155,157). The identification of risk factors for bladder pain syndrome is particularly challenging because of the typically long delay in diagnosis (154). The Interstitial Cystitis Database study confirms many of the previous epidemiologic observations: affected individuals are predominately female (92%), white (91%), and report an average age of symptom onset of 32.2 years (150,155).

Diagnosis
A careful history should be obtained, along with a sterile urine specimen for analysis and culture. Many women treated repetitively for chronic cystitis take multiple courses of antibiotics on the basis of symptoms without ever having the presence of an infection confirmed by cultures. Detrusor overactivity may be the cause of frequency, urgency, and urge incontinence, but that is not usually a factor in dysuria or painful urination. **Women older than 50 years (particularly those who smoke or are exposed to chemicals at work) are at risk for bladder cancer, and this possibility must be considered, especially if hematuria is present.** Urinary cytologic assessment is sometimes helpful in detecting early tumors of the urinary tract, and cystoscopy and intravenous urography are mandatory in the evaluation of patients with hematuria.

Other possible causes for painful voiding must be considered in the differential diagnosis, including urethral diverticula; vulvar disease; endometriosis; chemical irritation from soaps, bubble bath, or feminine hygiene products; urinary stones; urogenital atrophy from estrogen deprivation; and sexually transmitted disease.

**The diagnosis of bladder pain syndrome or interstitial cystitis is largely one of exclusion. The ideal diagnostic test for interstitial cystitis is not determined, and there are myriad proposed tests.**

**Treatment**

Typically, the evaluation of bladder pain syndrome results in no definitive diagnosis, and management focuses on the treatment of symptoms.

Frequency–urgency syndromes should be managed with a careful voiding regimen (similar to that used in the treatment of urgency urinary incontinence) and local care.

The use of urinary tract analgesics such as Prosed DS may be helpful in reducing urethral irritation. Prosed DS is a polypharmaceutical agent containing a mixture of methenamine, methylene blue, phenyl salicylate, benzoic acid, and hyoscyamine that has a soothing effect on many irritative urinary tract symptoms.

There is no scientific evidence linking diet to painful bladder syndrome, but many doctors and patients find that alcohol, tomatoes, spices, chocolate, caffeinated and citrus beverages, and high-acid foods may contribute to bladder irritation and inflammation. Some patients note that their symptoms worsen after eating or drinking products containing artificial sweeteners. Patients may try eliminating various items from their diet and reintroducing them one at a time to determine which, if any, affect their symptoms.

Instruction in the basics of vulvar and perineal hygiene is important (thorough drying; avoidance of most body powders, perfumes, or colored irritating soaps; avoidance of tight-fitting undergarments) to avoid other factors that may contribute to painful voiding.

Hydrodistention of the bladder (usually under anesthesia) is recommended as a treatment option and can result in clinical improvement in some patients. Likewise, bladder installations are commonly used for acute treatment of bladder pain syndrome.
The medications used range from local anesthetics to bladder specific medications including resiniferatoxin, dimethyl sulfoxide, BCG, pentosan polysulfate, and oxybutynin. Some patients benefit from the instillation into the bladder of 50 mL of a 50% solution of dimethylsulfoxide (DMSO) for 20 to 30 minutes every other week for four or five sessions. A recent Cochran review found that evidence is limited and randomized controlled trials are needed to adequately assess outcomes. Intravesical installations of BCG and oxybutynin are reasonably well tolerated, and evidence is the most promising for these agents (157).

Tricyclic antidepressants are commonly used in patients with pain. A trial by the Interstitial Cystitis Collaborative Research Network found that amitriptyline plus education and behavioral modification did not significantly improve symptoms in the treatment of naive patients with bladder pain syndrome, but the network did suggest that it may be beneficial in those patients who could tolerate a daily dose of 50 mg or greater (158).

Pentosan polysulfate (Elmiron) is an FDA-approved oral agent with heparin-like activity that attempts to replace the glycosaminoglycan sulfate layer that is believed deficient in these patients. The FDA-recommended oral dosage of pentosan polysulfate is 100 mg, three times a day. Patients may not feel relief from pain for the first 2 to 4 months, and it may take up to 6 months for a decrease in urinary frequency to occur.

It is theorized that bladder pain may result from increased histamine release, and some patients benefit from medications that block these inflammatory mediators, such as diphenhydramine hydrochloride, 25 to 50 mg orally three times per day, in combination with 300 mg of cimetidine three times per day. Tricyclic antidepressants help some women by modulating sensory nerve pain.

Transcutaneous electrical nerve stimulation (TENS), through wires placed on the lower back or just above the symphysis, may help some women, though the mechanism of action is unclear. Ongoing preliminary research suggests that some women with severe bladder pain syndrome may find relief following sacral neuromodulation (InterStim), acupuncture, or intravesical Botox injection associated with hydrodistension.

Pelvic organ prolapse is an increasingly common condition seen in women with the aging of the population. Causes of pelvic organ prolapse are multifactorial and contribute to the weakening of the pelvic support connective tissue and muscles as well as nerve damage. Patients may be asymptomatic or have significant symptoms such as those related to the lower urinary tract, pelvic pain, defecatory problems, fecal incontinence, back pain, and dyspareunia.

Physical examination includes thoughtful attention to all parts of the vagina, including the anterior, apical, and posterior compartments, levator muscle, and anal sphincter complex. Nonsurgical treatment options include pelvic floor muscle training and the use of intravaginal devices. Surgical treatment involves an individualized, multicompartmental approach consistent with the patient’s previous treatment attempts, activity level, and health status. Studies are needed to determine the characteristics of those patients who would derive long-term benefit from vaginal versus abdominal approaches to the surgical repair of pelvic organ prolapse.

Pelvic organ prolapse (POP) is a bulge or protrusion of pelvic organs and their associated vaginal segments into or through the vagina (1). It is a common and costly affliction of older women (2,3). *It has been estimated that over the next 30 years, the demand for treatment of POP will increase 45%, commensurate with an increase in the population of women older than 50 years of age* (4,5). As this problem grows in significance, it becomes increasingly important to comprehend the pathophysiology and risk factors associated with pelvic organ prolapse and try to prevent its occurrence. Furthermore, continued efforts are needed to understand factors that result in long-lasting, robust repair of pelvic organ prolapse for those patients undergoing
surgical management. Despite extensive anecdotal experience, the optimal surgical approach to apical and other compartment prolapse remains elusive (6).

In the United States, 11% of women up to the age of 80 years have surgery for pelvic organ prolapse or urinary incontinence, and nearly one-third of procedures are repeat surgery (3). Data from the Women’s Health Initiative revealed anterior pelvic organ prolapse in 34.3%, posterior wall prolapse in 18.6%, and uterine prolapse in 14.3% of women in the study (7). In this study, a significant risk factor associated with prolapse was vaginal delivery. After adjusting for age, ethnicity, and body mass index, women with at least one vaginal delivery were twice as likely as nulliparous women to have pelvic organ prolapse. Causes of pelvic support disorders are most likely multifactorial, however; factors other than vaginal delivery also are associated with the development of these disorders. One study found that the incidence of prolapse doubled with each decade of life between the ages of 20 and 59 years (8). In another study, each year of increasing age was associated with a 12% increase in the risk of developing prolapse (9). Other associated risk factors for the development of POP include history of hysterectomy (8), obesity (7,10,11), history of previous prolapse operations, and race (11).
Pathophysiology

Pelvic organ prolapse results from attenuation of the supportive structures, whether by actual tears or “breaks” or by neuromuscular dysfunction or both. Support of the vaginal canal is provided by the enveloping endopelvic connective tissue and its condensations at the vaginal apex, which form the cardinal uterosacral ligament complex. The endopelvic connective tissue is the first line of support, buttressed intimately with the pelvic diaphragm, composed of the levator ani and coccygeus muscles. These muscles provide a supportive diaphragm through which the urethra, vagina, and rectum egress (Fig. 27.1). The muscular support provides basal tonicity and support of the pelvic structures; when contracted, as in the setting of increased abdominal pressure, the rectum, vagina, and urethra are pulled anteriorly toward the pubis.

Figure 27.1 A sagittal view of the female pelvis with bladder and uterus removed (ureters, trigone, and cervix intact) illustrating anterior and posterior vaginal fibromuscular planes, their endopelvic fascial attachments, and a functional pelvic floor. (Redrawn by J. Taylor from Skandalakis JE, ed. Hernia: surgical anatomy and technique. New York: McGraw-Hill: 244–250.)

The support system for the uterus and vagina has been described as consisting of three levels (12).

Level I refers to the uterosacral/cardinal ligament complex, which serve to maintain the vaginal length and axis.

Level II support consists of the paravaginal attachments of the lateral vagina and
endopelvic fascia to the arcus tendineus that maintain the midline position of the vagina. **Level III** support pertains to the distal vagina and is made up of the muscles and connective tissue surrounding the distal vagina and perineum.
Definitions

The more common pelvic support disorders include rectoceles and cystoceles (Fig. 27.2), enteroceles (Fig. 27.3), and uterine prolapse (Fig. 27.4); reflecting displacement of the rectum, small bowel, bladder, and uterus, respectively; resulting from failure of the endopelvic connective tissue, levator ani muscular support, or both (12).

Figure 27.2 A: Sagittal section of the pelvis showing normal anatomy. B: Cystocele and rectocele.

Figure 27.3 A: Posterior enterocele without eversion. B: Enterocele with eversion.
Figure 27.4 Uterine prolapse with apical detachment from the uterosacral ligament complex and lateral wall detachment from the endopelvic connective tissue.
A rectocele is a protrusion of the rectum into the vaginal lumen resulting from weakness in the muscular wall of the rectum and the paravaginal musculoconnective tissue, which holds the rectum in place posteriorly.

An enterocele is a herniation of the peritoneum and small bowel and is the only true hernia among the pelvic support disorders. Most enteroceles occur downward between the uterosacral ligaments and the rectovaginal space, but they may also occur primarily apically, especially in the setting of a previous hysterectomy.

A cystocele is descent of the urinary bladder with the anterior vaginal wall. Cystoceles usually occur when the pubocervical musculoconnective tissue weakens midline or detaches from its lateral or superior connecting points.

Uterine prolapse is generally the result of poor cardinal or uterosacral ligament apical support, which allows downward protrusion of the cervix and uterus toward the introitus.

Procidentia, which involves prolapse of the uterus and vagina, and total vaginal vault prolapse, which can occur after hysterectomy, represent eversion of the entire vagina (Fig. 27.5).

Figure 27.5 Procidentia of the uterus and vagina.
These descriptive terms are somewhat inaccurate and misleading, focusing on the bladder, rectum, small bowel, or uterus rather than the specific defects responsible for the alterations in vaginal support. Specific defect support issues will be discussed in the setting of the surgical management section.
Surgical Anatomy

Pelvic support structures include:
The muscles and connective tissue of the pelvic floor
The fibromuscular tissue of the vaginal wall
The endopelvic connective tissue

Endopelvic connective tissue includes:
The cardinal/uterosacral complex, which attaches the upper vagina and cervix posteriorly
Lateral connective tissue attachments of the anterior vaginal wall to the arcus tendineus pelvis and of the posterior vaginal wall to the fascia of the levator ani and to the posterior arcus tendineus near the ischial spine
Less dense areolar connective tissue surrounding retroperineal portion of the pelvic organs

The orientation of these structures is noted in Figure 27.1. In general, an intact pelvic floor, including a functional puborectalis muscle and an intact cardinal/uterosacral complex, should prevent pelvic organ prolapse by allowing posterior deflection of the rectum and vagina and compression of these structures against the pelvic floor in the upright position (Fig. 27.6). The fibromuscular layer of the vaginal wall and the other endopelvic connective tissue attachments augment the support structure and are particularly important when pelvic floor function is compromised.

Figure 27.6 Vaginograms from the same patient at rest (A) and during Valsalva maneuver (B). Illustrates posterior vaginal deflection maintained by apical cardinal/uterosacral posterior suspension and the anterior sling effect of the puborectalis muscle and more distal perineal structures. (From Nichols DH, Randall CL. Vaginal surgery. 4th ed. Baltimore, MD: Williams & Wilkins, 1996:4–5, with permission.)
Apical Compartment

Normal apical support includes the integrity of the cardinal/uterosacral ligaments, the upper paravaginal fibromuscular connective tissue, and, when the uterus is present, the paracervical fascia. The fibromuscular tissue of the upper vagina blends in with the paracervical fascia. Both of these are attached laterally and posterior laterally to the cardinal ligaments and uterosacral ligaments (Fig. 27.1). The vaginal fibromuscular tissue is also attached to the upper anterior rectum at its sigmoid junction and forms the inferior border of the cul-de-sac of Douglas. The cardinal and uterosacral ligaments are condensations of areolar connective tissue and they contribute level I support for the vagina. Their origin is at the lateral borders of sacral vertebra 2 to 4, and they travel retroperitoneally to their insertion at the upper vagina and cervix (Fig. 27.1). They serve as the anterior and lateral borders of the cul-de-sac and cross at or just anterior to the ischial spines. The ureter is closest to the uterosacral ligament at or just posterior to its insertion on the posterior lateral cervix. If anterior cephalad traction is placed on the ureter or cervix, frequently the cardinal uterosacral ligaments will stand out as ridges lateral to the cul-de-sac; however, peritoneal folds may have similar appearance. Therefore, placement of sutures in such structures based on visual appearance may not be reliable.

Defects in apical support include:

The loss of cardinal/uterosacral support with resultant cervical/uterine or vaginal cuff descent
The detachment of the fibromuscular vagina from the anterior rectum with resultant enterocele or, at times, sigmoidocele into the rectovaginal space
Tears or attenuation of the upper fibromuscular tissue, usually after hysterectomy, leading to a central apical descent that frequently presents as a ballooning defect

Often, these defects occur concurrently. Defects in cardinal/uterosacral attachment are at sites close to their insertion into the cervix and upper vagina where breaks or tears occur; in those with apical descent, condensations of cardinal/uterosacral tissue can be found adjacent to the peritoneum just cephalad to the ischial spines (13).
Anterior Compartment

The anterior vaginal compartment includes the anterior vaginal wall, its attachments, the urethra, and the bladder. The support structure for the bladder is the rhomboid-shaped anterior vaginal wall (specifically its fibromuscular layer), which is attached laterally to the arcus tendineus fascia (Fig. 27.7). Inferiorly, the fibromuscular layer blends in with the connective tissue, which spans the two bands of puborectalis and pubococcygeus muscles and the pubic rami. The urethra appears to be preferentially supported by these connective tissues as well as by the pubourethral ligaments. In the apical area, the vaginal fibromuscular layer blends in with the precervical fascia and the connective tissue of the cardinal ligament complex. In the upright position, the rhomboid-shaped anterior vaginal wall is oriented approximately 30 degrees from the horizon (from pubis to ischial spines). There is some downward bulge of the central area of the rhomboid plate, which should be minimized by the back-stop effect of the posterior vagina and rectum if the pelvic floor anatomy and function are normal.

Defects of this support structure may include tears or attenuation of the vaginal fibromuscular wall, or detachment from the pelvic sidewalls, the cervix or cardinal ligament complex, or from the pubis. Specific sites of fibromuscular tears are frequently difficult to recognize.

Physical examination may reveal the following findings:

- The presence of a central ballooning-type defect
- Descent of the area of the vaginal wall below the bladder neck
- Descent of the cervix or apical vaginal area
The presence or absence of sulci extending lateroanteriorly, which would indicate that lateral detachment to the arcus is maintained or lost.
Posterior Compartment

The support of the rectum and posterior vagina includes the pelvic floor musculature and connective tissue posteriorly and Denonvillier’s (pararectal) fascia, which is the fibromuscular layer of the posterior vaginal wall and its lateral attachments to the lateral pelvic floor (levator) musculature and its fascia (Fig. 27.8). This lateral attachment site, the fascia levator ani, fuses with the arcus tendineus fascia pelvis at the middle to upper level of the vagina and continues to the level of the ischial spine. Less dense, areolar, connective tissue surrounds the rectum and vagina and may supply some support to these structures as well.

Figure 27.8 Sagittal oblique view of the distal midvagina illustrating lateral connection of the posterior musculoconnective tissue wall to the fascia levator ani and anterior wall to the arcus tendineus pelvis. The attachment sites fuse together at a point closer to the ischial spine where the vagina assumes a more oval shape. (Modified by J. Taylor from illustration by Lianne Krueger Sullivan. From Cundiff GW, Fenner D. Evaluation and treatment of women with rectocele: focus on associated defecatory and sexual dysfunction. Obstet Gynecol 2004;104:1403–1421, erratum in Obstet Gynecol 2005;105:222, with permission.)

The fibromuscular layer at the upper vagina fuses with the paracervical fascia and the fan-shaped cardinal ligament structure. The integrity of the attachment of this posterior vaginal layer to the anterior rectal wall just below the rectal sigmoid junction prevents enterocoele formation. In the distal vagina, the fibromuscular layer fuses laterally with the fascia of the puborectalis and then the bulbocavernous muscle and centrally with the perineal connective tissue. Thus, normal posterior support includes a plate of connective tissue that is attached laterally as noted, posteriorly toward sacral segments 2 to 4, and inferiorly to the perineum. This fibromuscular plane not only holds the rectum in place posteriorly, but also aids in preventing perineal descent by suspending the perineum to the sacrum. The constant resting tone of the pelvic floor muscles, particularly the puborectalis, serve to close the genital hiatus, pulling the distal vagina
and anorectal junction toward the pubic symphysis and creating an anorectal angle and a posterior deflection of the rectum, vagina, and bladder base.

It has been hypothesized, based on careful cadaveric dissections, that most rectoceles were due to discrete tears in the Denonvillier’s fascia at its lateral, apical, and perineal attachments and centrally within the fascia itself (14). Perineal detachment, along with a defect in the perineal membrane, has been described as a perineal rectocele, which is most commonly associated with reports of difficulty with defecation. Apical attachment defects are generally associated with enteroceles and occasionally sigmoidoceles.
Evaluation
Although as many as 50% of women older than age 50 have some degree of pelvic organ prolapse (15), fewer than 20% seek treatment (16). This may result from a number of causes, including lack of symptoms, embarrassment, or misperceptions about available treatment options. Although pelvic organ prolapse is not life threatening, it can impose a significant burden of social and physical restrictions of activities, impact on psychological well-being, and overall quality of life.
Symptoms

Pelvic organ prolapse often is accompanied by symptoms of voiding dysfunction, including urinary incontinence, obstructive voiding symptoms, urinary urgency and frequency, and, at the extreme, urinary retention and upper renal compromise with resultant pain or anuria. Other symptoms often associated with POP include pelvic pain, defecatory problems (e.g., constipation, diarrhea, tenesmus, fecal incontinence), back and flank pain, overall pelvic discomfort, and dyspareunia. Patients seeking care for prolapse may have one or several of these symptoms involving the lower pelvic floor. **Choice of treatment usually depends on severity of the symptoms and the degree of prolapse consistent with the patient’s general health and level of activity** (16).

Data relating pelvic floor symptoms to the extent and location of prolapse are weak (17–19). Any symptoms associated with physical findings of lower stage prolapse require careful evaluation, especially if surgery is being considered. A recent retrospective study of 330 patients reported that women with more advanced prolapse were less likely to have symptoms of stress incontinence and more likely to use manual reduction of the prolapse to void. Therefore, careful consideration of lower urinary tract symptoms is important. Prolapse severity was not associated with bowel or sexual problems in this study (20).
Physical Examination

In evaluating patients with pelvic organ prolapse, it is particularly useful to divide the pelvis into compartments, each of which may exhibit specific defects. The use of a Graves speculum or Baden retractor can help to evaluate the apical compartment of the vagina. The anterior and posterior compartments are best examined with the use of a univalve or Sims speculum. The speculum is placed posteriorly to retract the posterior wall downward when examining the anterior compartment and placed anteriorly to retract the anterior wall upward when examining the posterior compartment. A rectovaginal examination may be useful in evaluating the posterior compartment to distinguish a posterior vaginal wall defect from a dissecting apical enterocele or a combination of both.

If an anterior lateral detachment defect is suspected, an open ring forceps (or a Baden retractor) may be placed in the vagina at a 45-degree angle posteriorly cephalad to hold the lateral fornices adjacent to the pelvic sidewall.

During the evaluation of each compartment, the patient is encouraged to perform Valsalva so the full extent of the prolapse can be ascertained. If the findings determined with Valsalva are inconsistent with the patient’s description of her symptoms, it may be helpful to perform a standing straining examination with the bladder empty (20,21).

Pelvic Organ Prolapse Quantitation System

Many systems for staging prolapse have been described. Typically it is graded on a scale of 0 to 3 or 0 to 4, with the grade increasing with the severity of prolapse (22). Currently the system approved by the International Continence Society is the Pelvic Organ Prolapse Quantification system, or POP-Q (23). This standardized quantification system facilitates communication between physicians in practice and research and enables progression of these conditions to be followed accurately. In this system, anatomic descriptions of specific sites in the vagina are used in place of traditional terms. The system identifies nine locations in the vagina and vulva in centimeters relative to the hymen, which are used to assign a stage (from 0 to IV) of prolapse at its most advanced site (Fig. 27.9). Although probably more detailed than necessary for general practice, clinicians should be familiar with the POP-Q system because most published studies use it to describe research results. Its two most important advantages over previous grading systems are (i) it allows the use of a standardized technique with quantitative measurements at straining relative to a constant reference point (i.e., the hymen), and (ii) its ability to assess prolapse at multiple vaginal sites.

Figure 27.9 Standardization of terminology for female pelvic organ prolapse (POP-Q) classification. This diagram demonstrates the anatomic position of the POP-Q sites, including six sites involving the anterior (Aa, Ba), middle (C, D), and posterior (Ap, Bp) compartments with the genital hiatus (gh), perineal body (pb), and total vaginal length (tvl). (From Bump RC, Mattiason A, Bo K, et al. The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. Am J Obstet Gynecol 1996;175:12, with permission.)
The classification uses six points along the vagina (two points on the anterior, middle, and posterior compartments) measured in relation to the hymen. The anatomic position of the six defined points should be measured in centimeters proximal to the hymen (negative number) or distal to the hymen (positive number), with the plane of the hymen representing zero. Three other measurements in the POP-Q examination include the genital hiatus, perineal body, and the total vaginal length (23).

The genital hiatus is measured from the middle of the external urethral meatus to the posterior midline hymen. The perineal body is measured from the posterior margin of the genital hiatus to the midanal opening. The total vaginal length is the greatest depth of the vagina in centimeters when the vaginal apex is reduced to its full normal position. All measurements except the total vaginal length are measured during maximal straining.

The anterior vaginal wall measurements are termed Aa and Ba, with the Ba point moving depending on the amount of anterior compartment prolapse. Point Aa represents a point on the anterior vagina 3 cm proximal to the external urethral meatus, which corresponds to the bladder neck. By definition, the range of position of this point is −3 to +3. Point Ba represents the most distal or dependent point of any portion of the anterior vaginal wall from point Aa to just anterior to the vaginal cuff or anterior lip of the cervix. This point can vary depending on the nature of the patient’s support defect. For example, point Ba is −3 in the absence of any prolapse (it is never less than −3) to a positive value equal to the total vaginal length in a patient with total eversion of the vagina.

The middle compartment consists of points C and D. Point C represents the most dependant edge of the cervix or vaginal cuff after hysterectomy. Point D is the location of the posterior fornix; it is omitted if the cervix is absent. This point represents the level of the attachment of the uterosacral ligament to the posterior
The posterior compartment is measured similarly to the anterior compartment: the corresponding terms are \( A_p \) and \( B_p \). The nine measurements can be recorded as a simple line of numbers (i.e., \(-3, -3, -8, -10, -3, -3, 11, 4, 3\) for points \( A_a, B_a, C, D, A_p, B_p, \) total vagina length, genital hiatus, and perineal body, respectively). The six vaginal sites have possible ranges that depend on the total vaginal length (Table 27.1). After collection of the site-specific measurements, stages are assigned according to the most dependent portion of the prolapse (Table 27.2).

TVL, total vaginal length.

**Table 27.2 Stages of Pelvic Organ Prolapse**

Stage No prolapse is demonstrated. Points \( A_a, A_p, B_a, B_p \) are all at \(-3\) cm, and point \( C \) is between total vaginal length (TVL) and \(-(TVL - 2)\) cm.

Stage The most distal portion of the prolapse is greater than 1 cm above the level of the hymen.

Stage The most distal portion of the prolapse is less than 1 cm proximal or distal to the plane of the hymen.

Stage The most distal portion of the prolapse is less than 1 cm below the plane of the hymen but no further than 2 cm less than the total vaginal length.

Stage Complete to nearly complete eversion of the vagina. The most distal portion of the prolapse protrudes to greater than \((TVL - 2)\) cm.

The POP-Q examination often appears confusing on initial review; however, a measuring device (i.e., a marked ring forceps or marked cotton-tip applicator) can assist in
instructing those unfamiliar with this staging system. The POP-Q examination provides a standardized measurement system to allow for more accurate assessments of postoperative outcome and to ensure uniform, reliable, and site-specific descriptions of pelvic organ prolapse. There is interest in using the POP-Q examination to measure prolapse as a continuous variable rather than in stages because it would provide greater statistical power in clinical research (24). The American Urogynecology Society provides a video (25) that describes the POP-Q exam and demonstrates its use.

In a clinical setting, at least three measurements should be obtained: the most advanced extent of the prolapse in centimeters relative to the hymen that affects the anterior vagina, the posterior vagina, and the cervix or vaginal apex.

As noted previously, whether the older staging systems or the POP-Q system is used, it is important to document the most pertinent findings on examination. This will help in documenting the baseline extent of prolapse and the results of treatment.

**Pelvic Muscle Function Assessment**

**Pelvic muscle function should be assessed during the pelvic examination.** Following bimanual examination with the patient in the lithotomy position, the examiner can palpate the puborectalis and pubococcygeus muscles inside the hymen along the pelvic sidewalls at approximately the 4 and 8 o'clock positions. One can appreciate basal muscle tone and whether there is increased tone with contraction as well as strength, duration, and symmetry of contraction (26). A rectovaginal examination should also be performed to assess basal and contraction muscle tone of the anal sphincter complex.

As a part of the pelvic organ prolapse examination, urethral mobility often is measured. Many women with prolapse will have urethral hypermobility (defined as a resting urethral angle greater than 30 degrees or a maximal strain angle greater than 30 degrees). The presence of urethral mobility in combination with symptoms of stress incontinence may help determine whether an incontinence procedure should be performed. However, studies have shown that nearly all women with stage II to IV prolapse have urethral hypermobility, and asymptomatic parous women have an average maximum straining angle of 54 degrees (27,28). During pelvic examination, the urethra is typically swabbed with Betadine, and lidocaine jelly is placed in the urethra or on a cotton tip swab. The swab is placed in the urethra at the urethrovesical junction and, with the use of a goniometer (Fig. 27.10), the baseline urethral angle from the horizontal and maximal strain angles is measured.

**Figure 27.10 Goniometer, which is used to measure baseline urethral angle and maximal strain angle of the urethra with a cotton tip swab in place.**
Bladder Function Evaluation

Patients with prolapse exhibit the full range of lower urinary tract symptoms. Despite the fact that some patients may not have significant symptoms, it is important to obtain objective information about bladder and urethral function. With severe POP, the urethral kinking effect of the prolapse may mask a potential urine leakage problem; therefore, basic office bladder testing with prolapse reduction should be performed to mimic bladder and urethral function if the prolapse were treated. At a minimum, the following assessments should be performed: a clean catch or catheterized urine sample to test for infection, a postvoid residual (PVR) volume, and assessment of bladder sensation, which can be performed as a part of office cystometrics. Although there is no consensus as to what constitutes an abnormal PVR volume, provided the patient has voided 150 mL or more, a PVR less than or equal to 100 mL is acceptable (27). Reduction stress testing at the time of simple office cystometrics can be performed with the use of a pessary, large cotton swab, ring forceps, or the posterior blade of a speculum. Care should be taken that the urethra not be overly straightened (with a resultant false-positive test result) or obstructed (with a resultant false-negative test result), or that tension is not placed on the puborectalis muscles by excessive posterior retraction. These risks can be minimized by orienting the vaginal apex toward the sacrum.
Bowel Function Evaluation

Once a decision is made to perform surgical repair of the posterior compartment based on symptoms, type, and location of defects, an appropriate approach should be determined and the patient should be made aware of the expected outcomes and potential adverse effects such as pain and sexual dysfunction. If the patient has defecatory dysfunction with a rectocele and symptoms of constipation, pain with defecation, fecal or flatal incontinence, or any signs of levator spasm or anal sphincter spasm, appropriate evaluation and conservative management of concurrent conditions could be initiated before repair of the rectocele and continued postoperatively (28).
Diagnostic imaging of the pelvis in women with pelvic organ prolapse is not routinely performed. However, if clinically indicated, tests that may be performed include fluoroscopic evaluation of bladder function, ultrasound of the pelvis, and defecography for patients in whom intussusception or rectal mucosal prolapse are suspected. Magnetic resonance imaging is increasingly being used for the evaluation of pelvic pathology such as mullerian anomalies and pelvic pain; however, generalized use in women with prolapse is not currently clinically indicated and is used primarily for research purposes.
Nonsurgical Therapy

Nonsurgical therapy of pelvic organ prolapse includes conservative behavioral management and the use of mechanical devices. A nonsurgical treatment approach usually is considered in women with mild to moderate prolapse, those who desire preservation of future childbearing, those in whom surgery may not be an option, or those who do not desire surgical intervention.

Conservative Management

Conservative management approaches include alteration of lifestyle or physical intervention such as pelvic floor muscle training (PFMT). These approaches are used mainly in cases of mild to moderate prolapse; however, their true role in managing prolapse and associated symptoms is unclear (29,30). The goals of a conservative therapy approach to the treatment of prolapse are as follows (31):

- Prevent worsening prolapse
- Decrease the severity of symptoms
- Increase the strength, endurance, and support of the pelvic floor musculature
- Avoid or delay surgical intervention

Lifestyle intervention includes such activities as weight loss and reduction of those activities that increase intra-abdominal pressure. This interaction is typically anecdotal in practice. No case series, prospective studies, or randomized control trials exist that have examined the effectiveness of this approach to the treatment of prolapse.

Pelvic floor muscle exercises may limit the progression of mild prolapse and related symptoms (32,33); however, a lower response rate has been noted when prolapse extends beyond the vaginal introitus (34).

The efficacy of biofeedback therapy in the treatment of impaired defecation associated with a rectocele has been determined (35). Thirty-two female patients, median age 52 years (range, 34–77 years), experiencing impaired rectal evacuation with a rectocele greater than 2 cm at proctography underwent a structured behavioral retraining. Immediate and medium-term follow-up results were reported (median 10 months; range 2–30 months). Fifty-six percent of patients (n = 14) felt a little and 16% (n = 4) felt major improvement in symptoms, including 3 (12%) with complete symptom relief. Immediately after biofeedback there was a modest reduction in need to strain (67; 50%), feeling of incomplete evacuation (73; 59%), and need to assist defecation digitally (79; 63%) that was maintained at follow-up. Bowel movement frequency was significantly normalized at follow-up (p = .02). These investigators concluded that behavioral retraining, including biofeedback therapy, may be an effective primary therapy for some patients with a rectocele associated with impaired defecation.
Mechanical Devices

The use of mechanical devices such as pessaries is usually considered for women who cannot undergo surgery for medical reasons, desire to avoid surgery, or have a significant degree of prolapse that makes other nonsurgical approaches unfeasible. Some practitioners extend indications to include pregnancy-related prolapse as well as prolapse and incontinence in elderly women. Reports have shown that age older than 65 years, the presence of severe medical comorbidity, and sexual activity were associated with successful pessary user (36,37). Unsuccessful use or a preference for surgery has been associated with a shortened vaginal length (≤6 cm), a wide vaginal introitus, sexual activity, stress incontinence, stage III or IV posterior compartment prolapse, and desire for surgery at a first office visit (38). Few literature-based reviews and reports recommend pessaries as first-line treatment for women with POP, and there is little consensus regarding choice of pessary and management of pessary usage (39). Most of the information on pessary use is derived primarily from descriptive and retrospective studies, relatively small prospective series, manufacturer’s recommendations, and anecdotal experience.

Pessaries provide pelvic organ support within the vaginal vault. Two categories of pessaries—support and space filling—exist for prolapse (39). The ring pessary (with diaphragm) is a commonly used support pessary, and the Gelhorn pessary is a commonly used space-filling pessary. The ring and other support pessaries are recommended for stage I and II prolapse, whereas the space-filling pessaries are used for stage III and IV prolapse (40). It is unclear whether pessaries can prevent the progression of POP with regular use. A prospective cohort study addressed this issue in a series of 56 women who were fitted with a pessary, of which 33.9% (n = 19) continued use for at least 1 year (41). Baseline and follow-up pelvic examinations were performed using the POP-Q system (23). The women removed the pessary 48 hours before one visit, but there was no information to ascertain adherence to pessary use. No woman had worsening of the prolapse, and four women (21.1%; 95% confidence interval [CI], 0.2%–43.7%) had an improvement. Improvement overall was noted in women with anterior compartment prolapse.

In women with stages I and II prolapse with stress urinary incontinence, a continence pessary may be considered and has been shown to produce patient satisfaction above 50% at 12 months (42). There are no randomized controlled trials of pessary use in women with POP (43). Likewise, there are no consensus guidelines on the care of pessaries (i.e., intervals between changes), the role of local estrogens, or the type of pessary indicated for specific types of POP (43). Manufacturers recommendations and different pessary types can be seen in Figure 27.11. Effective and satisfactory outcomes have been reported for stage II or greater prolapse using the Gelhorn and ring diaphragm pessary (36). After 2 to 6 months, 77% to 92% of women with a successful pessary fitting were satisfied and, using intention-to-treat analysis, 44% to 67% of all women who were treated initially with a pessary for prolapse were satisfied. There are few other series describing pessary use for prolapse with greater than 4 weeks follow-up.
Possible complications associated with pessary use include vaginal discharge and odor. Failure to retain the pessary may occur or, conversely, the pessary may be too large, which could lead to excoriation or irritation. With reduction of vaginal prolapse, de novo or increased stress incontinence may occur, and in rare instances, more severe complications, including vesicovaginal or rectovaginal fistula, small bowel entrapment, hydronephrosis, and urosepsis, have been described (46–48).

**Placement and Management**

Pessary placement involves consideration of a number of issues, primarily the patient’s desire and motivation to use this type of device. Typically, if she has had previous surgery or strongly desires to avoid surgery, she may be motivated enough for a primary attempt at pessary placement. Other issues include current sexual function status, type and duration of exercise in which the patient engages, and the status of the vaginal walls and cervix. In hypoestrogenic women, treatment of the vagina with estrogen and maintenance of intravaginal estrogen treatment is recommended.

**Fitting a Pessary**

The patient should be examined in the lithotomy position after emptying her
bladder. The clinician should use a dry glove to better grasp the pessary and water-soluble lubricants as needed. The size of the pessary is estimated after a digital examination and use of ring forceps to reduce the prolapse or bladder neck. Once the approximate size is determined, the appropriate type is selected based on the patient’s needs and activity level. **When fitted, the patient is asked to stand, perform Valsalva, and cough to ensure the pessary is retained.** The pessary should be assessed to ensure it is providing the desired support and leakage control. The patient should be able to void with the pessary in place before leaving the office. Proper size is ensured by the ability to sweep the index finger between the pessary and the vaginal wall. The patient should feel comfortable with the pessary in place.

**Insertion of the pessary is eased by using a water-soluble lubricant for insertion, folding or collapsing the pessary to reduce its size, and when it is inside the vagina, pushing it high to an area behind the symphysis pubis and inserting the device more posteriorly to avoid the urethra.** Instructing the patient how to insert and remove the pessary may be done with the patient in a standing or supine position, depending on her dexterity (49).

**Ring pessaries,** with or without support, are the most commonly used type. They are the easiest to fold, insert, and remove. Gellhorn and cube pessaries are typically more difficult to insert and remove by the patient. They are held in place by significant space occupation and suction and offer strong support. The suction of the cube pessary needs to be broken, facilitating removal. Cube pessaries should be removed daily; Gelhorns can stay in longer (up to 6–8 weeks). **Donut pessaries,** which are very popular, are considered a space-fitting pessary for large vaginal vault prolapse, complete procidentia with decreased perineal support, and good introital integrity. **The patient should be questioned about a latex allergy and instructed to remove and clean the device every 2 to 3 days.** Continence pessaries, rings, and dishes with support typically also are easy to fold, insert, and remove (50).

**Follow-Up Recommendations**

After the initial fitting, the patient should return in 1 to 2 weeks and then at 4 to 6 weeks, depending on her independence with the pessary, her proficiency in placement and removal, and her cognitive and motor abilities (44). After this initial follow-up, follow-up should continue at 6- to 12-month intervals at the discretion of the provider and depending on the patient’s ability to insert and remove the pessary effectively. If the patient needs to return to the provider for removal and cleaning of the pessary, 4- to 12-week intervals are more appropriate.

**On follow-up visits, proper placement of the pessary and support of the prolapse as well as continence efficacy should be ensured.** Because pessaries are fitted through a process of trial and error, it is not uncommon to change the size or type at least once after the initial fitting. The pessary’s integrity should be checked, and the tissues should be evaluated for irritation, pressure sores, ulceration, and lubrication (44).
Surgical Management

The primary aims of surgery are to relieve symptoms, which may be caused by prolapse, and, in most cases, to restore vaginal anatomy so that sexual function may be maintained or improved without significant adverse effects or complications. Occasionally, when sexual function is not desired, obliterative or constrictive surgery is more appropriate and also may relieve symptoms. There is no steadfast rule as to when surgery is indicated. Many patients with more advanced prolapse have few or no symptoms, whereas some with lesser degrees of prolapse have what they describe as severe symptoms. This is confounded by the observation that many of the “symptoms” may not be specifically related to the anatomic defect or may be worsened by anxiety. In general, surgery should be offered to patients who have tried conservative therapy and were not satisfied with the results or who do not desire conservative therapy. The prolapse should be symptomatic or should be greater than or equal to stage II with apparent progression. All patients should be given the alternative of trying conservative treatments when applicable (51).

Approaches to surgery include vaginal, abdominal, and laparoscopic routes, or a combination of approaches. Depending on the extent and location of prolapse, surgery may involve a combination of repairs directed to the anterior vagina, vaginal apex, posterior vagina, and perineum. Concomitant surgery may be planned for urinary or fecal incontinence. The surgical route is chosen based on the type and severity of prolapse, the surgeon’s training and experience, the patient’s preference, and the expected or desired surgical outcome.

Procedures for prolapse can be broadly categorized into three groups: (i) restorative, which use the patient’s endogenous support structures; (ii) compensatory, which attempt to replace deficient support with permanent graft material; and (iii) obliterative, which close or partially close the vagina (51).

These groupings are somewhat arbitrary and not entirely exclusive. For example, grafts may be used to reinforce repairs, such as colporrhaphy, or to replace support that is deficient or lacking. Graft use in sacrocolpopexy substitutes for the connective tissues attachments (cardinal and uterosacral ligaments) that would normally support the vaginal apex. In addition to the primary goal of relieving symptoms related to prolapse, urinary, defecatory, and sexual function must be considered in choosing the appropriate procedures.

Whether to repair all defects is controversial. Restorative repairs may be less successful than compensatory repairs in patients with generally “poor tissue,” and at times one defect repair may exert more tension on the repair of another defect. Management should be based on the patient’s presentation, expectations, the specific anatomical defects noted (preoperatively and, at times, intraoperatively), and on the presence or absence of lower urinary and bowel dysfunction (51).
Vaginal Procedures

The Apical Compartment

Examination for apical defects is at times difficult. Such defects may be missed when large anterior or posterior defects are present. In cases when apical defects are suspected but not confirmed, surgeons should evaluate the apical support intraoperatively and plan for management of these defects when they are found. Traction on the cervix with a tenaculum or on the vaginal cuff both centrally and laterally with Allis clamps may reveal otherwise unrecognized defects.

Transvaginal repairs include extraperitoneal procedures such as sacrospinous suspensions, iliococcygeal suspensions, and high paravaginal suspensions of the apical vaginal fornice to the arcus tendineus at the level of the ischial spine or to the endopelvic fascia, and intraperitoneal suspensions such as uterosacral suspensions and McCall culdoplasties (51). Accepted practice is that the vaginal apex should be resuspended in a posterior cephalad direction to a site or sites posterior and caudad to the sacral promontory. Anterior apical suspensions change the direction of the vaginal axis and may be fraught with a greater incidence of posterior compartment defects, including rectoceles, enteroceles, and sigmoidoceles.

The general principles of the repair should include management of the specific apical defects:

- If present, the attenuated part of the upper vaginal wall (fibromuscular defect) should be repaired or covered by graft material.
- The vaginal cuff or, in some instances, the cervix should be suspended without excessive tension.
- Any defect in the attachment of the upper vagina to the rectum at or below its sigmoid junction should be corrected.

Enterocoele repairs may include:

- Removal of the peritoneal sac with closure of the peritoneal defect, followed by closure of the fascial or fibromuscular defect or both below it
- Dissection and reduction of the peritoneal sac and closure of the defect
- Obliteration of the peritoneal sac from within with transabdominal Halban or Moschcowitz type procedures or transvaginal McCall or Halban procedures (52).

Historically, the treatment for symptomatic uterine prolapse has been hysterectomy, which is performed vaginally or abdominally in combination with an apical suspension procedure, and repair of coexisting defects. Apical support procedures that have been described for use when the uterus or cervix is to be kept in place include Manchester and Gilliam procedures and fixation of the cervix to the sacrospinous ligament. The other procedures described in this section may also be used in women who desire uterine conservation. Adequate outcome data on such uterine-sparing procedures are not yet available. When
the cervix is absent, in addition to repair of fibromuscular defects, both fibromuscular planes anterior and posterior to the vaginal cuff should be attached to whatever suspension is employed.

**Sacropinous Ligament Fixation**

The fixation of the vaginal apex to the sacrospinous ligament, the tendineus component of the coccygeus muscle, was first described in 1958 and was subsequently modified in Europe and the United States (53–56). Access is traditionally extraperitoneal via the rectovaginal space with penetration of the pararectal (Denonvillier’s fascia) at the level of the ischial spine to expose the muscle and ligament. Variations in this approach to the ligament include entrances through an anterior lateral access, an apical passage posterior to the uterosacral ligament, and a laparoscopic approach (57–59). Bilateral sacrospinous ligament suspensions have also been advocated; however, these techniques may impose a greater degree of tension on the sutures and, at times, create a band of apical vagina across the rectum at the level of the suspension (60,61). Whether this can cause defecatory dysfunction remains unknown. The advantages of the sacropinous fixation procedure include (i) its transvagal extraperitoneal approach, (ii) resultant posterior vaginal deflection, and (iii) the fact that it is a durable repair if performed correctly. Reported success for apical support has been good (89%–97%) with follow-up times ranging from 1 month to 11 years (51,62). However, there have been subsequent reports of high rates of anterior vaginal prolapse (63,64). It is not clear whether this observation is related to the procedure and its exaggerated posterior vaginal deflection or to the fact that many patients with apical descent also have defects in the upper vaginal fibromuscular tissue. Failure to address an anterior defect concurrently with suspension of the posterior apical vagina may predispose the patient to such a defect postoperatively. Other disadvantages of the procedure include (i) relative difficulty in adequately exposing the ligament, (ii) an unnatural lateral vaginal deflection toward the fixation site, (iii) an inability to perform without excessive tension when the vaginal length is compromised, as may be the case in repeat procedures, (iv) potential risk for injury to the sciatic nerve or pudendal nerve or vessel, and (v) occasional need to shorten or narrow the upper vagina when a fibromuscular defect involves much of the apical area.

**Iliococcygeal Vaginal Suspension**

Iliococcygeal vaginal suspension involves the attachment, usually bilaterally, of the vaginal apex to the iliococcygeus muscle and fascia (61,65,66). Extraperitoneal access is achieved via the posterior vagina. Compared with other vaginal suspension procedures, the iliococcygeal suspension has the fewest case series in the literature (65–67); however, cure rates appear comparable to the sacropinous suspension technique (51). The dissection of the area to the ischial spine is approached from a midline posterior vaginal wall incision using the ischial spine as a landmark for identifying the sacropinous ligament and the iliococcygeal fascia anteriorly and caudad to it. A no. 1 polydioxanone suture is placed through the fascia and attached to the
vaginal apex as a pulley stitch. This procedure is more easily performed bilaterally than the sacrospinous suspension and should be considered preferentially in the presence of a shortened vagina. Risk of major vessel, nerve, or ureteral injury should be relatively low compared with other transvaginal suspensions.

Uterosacral Ligament Suspension

Surgical variations of the uterosacral ligament suspension originally described in 1938 have been used prophylactically during hysterectomy or therapeutically for vaginal apical suspension (68). A therapeutic procedure in which the vaginal apex is suspended to the uterosacral ligaments above the level of the ischial spines had excellent success rates in an observational study of 302 participants (69). When access to the posterior cul-de-sac is attained, the uterosacral ligament remnant can usually be found adjacent to the pelvic sidewall peritoneum just cephalad to the palpable ischial spine. Up to three sutures are placed in each ligament and incorporated into the anterior and posterior fibromuscular layer of the vagina. Some surgeons approximate the ligaments in the midline to close the cul-de-sac with the intention to treat or prevent enterocele formation (70). Other surgeons suspend the right and left vaginal apex to the ipsilateral uterosacral ligament, leaving the cul-de-sac open to avoid impinging on the rectum and adversely affecting bowel function.

Outcome studies have shown that recurrent apical prolapse occurs in 2% to 5% of cases within the first few years following the procedure, which is a rate comparable or superior to other transvaginal apical repairs, and the incidence of recurrent anterior defects may be less than that reported with sacrospinous suspensions (69,71). The most common serious complication was ureteral obstruction secondary to ureteral kinking or incorporation of an ureter in a suspension stitch. This occurred in as many as 11% of cases (71). Intraoperative cystoscopy—with documentation of ureteral patency after administration of indigo carmine dye, whereby such a problem can be corrected—is recommended.

Multiple sutures may increase the incidence of tissue devascularization and necrosis, thus resulting in failure of the suspension. One case series of bilateral single suture uterosacral suspensions demonstrated a 15% stage I and no stage II recurrence among 71 women with a mean follow-up of 21.3 months (72). Exposure can be accomplished through the vaginal cuff after hysterectomy, a transverse incision at the vaginal cuff in cases of vaginal vault prolapse or descent, and, rarely, through a posterior colpotomy when uterine or cervical conservation is desired. When the apical vaginal wall is attenuated, it is excised. The pelvic sidewall, lateral to the sigmoid colon, is exposed using Breisky-Navratil retractors and a pack to hold the small bowel cephalad and to place the sigmoid colon and sidewall peritoneum on stretch (Fig. 27.12A). After palpation of the ischial spine, single permanent sutures of 0 or 1 polypropylene are placed through the peritoneum and adjacent ligament approximately 1 cm cephalad to and at the same posterior level as the ischial spines. Traction on the sutures and palpation of the site should reveal that the sutures are firmly attached to the ligamentous structures. The
sutures are tagged for use after repair of defects of the anterior compartment. The peritoneum is dissected off the vaginal fibromuscular wall posterior to the vaginal cuff. The suspension sutures are then secured with large bites into the posterior vaginal fibromuscular tissue and anterior fibromuscular tissue, then locked in place to approximate anterior to posterior connective tissue and to fix the suture to the vaginal apex so that it may be moved up to the ligament (Fig. 27.12B). If a rectovaginal enterocele is present, it is dissected, reduced, and closed, approximating the prerectal fascia or anterior rectal wall to the posterior fibromuscular vaginal tissue just caudad to the suspension sutures. Absorbable cuff closure sutures are placed at each cuff angle and one to two bites are taken to approximate anterior to posterior vaginal cuff over the suspension suture sites. When indicated, plication of the central cuff anterior to the posterior fibromuscular tissue with a box stitch is also performed. These sutures are secured after the suspension (pulley) sutures are tied, then cuff closure is completed from each side with the absorbable sutures in a running fashion. Cystoscopy is performed to document ureteral patency. Ureteral compromise has been noted in only 2 of 150 cases performed. The procedure provides adequate support of POP-Q point C and D in all 58 subjects evaluated more than 1 year postoperatively (72).

Figure 27.12 Diagrams illustrating open vaginal apical area with (A) exposure of site for suture placement or lateral pelvic side wall and (B) suture placement through ligament then through the posterior and anterior paravaginal tissue where they are locked to enable pulley action to the ligaments when tied. (Redrawn from an image by J. Taylor.)
Anterior Vaginal Colporrhaphy

Anatomic correction of an anterior defect or cystocele will generally relieve symptoms of protrusion and pressure and usually will improve micturition function when abnormal micturition is associated temporally with the defect and if there is no associated neuropathy. If a single, well-defined midline defect is recognized, excision of the weak vaginal wall and an imbricating closure of the defect may be performed. Most central anterior defects require a more extensive dissection of the vesicovaginal space. Following this dissection, many surgeons then separate the vaginal mucosa and submucosal layers from the fibromuscular layer out to a point lateral to the defect, followed by midline plication of this tissue, then excision of excess epithelium, and closure (72–78). It appears important to maintain the continuum of repaired fibromuscular tissue to a well-supported vaginal apex. If the repair is being performed simultaneously with a vaginal apical suspension, the anterior colporrhaphy is typically performed after the apical support sutures have been placed and prior to tying them down. The dissection is carried out starting from the everted vaginal cuff edge and dissecting toward the bladder neck. A high central defect may also be corrected via a transabdominal approach by dissecting between the base of the bladder and the upper one-third of the anterior vaginal wall. The defective tissue may then be wedged out and the defect closed with running or interrupted sutures. This approach may be of use when performing transabdominal procedures for apical suspension.

If the patient has significant stress incontinence (based on report or the presence of occult or potential incontinence), an appropriate bladder neck suspension may be performed simultaneously with the anterior repair. When performing midurethral sling procedures, it may be preferable not to extend the repair procedure below the urethra, but instead to make a separate incision for the sling. Maintaining some degree of the urethrovesical angle may improve the results of any incontinence procedure. If the patient has voiding dysfunction (reports of incomplete emptying and a high residual urine) and stress incontinence, appropriate urodynamic evaluation should be performed before a procedure is selected, and the patient should be made aware of the potential for continued problems after surgery (78).

Recurrence rates of traditional “fibromuscular plication” anterior repairs vary from 3% to 92%; however, studies define recurrence in numerous ways, from minimal prolapse to stage III descent (63,73–81). The clinical significance of recurrent mild cystoceles (stage I) that are asymptomatic is debatable because many of these defects do not progress to larger ones. When traditional anterior repairs are performed in patients with POP-Q stage II or greater cystoceles (frequently concurrently with other procedures), a 20% recurrence rate of stage II or greater prolapse is not uncommon, although overall recurrence rates as low as 3% have been reported (76). Many studies do not define how the participants were evaluated postoperatively and vary with respect to patient
populations, type and severity of defects, presence of concurrent defects, surgical technique, and follow-up time and length. Some studies have suggested higher recurrence rates when these repairs are performed concurrently with sacrospinous suspensions and hypothesize that this type of apical suspension may predispose the repaired anterior wall to greater pressure transmission (63,64). These studies may show higher failure rates because patients having such concurrent repairs may be more likely to have more complicated forms of prolapse or more extensive pelvic floor defects than other patients.

Paravaginal Repair

The paravaginal or “lateral defect” repair involves reattachment of the anterior lateral vaginal sulcus to the obturator internus fascia and, in some cases, muscle at the level of the arcus tendineus pelvis (“white line”) (82,83). It is usually performed as a bilateral procedure via transvaginal or retropubic (abdominal or laparoscopic) access. The procedure essentially restores normal anatomy; however, because it is not practical to rebuild the defective endopelvic–fascial bridge to the pelvic sidewall, it attaches the vaginal wall itself. Observational studies have reported good success with this procedure (80%–95%); however, long-term data on durability and function are lacking (12,84–88). Most women with anteriolateral detachments usually have separation of the upper vaginal fornices from the arcus tendineus immediately adjacent to the ischial spine (Fig. 27.13) (89). Thus, it is important to resuspend those specific areas.

Figure 27.13 Schematics illustrating normal attachments of the anterior fibromuscular vaginal plane (A and C) and bilateral detachments of that plane from the arcus tendineus up to the level of the ischial spines (B and D). Note: For B and D to occur, there will either be concurrent apical descent or a detachment of the upper fibromuscular plane from the apical structures. (From Delancey JO. Fascial and muscular abnormalities in women with urethral hypermobility and anterior vaginal wall prolapse. Am J Obstet Gynecol 2002;187:93–98, with permission.)
It is difficult to achieve optimal results when the paravaginal repair is used in combination with traditional central repairs because of the creation of tension on opposing suture lines. A repair that removes a weakened central vaginal wall may decrease the side-to-side dimensions of the anterior vaginal wall, making it difficult to suspend its lateral points more laterally. When large central defects coexist with lateral defects, one option is an extensive central repair accompanied by an apical support procedure. This changes the shape of the vagina to a more cylindrical structure. Another choice is placement of a graft to span the entire anterior rhomboid-shaped plate, thus augmenting anterior paravaginal tissue strength. The graft with tension adjusted may be anchored to the arcus tendineus along with the adjacent vaginal wall from the level of the pubic rami to the ischial spine (88).

Although most reports indicate that repair of anterior defects with all of these procedures relieves symptoms directly related to prolapse, there are very few data on patient satisfaction and quality-of-life improvement over time (88).
The Posterior Compartment

Traditional Posterior Colporrhaphy

The first description of the posterior colporrhaphy involved plication of the pubococcygeus muscles across the anterior rectum as well as perineal body reconstruction (90). The technique has subsequently been modified in attempts to preserve sexual function. Typically a midline incision is extended from the perineal body to the vaginal apex or to the cephalad border of a small or distal rectocele. The Denonvillier’s fascia is mobilized from the vaginal epithelium, leaving as much of this tissue as possible attached laterally to the levator fascia. After obvious defects in the rectal muscularis are repaired, the fascia is then plicated in the midline with interrupted or continuous sutures. The authors prefer delayed absorbable sutures for this plication. Permanent nonbraided suture material also can be used. Braided permanent suture material is associated with a greater incidence of stitch infection and formation of granulation tissue (91). The vaginal epithelium is trimmed and closed with absorbable sutures.

When a defective perineal body or perineal membrane is present, reconstruction is performed after accompanying posterior colporrhaphy. The superficial muscles of the perineum and bulbocavernous fascia are plicated in the midline and the skin closed as in an episiotomy repair. Detachments of the inferior portion of the Denonvillier’s fascia from the perineal body are also corrected. The puborectalis muscles are plicated concurrently with these procedures by some surgeons, but this approach is associated with a high incidence of sexual dysfunction and thus is not recommended routinely (91). It may be worth consideration in patients who have severe prolapse accompanied by a large genital hiatus with palpable levator weakness or who are unable to contract their pelvic floor muscles. Sutures should be placed carefully through the puborectalis muscles at least 3 cm or greater posterior to their insertion on the pubic rami, thereby decreasing the tension of the plication. For those women with an enlarged hiatus and weakened puborectalis muscles who desire sexual function, an attempt can be made to plicate the muscles far enough posteriorly to allow two fingers to easily pass through the vaginal introitus and to reconstruct the distal posterior vagina and perineum, whereby there will not be a ledge at the site of the puborectalis plication (91). Outcome data on such procedures are inadequate to make conclusions regarding its efficacy; however, it is reasonable to postulate that pelvic floor defects producing an enlarged genital hiatus are common reasons for failure of support procedures, and puborectalis plication may decrease the incidence of such failures.

A complete review of rectocele, anorectal functional disorders, and various repairs can be found elsewhere (92). Reported anatomic cure rates for traditional posterior colporrhaphy have ranged from 76% to 90% with variable follow-up intervals (93–97). Most studies show a benefit in ease of defecation if patients are using splinting preoperatively; however, overall defecatory dysfunction (defined as constipation) was not relieved in most patients and increased (approximately 30%) after the procedure in one study (95).
These repairs appear to have little to no benefit in the treatment of fecal incontinence. It is not surprising that the repairs are not particularly effective for defecatory dysfunction related to disorders of constipation or for fecal incontinence because these problems have multifactorial causes. **De novo dyspareunia is reported to occur in 8% to 26% of sexually active patients who have traditional posterior colporrhaphy** and is not always associated with levator plication procedures (93–96,98,99). Potential causes for dyspareunia, other than vaginal strictures or introital tightness, include scarring with immobility of the vaginal wall, levator spasm, and neuralgia associated with sutures or dissection. Dyspareunia also may occur when a Burch procedure or other procedures that anteriorly displace the vaginal canal are combined with a posterior repair (96). Careful surgical technique and appropriate choice of procedure should decrease the incidence of postoperative dyspareunia.

**Defect Specific Posterior Repair**

Defect or site-specific posterior repairs are restorative procedures by which posterior defects are corrected. These repairs begin with midline posterior vaginal incision through the epithelium and continue with separation of the epithelium from the fibromuscular wall. After irrigation to provide better exposure, a finger is inserted into the rectum to help define defects of the rectal wall and the fibromuscular layer that has been dissected from the vaginal wall submucosa. The specific defects are closed with either interrupted or running sutures (preferably the delayed absorbable type). Defect closure is accomplished in such a way as to minimize tension on the surrounding tissue and may involve vertical, horizontal, or oblique approximation. When fibromuscular tissue has separated from the perineum, the upper anterior rectum, or a well-supported cervix or vaginal cuff, it is important to reapproximate these connections. Repairs of coexistent perineal and apical support defects are important. **The object of the surgery is to reestablish an intact plane of connective tissue that positions the rectum against the pelvic floor and obliterates any potential space between a well-supported cervix or vaginal cuff and the cephalad edge of the tissue plane and upper rectum.** The technique should minimize tension and potential strictures, which may be more likely to occur with traditional posterior colporrhaphy (97).

Initial case series reveal anatomical cure rates with mean follow-up times less than 18 months from 82% to 100% and de novo dyspareunia rates of 2% to 7%, which are much lower than those seen with traditional repairs (99–103). Symptom relief appears to be as good or better than that seen with traditional repairs. The greatest concern with these and other procedures has been durability. A recent report indicates that the recurrence rate of rectocele beyond the midvaginal plane was higher with defect-specific posterior repairs than with side-to-side plication procedures using laterally attached fascia pulled to the midline (33% vs. 14%) and beyond the hymenal ring (11% vs. 4%) (97). The study was not randomized; however, the procedures were performed during the same period with consistent follow-up evaluations 1 year after surgery. Symptoms (dyspareunia, constipation, and fecal incontinence) after surgery did not differ between the two groups.
Long-term follow-up of previously reported case series that had good short-term success or prospective randomized trials looking at modifications of traditional repairs versus defect-specific repairs should clearly delineate durability of these procedures.

Transanal Posterior Repair

The aim of transanal rectocele repair, usually performed by colorectal surgeons rather than gynecologists, is to remove or plicate redundant rectal mucosa, to decrease the size of the rectal vault, and to plicate the rectal muscularis. The rectovaginal adventitia and septum are plicated as well, probably along with the posterior vaginal muscularis. The vaginal epithelium is not incised or excised with this procedure, which probably accounts for the reported lack of adverse affects on sexual function in contrast to the vaginal approach to posterior repair. Two randomized trials and several case series from transanal repairs with mean follow-up intervals of 12 to 52 months report anatomic cure rates of 70% to 98%, improved constipation and fecal incontinence, with less need for vaginal digitation to expel stool (104–108). Complications included infections and rectovaginal fistulas, which are surprisingly rare in the reported series. From the gynecologic perspective, transanal posterior repair is an option only when the procedure is performed for defecatory dysfunction and not for prolapse of the posterior vaginal wall. The question remains whether the transanal approach with defect excision and repair improves defecatory dysfunction better than a defect-specific transperineal or transvaginal approach with imbrication of tissues to correct palpable weakness in the rectal wall and its adjacent connective tissues.

Transvaginal Mesh Procedures

Graft materials have been employed in repairing defects or hernias throughout the body. The purpose of grafts is to either completely replace “weak” tissue by spanning across that tissue or to provide a scaffold for fibroblast infiltration. The patient’s own connective tissue may grow into the graft, and, if the graft is degradable, replace the graft as a supportive structure. An ideal graft material should (i) be nonantigenic, (ii) exhibit a low infection rate, (iii) decrease or negate recurrence of anatomic defects, (iv) cause no harm with respect to bowel or renal function, and (v) be relatively inexpensive. Graft materials include autologous tissues, cadaveric allografts and fascia, dermis and other connective tissues, xenografts from animal sources, and various synthetic materials. Allografts and xenografts are treated with processes to remove living cells, thus negating their antigenic potential and allowing them to serve as a temporary connective tissue scaffold. It is assumed that fresh, autologous grafts work similarly; however, there may be some fibroblast survival in fresh harvested tissue. Autologous grafts have limitations in size and shape compared with tissue taken from cadaveric or animal sources. Synthetic grafts are permanent and, as long as the tissues to which they are secured retain their position and strength, they should be durable. Autografts, allografts, and xenografts depend on adequate tissue growth from the subject and potentially may have higher failure rates than synthetic ones. Synthetic grafts are more subject to erosion. Graft erosion
may produce bothersome discharge, pain, and sexual dysfunction with vaginal scarring. This may be more likely to occur in women with attenuated, scarred, or less vascular tissue at the time of the repair. More loosely woven polypropylene meshes appear to exhibit fewer problems with erosion and infection than the synthetic graft material that was previously used (109–113).

Midurethral sling procedures that use such mesh have reported erosion rates of 1% or less as compared with rates as high as 6% with more tightly woven polypropylene and polyethylene grafts (109–113). A greater incidence of graft infection has been reported when other synthetic grafts are used. One would expect higher rates of erosion and infection when large pieces of graft material are used adjunctively to the vaginal wall; however, there have been favorable reports in which loosely woven polypropylene mesh was used in this manner. Small areas of eroded polypropylene graft may be removed with the surrounding tissue to the point where there is good tissue growth into the graft, and the defect can then be closed. Graft erosion into the bladder, urethra, or rectum is less common than into the vagina. When erosion occurs, however, management is more difficult and long-term adverse effects more common. Numerous surgeons have been reticent to use synthetic graft materials to augment paravaginal musculoconnective tissue support because of complications from erosion. There remains a need for long-term follow-up on patients who have repairs with graft material, not only to assess anatomical results and complications, but also to assess subsequent sexual function, presence and absence of pain, and patient satisfaction.

Synthetic transvaginal mesh kits have become commonplace in the treatment of pelvic organ prolapse. These devices were quickly adopted by many surgeons in an effort to improve outcomes, particularly in patients who had failed native tissue repairs. Studies have provided mixed results as to the effectiveness of these devices. There may be a lower recurrence rate in the anterior compartment when compared with native tissue repairs; however, mesh erosions occur in 2% to 19% of those treated (109–113). The severity of mesh erosions ranges from subclinical to severe dyspareunia requiring surgical resection. Small mesh erosions are sometimes successfully managed with vaginal estrogen alone. As with anterior compartment procedures, graft materials have been used to improve the success of posterior compartment repairs. One recent systematic review concluded that there is insufficient evidence to evaluate the use of synthetic mesh in the repair of pelvic organ prolapse (114). It is also notable that the U.S. Food and Drug Administration (FDA) has recently released a warning about complications that may arise from the use of transvaginal mesh procedures for pelvic organ prolapse.

The FDA recommendations are that physicians should:

- Obtain specialized training for each mesh placement technique, and be aware of its risks.
- Be vigilant for potential adverse events from the mesh, especially erosion and infection.
- Watch for complications associated with the tools used in transvaginal placement, especially bowel, bladder, and blood vessel perforations.
Inform patients that implantation of surgical mesh is permanent, and that some complications associated with the implanted mesh may require additional surgery that may or may not correct the complication.
Inform patients about the potential for serious complications and their effect on quality of life, including pain during sexual intercourse, scarring, and narrowing of the vaginal wall (in POP repair).

**In summary, transvaginal mesh procedures that are currently in use utilize predominantly synthetic materials.** These devices may reduce recurrence of pelvic organ prolapse and are associated with some risk of vaginal mesh extrusion and chronic pain or dyspareunia. Patients should be counseled extensively about the risks and benefits of the use of these devices. Surgeons who use these devices should carefully follow their cases to identify complications.
Abdominal Procedures

Abdominal Uterosacral Suspension

Abdominal uterosacral colposuspension has been used prophylactically after hysterectomy and therapeutically for apical prolapse with cardinal/uterosacral defects (115). It can be performed through laparotomy incisions or by laparoscopic techniques. For the therapeutic procedure, a no. 1 polypropylene or delayed absorbable suture is placed cephalad and at the same level posterior as the ischial spines, which may be palpated transabdominally or with a vaginal finger to push a vaginal fornix to the spine under observation with a laparoscope. One technique is to place one or two permanent sutures through one ligament, then, after reefing across the cul-de-sac peritoneum at the sigmoid border, through the contralateral ligament, and then through the fibromuscular tissue just anterior to the vaginal cuff. Tying the suture suspends the vaginal cuff and obliterates any enterocele defect. Another technique employs separate sutures placed at the same level into each uterosacral ligament and anchored anteriorly and posteriorly to the ipsilateral side of the vaginal cuff, similar to procedures performed transvaginally. Cystoscopy is performed after the procedure to document ureteral patency. One study found subjective and objective recurrence rates to be low (12% and 5%, respectively) (115).

Abdominal Approach to Posterior Repair

When abdominal sacrocolpopexy is planned for apical vaginal prolapse and concomitant rectocele is present, some have advocated extending the posterior graft down the posterior vaginal wall to correct the defect (116). The technique of sacral colpoperineopexy is used to replace the normal vaginal suspensory ligaments and to augment or replace the posterior fibromuscular plane with graft material that runs from the sacrum to the perineal body (116). Its purpose is to correct the posterior compartment defects and to suspend the perineal body, thus preventing descent and opening of the genital hiatus. It has been performed transabdominally or as a combined abdominal and vaginal procedure with both Mersilene mesh and dermal allografts (116,117). Mesh erosion occurred frequently when the vagina was open: 16% for vaginal placed sutures and 40% for transvaginally placed mesh (117). The use of dermal allografts results in an anatomical cure rate of 82% with short-term follow-up and a mean of 12 months following surgery (116,117). Significant improvements also were seen in bowel symptoms. One author reported results on 205 of 236 subjects who underwent an abdominal sacral colpoperineopexy with polypropylene mesh (Marlex) without opening the vagina (118). This procedure included two straps of mesh attached from the lateral anterior vagina to Cooper’s ligament. Ten-year satisfaction rates were 68%, and erosion rates were 5%.

Laparoscopic Approach to Posterior Repair

Laparoscopic rectocele repair involves the dissection of the rectovaginal space to the
perineal body with either plication of levator fascia or suturing absorbable or permanent mesh in place (119,120). A few small case series have been reported with variable results.

### Abdominal Sacrocolpopexy

The standard approach to transabdominal apical vaginal suspension procedures is the abdominal sacrocolpopexy. A complete review of published data on these procedures developed by the Pelvic Floor Disorders Network, which is sponsored by the National Institute of Child Health and Human Development (NICHD), has been published (121). These procedures use graft material attached to the prolapsed region of the anterior and posterior vaginal walls at or encompassing the vaginal apex and suspended to the anterior longitudinal ligament of the sacrum. Cervical sacral suspensions may also be performed when uterine or cervical conservation is desired. Surgical variations abound and include configuration of the graft on the vagina, the extent to which the anterior and posterior vagina are attached to the graft, variable graft and suture materials, presence or absence of peritoneal closure over the graft, and obliteration of the cul-de-sac for treatment or prevention of the enterocele or sigmoidocele. **A thorough preoperative evaluation is important to exclude more distal defects or stress incontinence, which should be repaired concurrently, and other lower urinary tract or anorectal problems.** In published reports, cure rates for apical prolapse range from 78% to 100% (most greater than 90%); when cure is defined as no postoperative prolapse, the range widens from 56% to 100%, although subsequent anterior or posterior vaginal prolapse has not been as consistently reported as has apical prolapse (122–131). Potential advantages of this procedure over transvaginal procedures are less paravaginal scarring and denervation than may be present with transvaginal approaches, and fixation of the entire vaginal apical area by a permanent piece of material to a stable structure (the anterior sacral ligament), which may be more durable than the transvaginal techniques that use the patient’s own connective tissue.

Complications of these procedures include (i) erosions of graft material or suture material, which may be caused by graft or suture infection usually secondary to vaginal wall penetration, or performing the procedure adjacent to a vaginal incision, or securing the graft to an attenuated avascular wall with inadequate fibromuscular tissue (3.4%); (ii) significant intraoperative hemorrhage (especially in the presacral space) (4.8%); (iii) postoperative ileus, which may be secondary to the need for excessive packing of the bowel or to extensive Halban or Moschcowitz culdoplasty procedures (3.6%); (iv) small bowel obstruction, requiring reoperation (1.1%); (v) development of intra-abdominal adhesions with resultant pain and bowel dysfunction (unknown incidence); and (vi) wound complications, such as seromas and infections (4.6%) (120).

Several management techniques have been advocated to minimize these problems. Empiric ways to prevent graft erosions include (i) preoperative tissue optimization with vaginal administration of estrogen and treatment of vaginitis and infection of eroded...
areas; (ii) the use of small-gauge monofilament sutures placed in the fibromuscular tissue, thus avoiding full thickness passage; and (iii) excision of a portion of the vaginal apex when the vaginal wall is thin and depleted of its fibromuscular layer and vascularity. Graft attachment to “healthy” fibromuscular tissue rather than to thin avascular tissue should help prevent erosion. If such excision is necessary, or if the suspension is to be performed concurrently with a hysterectomy, good approximation of the fibromuscular layers above the mucosa, thorough irrigation, prophylactic use of antibiotics, and avoidance of graft placement across the suture line may decrease the likelihood of graft erosion. Choice of graft material may also be important. One would expect synthetic grafts to have greater durability than tissue grafts; however, erosion rates are more serious with the synthetic grafts. Anecdotally, some surgeons are convinced that less porous graft material, such as GORE-TEX, has a greater likelihood of becoming infected and eroding than do macroporous, filamentous polypropylene meshes. Numerous case series report serious episodes of hemorrhage from the presacral venous plexus (mean incidence 4.8%; range 0.18%–16.9% of sacrocolpopexies requiring, at a minimum, transfusion) (121). This problem is less likely if dissection and graft fixation is limited to the level of S1 and S2 just caudad to the promontory and with the use of good light and meticulous dissection techniques to expose the anterior sacral ligament.

Careful tissue handling and packing technique may minimize postoperative ileus and adhesions. Incorporation of the sigmoid into a closure of the cul-de-sac posterior to the graft may also slow bowel function postoperatively. Small bowel obstruction has resulted from direct adhesive processes involving grafts to small bowel (120). Complete extra peritonealization of the graft using flaps of peritoneum dissected from the prolapsed area and the peritoneum anterior to the sacral promontory and lateral to the right side of the sigmoid colon should prevent this complication. However, loops of bowel have been seen to prolapse through small defects in peritoneal closure with the same effect. Careful technique with adherence to basic surgical principles may help prevent this and other complications related to laparotomy.

**Laparoscopic and Robotic Techniques**

As with most pelvic operations, sacrocolpopexy has been successfully accomplished by the laparoscopic and robotic route and has the potential to offer patients the benefits of less postoperative discomfort and faster recovery as well as potential lower risks for adhesions and ileus. Outcomes depend on the expertise and experience of the surgeon; “cutting corners” to shorten the procedure could affect anatomical success. The applicability of the laparoscopic technique is limited by the need for a relatively high level of technical skill. In the authors' experience, ipsilateral suturing (through same sided ports) is preferred to contralateral suturing. The authors have also found that straight self-righting needle drivers and non-self-righting curved needle drivers are useful in attaching the mesh to the vagina. The Carter-Thompson suturing device is sometimes helpful to aid in elevating the sigmoid colon away from the
pelvic cul-de-sac by tagging the peritoneal edge. The robot has provided an easier platform for a minimally invasive approach to the sacrocolpopexy. Data about its use are limited to several case series that demonstrate comparable short-term results with open and laparoscopic techniques (121).

**For sacrocolpopexy, whether through laparotomy or laparoscopy, the pelvis should be completely exposed with the lower sigmoid colon stretched cephalad (Fig. 27.14).**

**Figure 27.14 Sacrocolpopexy.** A: Illustrates (i) graft attachment to the posterior area of prolapsed vagina to or below the rectal-sigmoid junction after the overlying peritoneum has been dissected and flapped laterally and (ii) exposure of the presacral space with suture placement through the anterior sacral ligament. An appropriately shaped second graft is placed anteriorly. B: Illustrates attachment of both grafts without tension to the sacrum. Prevention of subsequent enterocele and/or sigmoidocele is accomplished by box closure of the cul-de-sac peritoneum lateral to the left side of the sigmoid, attachment of the presigmoid fat to the graft centrally, and reperitonealization of the graft through the right side of the cul-de-sac. EEA, end-to-end anastomosis sizer. (Redrawn by J. Taylor.)
With a vaginal obturator (an EEA sizer) placed vaginally to visualize the area that is not covered by the bladder or rectum, the peritoneum is dissected from the underlying vaginal fibromuscular layer anteriorly to bladder reflection and posteriorly at least to the level of the sigmoid rectal junction, creating bilateral peritoneal flaps. Laterally, vascular bundles are visible.

Two separate loosely woven polypropylene mesh grafts are shaped similar to boat paddles. The “paddle” portions are shaped to cover the areas anterior to the apex and posterior to the apex, respectively, and the “handles,” which are approximately 8 to 10 cm in length and 1 cm wide, are anchored to the anterior sacral ligament. The paddle portions are secured circumferentially to the fibromuscular layers anteriorly and posteriorly with six to eight monofilament 3-0 nylon sutures and one or two sutures placed centrally (Fig. 27.14 A).

When the fibromuscular tissue in the area is attenuated, a portion of the vaginal wall is excised and closed, as noted previously.

The peritoneum overlying sacral vertebrae 1 and 2 is incised while retracting the sigmoid colon to the left, and careful dissection is employed down to the anterior ligament. Care is taken to stay well medial to the right ureter and hypogastric vessels.

Hemoclips are placed caudad and cephalad on the middle sacral vessels if it is felt that this will allow more optimal suture placement. The peritoneal incision is extended into the right cul-de-sac area adjacent to the sigmoid.

Closure of the cul-de-sac lateral to the sigmoid on the left and approximation of the distal presigmoid fat to the distal edge of the posterior graft is accomplished with box
stitches of 0-delayed absorbable sutures. It is thought that these procedures and the retroperitonealization of the graft through the right side of the cul-de-sac will prevent posterior enterocoele and sigmoidocele as well as a Halban or Moschcowitz procedure. The two “handle” ends of the graft are then brought to the point of sacral attachment, where their length is adjusted to remove any tension on the vaginal sutures and secured to the anterior sacral ligament with no. 1 permanent braided nylon sutures (Fig. 27.14B). Reperitonealization of the graft is then performed using the right cul-de-sac peritoneum and peritoneal flaps dissected from the vaginal apical area; occasionally presigmoid fat is used.

Following this procedure, adjunctive procedures, such as paravaginal repair, Burch procedure, midurethral sling, and any transvaginal procedure that is indicated, are performed. When rectocele and pelvic floor defects are present, one option is the sacral colpoperineopexy, as discussed in the posterior compartment section (116). A vaginal pack is inserted for approximately 24 hours to ensure that the graft is well applied to the fibromuscular layer at points other than where sutures are placed.
Vaginal Obliterative Procedures

Colpocleisis or vaginal narrowing procedures may be appropriate choices for debilitated patients who do not desire vaginal function, because complete vaginal reconstructive procedures may last several hours and are associated with potentially higher blood loss and increased morbidity (132,133). Many variations exist, from partial colpocleisis (where some portion of the vaginal epithelium is left to provide drainage tracts for cervical or upper genital discharge) to total colpectomy (where all of the vaginal epithelium is removed from the hymen posteriorly to within 0.5–2 cm of the external urethral meatus anteriorly). If hysterectomy is performed, blood loss is greater and operative time is longer than procedures without hysterectomy (134). These techniques should include a high perineorrhaphy and often a plication of the puborectalis muscles to reinforce posterior support and to reduce the genital hiatus, with the goal of decreasing the chance of recurrent prolapse. Case series have reported success rates as high as 100%, although the population of patients, by nature of their relatively short life expectancy and limited activity, are probably at lower risk for recurrence. In some instances in which most of the defects are anterior and posterior, a modified anterior and posterior colporrhaphy may be performed, whereby relatively large portions of the anterior and posterior vaginal wall are removed and closed, creating a narrow (1–2 cm diameter) cylindrical vagina. As with the colpocleisis, the success of the procedure is augmented by an extensive perineorrhaphy and puborectalis plication. Such a procedure may be performed quickly and with relatively low morbidity. The prevention or treatment of stress incontinence, voiding dysfunction, and colorectal dysfunction in the context of these procedures can be problematic. Careful preoperative history and evaluation, if indicated, is important so that additional conservative therapies or operative techniques such as pubourethral plications or less invasive tension-free slings may be employed.

Management of Urinary Symptoms with Pelvic Organ Prolapse Repair

All women who are undergoing surgery for repair of pelvic organ prolapse should be evaluated for urinary incontinence. Women who report stress urinary incontinence and who demonstrate it on preoperative examination and have no contraindications to a continence procedure should have concomitant procedures for the treatment of these symptoms. Women who do not report stress urinary incontinence may also benefit from a prophylactic procedure if they demonstrate incontinence with reduction of their prolapse. There is also evidence that the addition of a continence procedure in the absence of any evidence of urinary incontinence may improve outcomes without significantly increasing the number of complications (135). The addition of continence procedures to prolapse procedures in patients who have both significant stress incontinence and voiding dysfunction remains controversial.
Comparison of Abdominal versus Vaginal Approaches

In recent years there has been controversy as to whether transvaginal or transabdominal procedures are best for prolapse. One cannot discern which is optimal from reports of retrospective and prospective case series because of the considerable differences in numerous factors, including follow-up, characteristics of the subjects, definitions of success and failure, and the expertise or experience of the surgeons performing the procedures. Three prospective randomized trials have compared sacrocolpopexy and sacrospinous suspension procedures (136–138). All three trials showed some increased durability in the sacrocolpopexy group; however, in one of these studies the differences were not statistically significant (138). In the study in which sexual function was examined, there was a greater incidence of dyspareunia in the transvaginal group (137). Most case series reveal that the incidence of serious complications, such as small bowel obstructions, significant hemorrhage, presacral graft infections, pulmonary embolus, and short-term problems (i.e., ileus, hernias, wound seromas or infections, and longer hospitalizations), are more likely to occur in the group undergoing sacrocolpopexy. Vaginal scarring, strictures, and vaginal wall erosions or granulation tissue appear more likely in the group undergoing transvaginal surgery. To date, there is no randomized comparison of vaginal procedures using high uterosacral suspensions and innovative repairs of the fibromuscular tissues, which are less likely to produce strictures than was the case 10 or more years ago.

Most pelvic surgeons would agree that (i) older, less healthy individuals who are more likely to have surgical and medical complications and cannot or will not tolerate a pessary would derive greater benefit from transvaginal approaches and occasionally oblitative approaches, and (ii) relatively healthy, sexually active women with relatively short vaginas and apical prolapse or with isolated apical defects would derive greater benefit from sacrocolpopexy. For the remainder of the patients with apical prolapse, with or without more distal defects, it would be ideal if surgeons were equally skilled, knowledgeable, and experienced in both abdominal and vaginal approaches to provide care that is truly individualized, rather than emphasizing one approach to the exclusion of another.

Noblett K, Lane FL, Driskill CS. Does pelvic organ prolapse quantification exam predict urethral mobility in stages 0

Defecatory dysfunction and fecal incontinence are common conditions for women that have tremendous psychosocial and economic implications. The differential diagnosis for anorectal dysfunction is broad and can be classified into systemic factors, anatomic and structural abnormalities, and functional disorders.

A thorough history and physical examination are critical for the evaluation of fecal incontinence and defecatory dysfunction, as well as appropriate ancillary testing.

Treatment of anorectal dysfunction should focus on treatment of the underlying condition, with nonsurgical management attempted before surgery. Overlapping sphincteroplasty is the procedure of choice for fecal incontinence caused by a disrupted anal sphincter.

Anorectal dysfunction encompasses a variety of conditions that disrupt normal anorectal function. Such conditions can be subdivided as those that cause defecatory dysfunction and fecal incontinence. Although anorectal dysfunction transcends any individual medical specialty, the pathophysiology, evaluation, and management of conditions relevant to obstetricians/gynecologists are presented in this chapter.
Normal Colorectal Function

Anal continence and defecation are complex physiologic processes that require intact and coordinated neurologic and anatomic function, including colonic absorption and motility, rectal compliance, anorectal sensation, and the multifaceted continence mechanism. An understanding of normal physiology and pathophysiology is essential to the treatment of women with anorectal dysfunction.
Stool Formation and Colonic Transit
The colon plays an important role in absorption and regulation of water and electrolytes. **As much as 5 L of water and associated electrolytes can be absorbed in one day.** Parasympathetic-mediated peristaltic contraction of colonic smooth muscle transfers fecal material to the rectum. A delay in stool transit at the rectosigmoid region of the colon allows for maximal absorption of water and sodium.
Storage
As stool accumulates in the rectosigmoid, rectal distention triggers a transient decrease in the internal anal sphincter (IAS) tone and an increase in the external anal sphincter (EAS) tone, known as the rectoanal inhibitory reflex. Exposure of the anal canal to fecal matter facilitates sampling, whereby the anal canal and its abundant sensory nerves determine stool consistency (i.e., solid, liquid, or gas). Accommodation occurs as the normally compliant rectal vault relaxes in response to increased volume. This cycle, combined with increased rectal distention, stimulates an urge to defecate. This urge can be voluntarily suppressed through cortical control, resulting in further accommodation and activation of the continence mechanism.
Continence Mechanism

Muscles

The key muscles of the continence mechanism are the puborectalis, IAS, and EAS. The puborectalis muscle originates from the pubic rami at the level of the arcus tendineus levator ani and passes laterally to the vagina and rectum in a U-shaped configuration, creating a sling around the genital hiatus. Contraction of the puborectalis muscle narrows the genital hiatus, developing the near 90-degree anorectal angle. The resting tone of the puborectalis muscle serves as the primary continence mechanism for solid stool. The IAS and EAS are essential for continence of flatus and liquid stool. The internal sphincter maintains most of the resting tone for the sphincter complex through autonomic reflex arcs and is essential for passive continence. Although the external sphincter also maintains constant resting tone, it is ultimately responsible for preventing fecal urgency and stress incontinence associated with sudden increases in intra-abdominal pressure. This function is under both voluntary and involuntary control. The anal cushions act as the final anatomic barrier. They fill with blood, causing occlusion of the anal canal.

Nerves

Many pathologic states disrupt normal function through denervation. The IAS receives its sympathetic supply from L5, which passes through the pelvic plexus via the hypogastric plexus. The parasympathetic supply from S2–4 synapses at the pelvic plexus, where it joins the sympathetic nerves. In addition to the parasympathetic and sympathetic components, the autonomic nervous system of the gut has an enteric nervous system (ENS). The ENS provides local circuitry that can contract or relax the gut muscles, as well as impact absorption and secretion. The autonomic ganglia of the ENS, located in the gut, are interconnected to provide local integration and processing of information. The IAS acts through reflex arcs at the spinal cord without voluntary control. The puborectalis (levator ani) is innervated by branches of the S2–4 sacral roots and does not receive direct innervation from the pudendal nerve (1). The EAS is innervated bilaterally by the pudendal nerve (S2–4) via Alcock’s canal. The pudendal nerve fibers cross over at the level of the spinal cord, allowing preservation of EAS function in the event of unilateral damage. The rich sensory supply from the anal canal travels along the inferior rectal branch of the pudendal nerve.
Evacuation

Initiation of defecation is normally under cortical control. As previously discussed, delivery of stool to the rectum stimulates the rectoanal inhibitory reflex, permitting sampling followed by accommodation. Further rectal distention results in an urge to defecate. Evacuation occurs with voluntary relaxation of the pelvic floor muscles (puborectalis muscle and EAS) in conjunction with increased intra-abdominal and intrarectal pressure from Valsalva. This results in widening of the anorectal angle and shortening of the anal canal, which facilitates emptying. Coordinated peristaltic activity of the rectosigmoid assists evacuation. After this process is complete, the closing reflex is initiated, resulting in contraction of the pelvic floor muscles and activation of the continence mechanism.
Epidemiology
The epidemiology of anorectal dysfunction has been best defined in terms of the incidence and prevalence of fecal incontinence. Few studies have been done to assess the incidence and prevalence of defecatory dysfunction.
Defecatory Dysfunction

The term defecatory dysfunction often is used synonymously with the symptom of constipation. **Constipation is an imprecise term used by patients to report a variety of symptoms, including infrequent stools, dyschezia, straining, variation in stool consistency and caliber, incomplete emptying, bloating, and abdominal pain. The most common symptoms associated with constipation are straining and hard stools** (2,3). **Defecatory dysfunction is defined by many physicians as infrequent stools, typically fewer than three bowel movements per week.** This definition is based on stool frequency studies in which 95% of women have more than three bowel movements per week. Using this definition, the prevalence of constipation should be 5% (4). However, the prevalence of constipation has been estimated to range from 2% to 28%, depending on the definition applied (5–7).

**There is an increased prevalence of constipation among women and elderly individuals, nonwhite individuals, and those with low income and low education levels** (5–7). Based on an estimated 2.5 million visits to US physicians per year for constipation, with an average cost of $2,752 per patient, the annual cost for evaluation of constipation would be approximately $6.9 billion (8,9). An estimated 85% of physician visits results in a prescription; including drug costs would increase this amount substantially (8). More recently, evaluation of 76,854 California Medicaid patients without supplemental insurance found somewhat lower annual total direct costs to care for constipation at almost $19 million ($246 per patient) for this subset of the US population (10). Constipation has a detrimental effect on health-related quality of life (3,10). Constipation contributed to decreased mental and physical scores for quality of life on the SF-36 Health Survey in a Canadian-based population (11).
Fecal Incontinence

The reported prevalence of fecal incontinence varies between 2% and 3% for community-dwelling individuals, 3% to 17% for those of increased age, and 46% to 54% for nursing home residents (12). A prevalence of 28% has been reported among patients seeking benign gynecologic care and 36% of primary care patients surveyed (13,14). The prevalence of fecal incontinence in the United States is expected to increase 59% from 10.6 million in 2010 to 16.8 million in 2050 as the population ages (15). Epidemiologic studies of fecal incontinence are compromised by social stigmata and the lack of a uniform definition. Definitions of fecal incontinence vary with respect to the type of material passed (solid, liquid, or gas), the frequency and duration of events (once in a lifetime to twice a week), and the impact on quality of life. Most authors agree that the true prevalence of this condition is underestimated in the current scientific literature. A large health survey in the United States found age, female gender, physical limitations, and poor general health to be independent risk factors associated with fecal incontinence (16).

Fecal incontinence has tremendous psychosocial and economic implications for individuals and society as a whole. The loss of such a basic function can be emotionally devastating, leading to poor self-esteem, depression, social isolation, and decreased quality of life (13,14,17). Fecal incontinence is the second leading reason for nursing home placement in the United States, even though less than one-third of individuals with this condition seek medical attention (13,17). The overall annual cost to treat fecal incontinence is difficult to pinpoint, but accounts for more than $400 million per year in the cost of adult incontinence products alone (17).
Symptom-Based Approach to Colorectal Disorders

Several medical conditions cause defecatory dysfunction, fecal incontinence, or combined symptoms. Following is the differential diagnosis—a proposed classification system based on systemic factors, anatomic and structural abnormalities, and functional disorders.
Differential Diagnosis

Disordered Defecation

Causes of defecatory dysfunction have traditionally been divided into systemic disorders and idiopathic constipation (all nonsystemic causes). Idiopathic constipation can be subdivided into anatomic and structural abnormalities and functional disorders (Table 28.1).

Anismus/rectosphincteric dyssynergia

- Intussusception, rectal prolapse
- Volvulus
- Neoplasia
- Benign strictures
- Hemorrhoids

Anal Sphincter Disruption/Fistula

- Obstetrical trauma
- Surgical trauma
- Anal intercourse
- Injury (trauma, radiation proctitis)

**Functional**

Motility Disorders

- Global motility disorder
- Colonic inertia/slow-transit constipation
- Irritable bowel syndrome
- Functional constipation
- Functional diarrhea

Functional Limitations

- Decreased mobility
- Decreased cognition

Diabetes, hypothyroidism, and pregnancy are the most common endocrinologic systemic factors that cause constipation, and all have a component of decreased gastrointestinal motility and intestinal transit. In one study, gastrointestinal symptoms were present in 76% of patients with diabetes, including constipation, which occurred in 60% \(^{18}\). In patients with diabetes, constipation is believed to be secondary to intestinal autonomic neuropathy, resulting in delayed or absent gastrocolic reflex and decreased bowel motility. This enteric neuropathy may also cause gastroparesis and diarrhea. Although diabetes has been classified with the endocrinologic causes, it should also be grouped with the enteric neuropathies. Pregnancy is not considered a disease state; however, there is an 11% to 38% prevalence of constipation that is believed to result from the effect of progesterone on smooth muscle \(^{19,20}\). Iron supplements and prior constipation treatment are also associated with constipation during pregnancy \(^{20}\).

The neurologic systemic factors can be divided into central and peripheral processes. Spinal cord lesions, multiple sclerosis, and Parkinson disease affect the autonomic nervous system. Trauma to the sacral nerves often leads to severe constipation from decreased left-sided colonic motility, decreased rectal tone and sensation, and increased distention. These findings are also seen in patients with
Meningomyelocele, damage to the lumbosacral spine, and pelvic floor trauma (21, 22). Higher spinal cord lesions result in delayed sigmoid transit and decreased rectal compliance. In these upper motor neuron lesions, colonic reflexes are intact, and defecation can be initiated by digital stimulation of the anal canal (23, 24). Individuals with multiple sclerosis can have no gastrocolic reflex, decreased colonic motility, decreased rectal compliance, and even rectosphincteric dyssynergia (25, 26). Constipation worsens with the duration of illness and may be compounded by the side effects of medical therapy. Similar findings of rectosphincteric dyssynergia and medication side effects are present with Parkinson disease.

Among the peripheral neurogenic disorders, dysfunction occurs at the level of the ENS. The ultimate example of this is congenital aganglionosis (Hirschsprung disease). The absence of intramural ganglion cells in the submucosal and myenteric plexuses of the rectum causes loss of the rectosphincteric inhibitory reflex. Patients with this illness usually present with functional obstruction and proximal colonic dilation. In most patients, the condition is diagnosed within 6 months of age, although milder cases can be seen later in life.

Other systemic factors to consider are collagen vascular and muscle disorders. Importantly, some of the most commonly used prescription and over-the-counter medications, including aluminum antacids, beta-blockers, calcium channel blockers, anticholinergics, antidepressants, and opiates, cause defecatory dysfunction (Table 28.2). Lifestyle issues, such as inadequate fiber intake and insufficient fluid intake, can exert similar effects independently or in conjunction with other disorders.

</table>
Structural abnormalities refer to the obstructive disorders, such as pelvic organ prolapse, perineal descent, intussusception, rectal prolapse, and tumors. Functional disorders are those that do not have an identifiable anatomic or systemic etiology. Most functional disorders are motility disorders, such as slow-transit constipation or colonic inertia, irritable bowel syndrome (constipation predominant), and functional constipation. The Rome III criteria created strict definitions for these idiopathic conditions that are believed to result from the complex interaction of psychosocial factors and altered gut physiology via the gut-brain-gut axis (27). Patients also may have functional limitations, such as decreased mobility and cognition. It is important to understand that this classification system is somewhat arbitrary, and several of these conditions are interrelated.

Fecal Incontinence

Anal continence depends on a complex interaction of cognitive, anatomic, neurologic, and physiologic mechanisms. The continence mechanism can often compensate for a deficiency in one of these processes, but it can be overwhelmed with increased severity or decreased function over time. Systemic etiologies of fecal incontinence often are due to disease states that cause diarrhea. The rapid transport of large volumes of liquid stool to the rectum can produce urgency and incontinence even in healthy individuals (28). Fecal incontinence frequently results from infectious diarrhea caused by bacteria (e.g., Clostridium, Escherichia coli, Salmonella, Shigella, Yersinia, Campylobacter), viruses (e.g., Rotavirus, Norwalk, HIV), and parasites (e.g., Entamoeba, Giardia, Cryptosporidium, Ascaris). Numerous medications and dietary items cause diarrhea and fecal incontinence (Table 28.3). Endocrine factors that can lead to fecal incontinence include diabetes mellitus and hyperthyroidism. With diabetes, diarrhea can develop from autonomic dysfunction, bacterial overgrowth, osmotic diarrhea with sugar substitutes, and pancreatic insufficiency. Inflammatory bowel disease is considered an idiopathic or autoimmune systemic factor. Ulcerative colitis and Crohn disease cause fecal incontinence during exacerbations with bouts of bloody diarrhea. Inflammatory bowel disease can also result in structural abnormalities, such as anal fissures, fistulas, abscesses, and operative complications that lead to fecal incontinence.

As with defecatory dysfunction, neurologic causes of fecal incontinence can be divided into central and peripheral disorders. Among the central nervous system disorders, upper motor neuron lesions above the level of the defecation center (located in the sacral cord) cause spastic bowel dysfunction. Cortical communication is disrupted, resulting in impaired cognitive control and sensory deficit. The anal sphincter is under spastic contraction, but digital stimulation can be performed to initiate reflex evacuation. Head trauma, neoplasms, and cerebral vascular accidents that damage portions of the frontal lobe result in loss of control of both micturition and defecation. Greater loss of inhibition is present when the lesion is located more anteriorly in the frontal lobe. Spinal cord trauma and lower motor neuron lesions above the defecation center tend to cause permanent loss of cortical control. For 2 to 4 weeks following spinal cord injury, “spinal shock” occurs, resulting in a temporary loss of reflexes below the level of the lesion, flaccid bowel function, constipation, and fecal impaction. After the initial shock, spastic paralysis ensues with hyperactive bowel function. The gastrocolic reflex, along with digital stimulation, initiates reflex evacuation in the absence of cortical inhibition. Fortunately, IAS tone is maintained despite the loss of EAS control for stress and urge situations. Both constipation and fecal incontinence can occur in these patients.

The demyelination that is seen in multiple sclerosis is randomly distributed and can occur at any level in the central nervous system. In addition to the somatic disruption that is similar to spinal cord injury, autonomic dysfunction frequently is present. People with dementia and other degenerative disorders that cause cognitive impairment frequently have fecal incontinence caused by overflow incontinence. Although sensory nerves are functioning properly, these individuals lack the cognitive awareness necessary to inhibit defecation until a socially acceptable time, and they develop overflow incontinence.

Lower motor neuron lesions occurring at or below the level of the defecation center in the sacral cord cause flaccid bowel dysfunction. Cortical communication is disrupted, resulting in impaired cognitive control and sensory deficit. The bowel reflexes, including the bulbocavernosus and anal reflexes, are interrupted. The anal sphincter is flaccid, and fecal retention with overflow incontinence usually occurs. Digital disimpaction and Valsalva often are required for evacuation. Digital stimulation has no effect, and medications tend to work poorly. Examples of motor neuron lesions include tumor or trauma to the cauda equina, tabes dorsalis, spina bifida, and peripheral
neuropathy.

The classic example of peripheral neuropathy is congenital aganglionosis (Hirschsprung disease), which was discussed earlier. The most common peripheral neuropathy occurs with diabetes. **Approximately 20% of individuals with diabetes have fecal incontinence** (29). The cause tends to be multifactorial with the exact mechanism uncertain. Fecal incontinence can occur with diabetic diarrhea or years later from progressive disease. Individuals with diabetes frequently experience intestinal autonomic neuropathy, an abnormal gastrocolic reflex, and chronic constipation. The subsequent pelvic floor denervation causes fecal incontinence by sensory neuropathy, failure of the rectoanal inhibitory reflex, and sphincter dysfunction (30). Consequently, fecal incontinence from peripheral neuropathy can be the result of defective sampling, a disrupted rectoanal inhibitory reflex, or pudendal neuropathy with sphincter dysfunction. Patients may experience stress or urge incontinence as well as overflow incontinence.

**Anatomic and structural causes of fecal incontinence are usually due to obstetric or surgical trauma.** Damage or dysfunction of the IAS, EAS, and puborectalis can result in varying degrees of fecal incontinence. Those with impaired resting tone from a defective IAS will have passive incontinence (incontinence at rest), which is worse during sleep because of decreased EAS activity (31). An inability to respond to sudden distention and to suppress defecation is often seen with external sphincter dysfunction. External and internal sphincter dysfunction often causes incontinence of liquid stool. Incontinence of solid stool is usually seen with widening of the anorectal angle from damage to the puborectalis muscles. Damage to the anal cushions usually causes minor soiling. Other anatomic and structural abnormalities associated with fecal incontinence include obstructive disorders such as pelvic organ prolapse, descending perineum syndrome, anismus, and intussusception; fistulas from diverticulitis, inflammatory bowel disease, cancer, or surgical trauma; and decreased rectal compliance from inflammatory bowel disease, cancer, and radiation. Decreased compliance results in higher intraluminal pressures with smaller volumes of stool, poor storage capacity, urgency, and incontinence (32).

**Functional disorders associated with fecal incontinence include irritable bowel syndrome (diarrhea variant), functional diarrhea, decreased mobility, and decreased cognition.**

**Combined Disorders of Defecation and Fecal Incontinence**

Several conditions have the potential to cause both defecatory dysfunction and fecal incontinence (Table 28.1). Most of these disorders cause combined symptoms through the development of fecal impaction followed by overflow incontinence. This situation can be seen with many of the neurologic conditions, pelvic outlet obstructive disorders, functional disorders of irritable bowel syndrome, decreased mobility, and decreased cognition. The cause of these symptoms is often multifactorial.
Disordered Defecation

Disordered defecation can result from outlet obstruction or functional motility disorders.

Outlet Obstruction

Anismus/Rectosphincteric Dyssynergia

Anismus is otherwise known as rectosphincteric dyssynergia, pelvic floor dyssynergia, spastic floor syndrome, and paradoxical puborectalis syndrome. The anorectal angle narrows as a result of paradoxical contraction of the puborectalis and external anal sphincter during defecation. Frequent symptoms include dyschezia, straining, hard stools, incomplete emptying, and tenesmus. A recent prospective study of 120 patients with dyssynergic defecation found a higher prevalence in women (77%) (33,34). The need for digital assistance (digital disimpaction or splinting) to evacuate the rectum occurs in up to 58% of patients. **Psychosocial factors, such as a history of sexual abuse, depression, eating disorder, obsessive-compulsive disorder, and stress, may play an important role in this disease.** In this study, 22% reported a history of sexual abuse, and 31% reported a history of physical abuse. One-third believed the problem began during childhood, and 24% reported a precipitating illness or surgery was related to a particular event. Five percent of women claimed that pregnancy or childbirth was a precipitating factor. This condition also is seen in young children with constipation and dyschezia. The response to biofeedback and pelvic floor physical therapy, as well as the aforementioned patient characteristics, indicate a learned response mechanism is involved (33,34). Although this is often categorized as an outlet obstruction, the Rome III criteria for functional gastrointestinal disorders places this in the category of functional defecation disorders. The specific Rome III diagnostic criteria for dyssynergic defecation includes “inappropriate contraction of the pelvic floor or less than 20% relaxation of basal resting sphincter pressure with adequate propulsive forces during attempted defecation” (35).

Pelvic Organ Prolapse

Pelvic organ prolapse bears special mention because it is often seen by gynecologists but inconsistently associated with defecatory dysfunction. Prolapse is very common, although many women with this condition are asymptomatic. Those with symptoms may report incomplete evacuation and the need to apply digital pressure to the posterior vaginal wall or perineum to aid in evacuation of stool (digitation or splinting). It is important to rule out other causes of constipation, because these symptoms are nonspecific, and rectocele can result from chronic straining and increased intra-abdominal pressure due to other etiologies of defecatory dysfunction. **Defecatory dysfunction related to pelvic organ prolapse can result from rectocele, enterocoele, or perineal descent, either individually or in**
Rectocele is a herniation of the rectal mucosa through a defect in the rectovaginal septum. These site-specific defects can be transverse or longitudinal through the inferior, middle, or superior regions of the rectovaginal septum (36). Enterocele is a herniation of a peritoneal sac and bowel through the pelvic floor, typically between the uterus or vaginal cuff and rectum. It is more common following hysterectomy and retropubic urethropexy. There are two theories surrounding the formation of an enterocele. The first theory implicates a defect in the fibromuscular endopelvic fascia of the vagina, allowing peritoneum and bowel to herniate. The second theory attributes its formation to a support defect with full thickness protrusion, including endopelvic fascia (37). Ultimately, the mechanism might be attributed to a combination of the two theories because some support defects are secondary to superior breaks in the rectovaginal and pubocervical fascia. Patients with rectocele and enterocele may have similar symptoms, including pelvic pressure, vaginal protrusion, obstipation, fecal incontinence, and sexual dysfunction. Although associations have been made between defecatory dysfunction and advanced stages of pelvic organ prolapse, a causal relationship remains to be established. Controversy remains as to whether anatomic herniation is the cause of these symptoms or the effect of underlying colonic dysfunction, chronic constipation, and straining.

Descending perineum syndrome is defined as descent of the perineum (at the level of the anal verge) beyond the ischial tuberosities during Valsalva. Excessive perineal descent was first described in the colorectal literature by Parks et al. in 1966 (38,39). It occurs as a result of inferior detachment of the rectovaginal septum from the perineal body. As the condition progresses, the patient can develop pudendal neuropathy from stretch injury. Perineal descent has been associated with a variety of defecatory disorders, including constipation, fecal incontinence, rectal pain, solitary rectal ulcer syndrome, rectocele, and enterocele (40).

Rectal Intussusception

Rectal intussusception or intrarectal prolapse is the circumferential prolapse of the upper rectal wall into the rectal ampulla but not through the anal verge. It occurs most often in women in their fourth and fifth decades. The most common symptoms are obstructive, including incomplete emptying, manual disimpaction, splinting, pain with defecation, and bleeding. Other symptoms include fecal incontinence, decreased urge to defecate, inability to distinguish between gas and feces, and mucus discharge with pruritus ani. Bleeding often originates from a solitary rectal ulcer or localized proctitis of the involved bowel segment (41). Intussusception is seen in as many as one-third of women with defecatory dysfunction and other symptoms, such as constipation, rectal pain, and fecal incontinence (42). It has also been seen in 29% of asymptomatic patients (43). The intussusception rarely develops into total rectal prolapse (44).
Irritable bowel syndrome (IBS) has been estimated to have a prevalence of 10% to 20% and is more common in women and younger individuals. It accounts for 25% to 50% of all referrals to gastrointestinal clinics. Irritable bowel syndrome has distinct diagnostic criteria, including the exclusion of structural or metabolic abnormalities. These patients often have other gastrointestinal, genitourinary, and psychological illness, including gastroesophageal reflux disease, fibromyalgia, headache, backache, chronic pelvic pain, sexual dysfunction, lower urinary tract dysfunction, depression, and anxiety. Stressful life events seem to correlate with the onset and exacerbation of symptoms. A detailed history frequently reveals past physical or sexual abuse. Currently, specific criteria allow for classification of IBS into diarrhea-, constipation-, and pain-predominant categories (Table 28.4). The constipation variant is most commonly associated with defecatory dysfunction, whereas the diarrhea variant causes fecal incontinence. The pain or spastic variant causes predominantly abdominal discomfort but can also be associated with both defecatory dysfunction and fecal incontinence. After excluding organic disease, the criteria listed in Table 28.4 have a sensitivity of 65%, specificity of 100%, positive predictive value of 100%, and negative predictive value of 76%.

aCriterion fulfilled for the last 3 months with symptom onset at least 6 months prior to diagnosis.

b“Discomfort” means an uncomfortable sensation not described as pain.

In pathophysiology research and clinical trials, a pain/discomfort frequency of at least 2 days a week during the screening evaluation is recommended for subject eligibility.

Functional constipation is a term created by the Rome II criteria as a unifying definition of constipation (Table 28.5). The rationale for the criteria listed in Table 28.5 stems from the variability in patient definitions of constipation (46).

**Table 28.5 Functional Constipation**

**Diagnostic Criteria**

- Must include two or more of the following:
  - Straining during at least 25% of defecations
  - Lumpy or hard stools in at least 25% of defecations
  - Sensation of incomplete evacuation for at least 25% of defecations
  - Sensation of anorectal obstruction/blockage for at least 25% of defecations
  - Manual maneuvers to facilitate at least 25% of defecations (e.g., digital evacuation, support of the pelvic floor)
  - Fewer than three defecations per week
  - Loose stools are rarely present without the use of laxatives, and there are insufficient criteria for IBS.
  - Insufficient criteria for irritable bowel syndrome

- Criteria fulfilled for the last 3 months with symptom onset at least 6 months prior to diagnosis

**Functional Defecation Disorders**

Functional defecation disorders are divided into dyssynergic defecation and inadequate defecatory propulsion (colonic inertia). (For the purposes of this chapter, dyssynergic defecation has been included in the structural category of outlet obstruction; however, it is important to recognize that Rome III considers it a functional disorder.) Both of the functional defecation disorders require the presence of functional constipation. Table 28.6 lists the criteria for diagnosing these conditions.

**Table 28.6 Functional Defecation Disorders**

**Diagnostic Criteria**

- The patient must satisfy diagnostic criteria for functional constipation (Table 28.5)
- During repeated attempts to defecate must have at least two of the following:
Evidence of impaired evacuation, based on balloon expulsion test or imaging
Inappropriate contraction of the pelvic floor muscles (i.e., anal sphincter or puborectalis) or less than 20% relaxation of basal resting sphincter pressure by manometry, imaging, or EMG
Inadequate propulsive forces assessed by manometry or imaging

Criteria fulfilled for the last 3 months with symptom onset at least 6 months prior to diagnosis

Colonic Inertia/Slow-Transit Constipation
Severe constipation, defined as fewer than three stools per week and refractory to therapy, is relatively rare; however, these patients frequently suffer from motility disorders such as global motility disorder and colonic inertia. Women are more likely to be affected than men. Colonic inertia or slow-transit constipation is defined as the delayed passage of radiopaque markers through the proximal colon without retropulsion of markers from the left colon and in the absence of systemic or obstructive disorders. The cause remains unclear. Patients with this disorder have impaired phasic colonic motor activity and diminished gastrocolic reflexes (48,49). Studies on the role of laxatives, absorption, hormones, psychological abnormalities, and endogenous opioids have been inconclusive. Current literature suggests a possible neurologic or smooth muscle disorder (49,50).

Fecal Incontinence

Sphincter Disruption
In young women, obstetric injury is the most common cause of fecal incontinence. The mechanism of injury can be from anatomic disruption of the anal sphincter complex, pelvic floor denervation, or a combination of the two conditions. The risk factors for anal sphincter laceration are primiparity, high birth weight, forceps delivery, and episiotomy (51–53). Recent work suggests that women with anal sphincter injuries have slower labor, without the normal deceleration phase, and with late descent of the fetal head (54). Although there are limited long-term prospective studies demonstrating the natural history of anal sphincter injury, pelvic floor neuropathy, and the progression of these conditions to fecal incontinence, current literature supports the relationship of early-onset symptoms to sphincter damage and delayed-onset symptoms to neuropathy (55). This relationship would account for the large discrepancy in the prevalence of fecal incontinence between younger men and women that decreases as the population ages (56).
Obstetric Trauma

Third- and fourth-degree lacerations at delivery are associated with an increased risk of fecal incontinence (odds ratio [OR] 3.09) \(^\text{[MB2]}\) \(^{[55]}\). Whereas the incidence of clinically documented third- and fourth-degree anal sphincter tears is between 0.5% and 5.9% \(^{[51,53,57]}\), occult third- and fourth-degree defects are present in 28% to 35% of primiparous women and 44% of multiparous women, and approximately one-third of these patients have symptoms of anal incontinence. Patients with occult anal sphincter tears are 8.8 times more likely to have fecal incontinence \(^{[53,58]}\). Forceps-assisted vaginal delivery significantly increases this risk, but the data on vacuum-assisted delivery are less conclusive \(^{[52,59,60]}\). Elective cesarean delivery, in contrast with emergency cesarean delivery, was believed to prevent anal incontinence, but recent studies argue against any protective effect with cesarean delivery, irrespective of timing \(^{[46,51,53,59,61,62]}\). A recent Cochrane review concludes that there is insufficient evidence to support primary elective cesarean delivery for the purpose of preserving fecal continence \(^{[63]}\). Midline episiotomy is strongly linked to sphincter damage and fecal incontinence \(^{[52,64]}\). One study of a large population found conflicting results, with an overall protective effect seen with episiotomy (OR 0.89). The likelihood of fourth-degree laceration was increased (OR 1.12) and of third-degree laceration was decreased (OR 0.81) \(^{[51]}\). A Cochrane review supports the restrictive use of both midline and mediolateral episiotomy due to less posterior perineal trauma, less suturing, and fewer healing complications. There were no differences in severe trauma, pain, dyspareunia, or urinary incontinence, but there was an increase in anterior perineal trauma with restrictive use \(^{[65]}\). An important finding in another study was that one-half of patients who underwent immediate repair of a third-degree laceration had symptoms of anal incontinence, and 85% had persistent sphincter defects on endoanal ultrasonography \(^{[66]}\).

Surgical Trauma

Iatrogenic injury follows obstetric trauma as the second most common cause of direct sphincter damage. Surgical procedures that have been associated with fecal incontinence include anal fistula repair, anal sphincterotomy, hemorrhoidectomy, and anal dilation. Fistulotomy is the most common procedure that results in fecal incontinence. Rectovaginal or anovaginal fistulas can develop after obstetric injury, operative complications during pelvic surgery, and inflammatory bowel disease exacerbations. Fistulas cause fecal incontinence, and the degree of postoperative dysfunction depends on the location of the fistula and the amount of sphincter that is disrupted during the surgical repair. It also depends on the preoperative level of sphincter function and pudendal nerve function. Anal sphincterotomy to treat painful anal fissures can lead to incontinence by disruption of rectal sensory innervation and anal cushions and transection of the anal sphincter \(^{[67,68]}\). Hemorrhoidectomy often results in minor soiling as a result of resection of the anal cushions, which act as the final mucosal barrier. Similar to sphincterotomy, rectal sensory innervation can be disrupted, and injury to the
The internal sphincter can occur during sharp dissection (68,69).

Sphincter Denervation

**Idiopathic (primary neurogenic) fecal incontinence results from denervation of both the anal sphincter and pelvic floor muscles.** Denervation injury related to obstetric trauma accounts for approximately three of four cases of idiopathic fecal incontinence and is the most common overall cause of fecal incontinence (70,71).

**Obstetric Trauma**

The two proposed mechanisms of pudendal neuropathy are stretch injury during the second stage of labor and compression of the nerve as it exits Alcock’s canal (70). **Established risk factors for pelvic floor neuropathy include multiparity, high birth weight, forceps delivery, prolonged active second stage, and third-degree laceration** (72,73). Several studies have shown increased pudendal nerve terminal motor latencies following vaginal delivery, especially after sphincter laceration (53,71,74). Most women will recover function within a few months postpartum. Others will have evidence of injury several years later, which may represent the cumulative effects of subsequent deliveries (71,75). However, fecal incontinence will develop in only a fraction of patients with neuropathy (73).

**Descending Perineum Syndrome**

As noted previously, prolonged straining for any reason could cause descending perineum syndrome. This syndrome is defined as descent of the perineum beyond the ischial tuberosities during Valsalva (38,39). Pudendal neuropathy results from stretching and entrapment of the pudendal nerve. This diagnosis is supported by findings of elongation of the pudendal nerve, prolonged pudendal nerve motor terminal latency, and decreased anal sensation in women with perineal descent (76–78). As pudendal neuropathy progresses, it ultimately leads to fecal incontinence (40,79).

**Functional Bowel Disorders**

**Functional Fecal Incontinence**

The **Rome III criteria established well-defined guidelines for functional causes of fecal incontinence** (Table 28.7). The criteria essentially exclude systemic and anatomic abnormalities; however, minor abnormalities of sphincter innervation or structure are permitted.

**Table 28.7 Functional Fecal Incontinence**

**Diagnostic Criteria**

1. Recurrent uncontrolled passage of fecal material in an individual with a
developmental age of at least 4 years and one or more of the following:
Abnormal functioning of normally innervated and structurally intact muscles
Minor abnormalities of sphincter structure and/or innervation
Normal or disordered bowel habits, (i.e., fecal retention or diarrhea)
Psychological causes
AND
. Exclusion of all of the following
Abnormal innervation caused by lesion(s) within the brain (e.g., dementia), spinal cord, or sacral nerve roots, or mixed lesions (e.g., multiple sclerosis), or as part of a generalized peripheral or autonomic neuropathy (e.g., due to diabetes)
Anal sphincter abnormalities associated with a multisystem disease (e.g., scleroderma)
Structural or neurogenic abnormalities believed to be the major or primary cause of fecal incontinence.

Criteria fulfilled for the last 3 months

Irritable Bowel Syndrome

The diarrhea variant of irritable bowel syndrome is often associated with fecal incontinence as well as disordered defecation. The criteria for diagnosis are presented in Table 28.4.

Functional Diarrhea

The Rome III criteria create a unifying definition of diarrhea called functional diarrhea (Table 28.8). The rationale for the criteria listed in Table 28.8 stems from the variability in patients' descriptions of diarrhea (46).

Table 28.8 Functional Diarrhea

Diagnostic Criterion
Loose (mushy) or watery stools without pain occurring in at least 75% of stools

Criteria fulfilled for the last 3 months with symptom onset at least 6 months prior to diagnosis

Pitfalls for the Pelvic Floor Surgeon

It sometimes is easy to overlook or misinterpret signs and symptoms of constipation and defecatory dysfunction. Any acute change in bowel habits must be evaluated thoroughly, and malignancy must be considered in the differential diagnosis. Even in the presence of chronic disease, malignancy must still be excluded. Persistent symptoms after an empiric trial of medical therapy should prompt further evaluation, including colonoscopy or flexible sigmoidoscopy. It is also possible to mistakenly attribute symptoms of defecatory dysfunction and constipation to pelvic organ prolapse when prolapse is actually the result of an underlying bowel disorder. In this case, surgical treatment of prolapse will have little lasting benefit if the underlying bowel disorder remains untreated.
A thorough history and physical examination are critical to the evaluation of fecal incontinence and defecatory dysfunction. The history of present illness should focus on the bowel habits, including frequency and consistency of bowel movements (hard vs. soft, formed vs. unformed, diarrhea vs. constipation). Determining the duration and severity of symptoms, as well as exacerbating factors, is important for understanding the impact on quality of life. Patients should be questioned about straining with bowel movements, symptoms of incomplete emptying, and splinting of the perianal region, perineal body, or posterior vaginal wall to assist with evacuation. Patients should also be asked about the need to perform digital disimpaction because they are unlikely to volunteer this information. With respect to fecal incontinence, information should be obtained about leakage with solids, liquid, and flatus and the ability to discriminate between these different types of stool (sampling). Similar to urinary incontinence, fecal incontinence can be stress related, urge related, or unconscious. Questions about alternating diarrhea and constipation, mucus or blood in the stools, constitutional symptoms, and changes in stool caliber can help the investigator uncover systemic and functional etiologies. Finally, it is important to ask about adaptive behaviors, incontinence product usage, and past and present treatments, including surgery, physical therapy, and medications.

A large amount of information can be obtained efficiently through questionnaires. Validated questionnaires quantify symptoms, which are subjective in nature, to objectively measure response to treatment. A valuable survey to assess defecatory dysfunction is the Colorectal-Anal Distress Inventory (CRADI), which has been incorporated into the Pelvic Floor Distress Inventory (PFDI) \(^{(80)}\). The latter is a useful tool for evaluating symptoms of prolapse, urinary incontinence, fecal incontinence, voiding dysfunction, and defecatory dysfunction. Other useful symptom scales and bother scores for fecal incontinence include the Wexner Score, Fecal Incontinence Severity Index, and Fecal Incontinence Quality of Life Scale \(^{(81–83)}\).

The medical history, surgical history, family history, and review of systems should focus on uncovering potential systemic and obstructive disorders shown in Table 28.1. A complete obstetric history should include the number of vaginal deliveries, operative vaginal deliveries, or presence of a third- or fourth-degree laceration, which is critical for patients with fecal incontinence. Length of the second stage of labor, birth weight, and the use of episiotomy should be ascertained because they may pose risk factors for sphincter damage and denervation. The sexual history should include questions about rape, anal intercourse, and dyspareunia. Use of over-the-counter, prescription, and illegal drugs should be recorded as well as food allergies.
Physical Examination

The evaluation of anorectal dysfunction requires a basic general examination as well as a focused abdominal and pelvic examination. The general physical survey should include a global assessment of mobility and cognitive function. Routine examination of the abdomen involves inspection, palpation, and auscultation to rule out the presence of masses, organomegaly, and areas of peritoneal irritation. This examination should be followed by a detailed evaluation of the vagina, perineum, and anorectum. The goals of the pelvic examination are to define objectively the degree of prolapse and determine the integrity of the connective tissue, neurologic function, and muscular support of the pelvic organs.

Neurologic Examination

Important elements of the neurologic examination are assessment of cranial nerve function, sensation and strength of the lower extremities, and reflexes for the lower extremities, bulbocavernosus, and anal wink. These examinations evaluate the function of the lower lumbar and sacral nerve roots, recognizing the importance of the second through fourth sacral nerve roots in pelvic floor dysfunction. The perineal reflexes can be elicited by stroking the labia majora and perianal skin or tapping the clitoris with a cotton-tipped swab. The anal wink, bulbocavernosus, and cough reflexes all test the integrity of motor innervation to the external anal sphincter (S2–4). Sensation over the inner thigh, vulva, and perirectal areas should be tested for symmetry to light touch and pinprick.

Muscle Strength

The integrity of the pelvic floor muscles should be assessed at rest and with voluntary contraction to determine strength, duration, and anterior lift. The ability to relax these muscles and tenderness on palpation should also be evaluated. Several standardized systems have been described to objectively measure muscle strength, but none has been accepted as a standard. The puborectalis muscle should be readily palpable posteriorly as it creates a 90-degree angle between the anal and rectal canals. Voluntary contraction of this muscle “lifts” the examining finger anteriorly toward the pubic rami. An intact external anal sphincter muscle that has decreased tone and contractility often indicates pudendal neuropathy. Similarly, neuropathy affecting the puborectalis can be recognized by an obtuse anorectal angle and weak voluntary contraction. Similar to the urethral axis, the anorectal angle can also be tested using a cotton-tipped swab, although this test is rarely performed. Deflection is measured in the supine position at rest, with strain, and with squeeze.

Vaginal Support

The salient points of pelvic organ prolapse (see Chapter 27 for patients with defecatory dysfunction are the support of the vaginal apex, posterior wall, and
The integrity of the external anal sphincter and puborectalis muscle can be evaluated by observation and palpation of these structures during voluntary contraction. Evidence of dovetailing of the perianal skin folds and the presence of a perineal scar with an asymmetric contraction often indicates a sphincter defect. When a patient is asked to contract her pelvic floor muscles, two motions should be present: The
external anal sphincter should contract concentrically, and the anal verge should be pulled inward. These actions should also be apparent on digital rectal examination. As mentioned previously, the 90-degree angle created by the puborectalis should be readily palpable posteriorly and, with voluntary contraction, the examining finger should be lifted anteriorly toward the pubic rami. Both the puborectalis and external anal sphincter should relax during Valsalva effort. Patients with anismus may experience a paradoxical contraction of these muscles during straining. Finally, defects in the anterior aspects of the external anal sphincter may be detected by digital examination.
Testing
Sophisticated diagnostic testing is currently being used in clinical research and in anorectal physiology laboratories to quantify the function of the colon and anorectum. Following is a description of these techniques as they relate to the management of fecal incontinence and disordered defecation.
Fecal Incontinence

Endoanal Ultrasonography

Endoanal ultrasonography permits accurate imaging of both the internal and external anal sphincters. It can assess the continuity and thickness of the muscle and currently is considered the single best method for detecting anal sphincter defects. Endoanal ultrasonography is performed using a Bruel-Kjaer (Copenhagen, Denmark) ultrasound scanner with a 360-degree rectal endoprobe (type 1850) with a 7.0 MHz transducer (focal length, 2–5 cm) housed within a plastic cone (Fig. 28.1). The normal IAS is a continuous hypoechoic band of smooth muscle surrounded by the thick echogenic layer of the striated EAS. A sphincter defect occurs when there is disruption in these muscle bands. Location and severity of the defect can be described by circumferential distance in degrees, percentage of thickness, and distance from the anal verge (Fig. 28.2). Measurements are usually taken in the proximal, middle, and distal anal canal. It is important to recognize the physiologic split in the proximal EAS as it merges with the puborectalis muscle of the levator ani. Misinterpretation of this finding as a sphincter defect can result in an increased prevalence of reported defects. The puborectalis muscle appears as a U-shaped or V-shaped thick echogenic layer outside the IAS in the proximal anal canal. Magnetic resonance imaging (MRI) may be equally as effective or better at diagnosing sphincter defects, especially with the use of a vaginal or rectal coil. For this purpose, MRI is more expensive, and currently its use is largely investigational. It may be beneficial in cases in which endoanal ultrasonography results are inconclusive or the quality of the study is poor.

Figure 28.1 Bruel-Kjaer (Copenhagen, Denmark) ultrasound probe (type 1850) with a 7.0 MHz transducer (focal length, 2 to 5 cm) housed with a plastic cone.

Figure 28.2 A: Endoanal ultrasound image from the distal anal canal demonstrating defects in the internal sphincter from 10 to 3 o’clock and the external sphincter from 10 to 2 o’clock. B: Endoanal ultrasound image from the middle anal canal demonstrating defects in the internal sphincter from 12 to 2 o’clock and the external sphincter from 10 to 1 o’clock. C: Endoanal ultrasound image from the proximal anal canal demonstrating an intact IAS and a normal physiologic split in the external sphincter.
Electromyography (EMG) is used to evaluate neuromuscular integrity of the EAS following a traumatic injury such as childbirth, as well as to document the presence of pelvic floor neuropathy (86). This technique measures the electrical activity arising in muscle fibers during contraction and at rest. Different types of electrodes may be employed, including surface electrodes, concentric needle electrodes, and single-fiber electrodes. Surface electrodes are less invasive because they are applied near or within the anal canal, but they are capable only of recording basic anal sphincter activity. This technique often is used in conjunction with biofeedback therapy. Concentric needle electrodes are most commonly used in anorectal physiology laboratories to selectively survey an individual muscle’s activity. Insertion of the thin needlelike cannulas containing steel wire electrodes can be painful. Even smaller single-fiber EMG electrodes
are used to record the activity of single muscle fibers, which can be quantified to calculate fiber density. Following denervation injury, increased muscle fiber density occurs during reinnervation. Thus, single-fiber EMG can provide indirect evidence of neurologic injury by mapping the EAS and identifying injured areas. This technique is used rarely in clinical practice. Endoanal ultrasonography offers increased patient comfort and more reliable results than EMG and has replaced this technique for the detection of EAS disruption because of increased patient comfort and more reliable results.

**Motor nerve conduction studies provide another means of measuring pelvic floor neuropathy.** The axon of a nerve is stimulated, and the time it takes the action potential to reach the muscle supplied by the nerve is recorded. The delay between stimulation and the muscle response is called the nerve latency. Pudendal nerve terminal motor latency (PNTML) can be determined by transrectal stimulation of the pudendal nerve using a St. Mark’s electrode (87). A nerve stimulator is mounted on an examination glove at the fingertip (Fig. 28.3) and positioned transrectally over each ischial spine. A stimulus of up to 50 mV for 0.1 milliseconds is applied, and the latency of the EAS muscle contraction is measured. A value of 2.2 milliseconds or less is considered normal. A recent study evaluating normative values for pudendal and perineal nerve latencies observed increased latencies with increased age (88). Prolongation of the PNTML is indicative of damage to that nerve or the presence of a demyelinating condition. Pudendal nerve function has prognostic value in the surgical repair of traumatic sphincter injuries and is useful in preoperative counseling (89).

*Figure 28.3 St. Mark’s electrode used for measuring pudendal nerve motor terminal latency. The stimulating electrode is on the fingertip, and the receiving electrode is on the proximal finger near the knuckle.*

**Anal Manometry**

**Anal manometry is used to quantify function of the anal sphincter mechanism.** Water-perfused manometry catheters or water-filled balloons are most often used to measure anal canal pressures. Resting anal canal pressures reflect IAS function, and
pressures in the lower anal canal during maximal voluntary contraction reflect EAS function. Vector analysis can be used to detect asymmetry within the anal sphincter. Anal manometry provides indirect evidence of sphincter injury; low resting tone indicates IAS injury, and decreased maximum squeeze pressure indicates EAS injury. Anal pressures are influenced by a variety of factors, including tissue compliance and muscular tone. Consequently, anal manometry results are difficult to interpret and correlate poorly with the specific anatomic defect. Interpretation is further complicated by the wide variation of normal pressure values that change with age and parity. Significant overlaps occur between manometric values for incontinent patients and those without incontinence. Thus, anal manometry may be of limited value in the evaluation and treatment of anal sphincter defects and fecal incontinence.

**Proctoscopy and Flat Tire Test**

Proctoscopy has an important role in the evaluation of fecal incontinence. It can be performed independently or during colonoscopy, flexible sigmoidoscopy, and the flat tire test. Proctoscopy can detect anorectal pathology, such as prolapsing hemorrhoids, intussusception, ulcerative or radiation proctitis, or a solitary rectal ulcer. The flat tire test is added when a rectovaginal or colovaginal fistula is suspected but cannot be visualized on routine office evaluation. This test usually is performed under anesthesia but can also be done in the office setting. Saline or water is placed in the vagina with the patient in Trendelenburg position. Using a proctoscope or rigid sigmoidoscope, air is instilled into the rectum. Vaginal retractors provide visualization of the posterior vaginal epithelium and vaginal apex. Observation of bubbling into the vaginal fluid confirms the diagnosis and location of a rectovaginal or colovaginal fistula. The rectal site of the fistula usually is identifiable, depending on the size and location of the fistula as well as the quality of the bowel preparation.
Disordered Defecation

Sitzmark Study
Colonic transit studies are performed using ingested radiopaque markers followed by serial abdominal radiography. Patients are asked to follow a high-fiber diet over the test period and avoid the use of laxatives, suppositories, or enemas. A capsule containing 20 to 24 markers is ingested initially, and abdominal radiography is performed either daily or on the fourth day, the seventh day, and every 3 days thereafter until all the markers are gone. Segmental transit times are then calculated using a mathematical formula. Colonic transit study results are used to classify patients with constipation into delayed transit, normal transit, and outlet obstruction. After day 6, there should be fewer than five markers remaining in the colon. With slow transit, more than five markers are scattered throughout the colon. With outlet obstruction, more than five markers are in the rectosigmoid region, and transit is normal throughout the rest of the colon.

Pelvic Floor Fluoroscopy and Magnetic Resonance Imaging
Pelvic fluoroscopy permits radiological evaluation of pelvic floor and anorectal anatomy and physiology. It is particularly useful in obstructive defecation disorders, such as intussusception, rectocele, enterocele, anismus, and perineal descent. The patient is placed on a radiolucent commode, and contrast material is instilled into the rectum. The addition of vaginal, bladder, and oral contrast material is helpful diagnostically when multicompartamental prolapse is suspected. A series of lateral still images or continuous imaging using videography are made with fluoroscopy while the patient is at rest, during defecation, and with contraction of the anal sphincter. Similar films can be obtained for evacuation of the bladder. Pelvic fluoroscopy has many names, including defecography, defecating proctography, defecating cystoproctography, and colpocystoproctography, depending on the technique used. The measurements obtained include size of the rectal ampulla, length of the anal canal, anorectal angle, puborectalis motion, and pelvic floor descent. Severity of prolapse and pelvic floor descent is quantified in relation to the pubococcygeal line. Pelvic fluoroscopy is superior to physical examination for diagnosing enterocele, and this technique has the advantage of being able to distinguish enteroceles from sigmoidoceles (90). Rectosphincteric dyssynergia may be present when the patient experiences incomplete relaxation of the puborectalis muscle during rectal evacuation, the anorectal angle is preserved, and there is incomplete emptying. Pelvic fluoroscopy is considered the definitive test for diagnosing intussusception, and it is the preferred technique for quantifying perineal descent (91).

Dynamic MRI with luminal contrast is an imaging modality similar to pelvic fluoroscopy. Its ability to detect prolapse is similar to that of fluoroscopy, but MRI can visualize pelvic floor musculature and soft tissue, thus giving it the advantage of detecting ballooning of the levator muscles and levator ani hernias. The supine position of the testing is a drawback; however, there are isolated reports of upright dynamic MRI
using open scanners that show results comparable to fluoroscopy for detection of anorectal pathology (92). Fluoroscopy and dynamic MRI can be used in situations involving severe multicompartmental prolapse or in which the severity of the symptoms is disproportionate to examination findings.
Anal Manometry

Anal manometry is used to determine maximum resting pressure, maximum squeeze pressure, rectal sensation and compliance, as well as the presence of an intact rectoanal inhibitory reflex. With disordered defecation, it can be used to diagnose Hirschsprung disease and anismus. The addition of surface EMG to document relaxation helps exclude anismus as a cause of obstructed defecation. Failure of the anal sphincter to relax with defecation and increased electrical activity of the EAS and puborectalis are seen in patients with anismus. In contrast, there should be no increase in the electrical activity measured by surface electrodes for patients with Hirschsprung disease. A rectal balloon expulsion test can also be of assistance in the evaluation of rectal emptying and may be valuable during physiotherapy for diagnosing dyssynergic defecation.

Colonoscopy and Proctoscopy

Standard gastrointestinal evaluation for patients with symptoms of disordered defecation should include a barium enema or colonoscopy to eliminate the possibility of colorectal malignancy. Proctoscopy should be included as part of the routine examination because it may reveal anorectal pathology.
Therapeutic Approach to Fecal Incontinence

Treatment of fecal incontinence should first focus on nonsurgical options, including dietary modification, medical therapy, and biofeedback. Any underlying systemic conditions or gastrointestinal disorders should be treated before initiating an extensive evaluation for other causes of fecal incontinence. If symptoms persist, further investigation should be undertaken. If the evaluation discloses an underlying EAS defect and conservative therapy has been unsuccessful, it is reasonable to proceed with surgical treatment.

Following is an overview of treatment options and the efficacy of each approach. The lack of consistent outcome measures makes it difficult to compare efficacy among treatments. Some studies base success on strict conformity with criteria for continence, but the results vary for continence of flatus, liquid, or solid stool. Other studies base success on more subjective criteria, such as improvement following treatment. Daily diaries can be maintained, but the results may be unreliable. Even if a validated symptom survey and quality-of-life scale are employed, few studies use the same outcome measure.
Nonsurgical Treatment

Nonsurgical management focuses on maximizing the continence mechanism through alteration of stool characteristics or behavioral modification. Stool consistency and volume can be manipulated by dietary and pharmacologic means to achieve passage of one to two well-formed stools per day. The rationale for this approach is that formed stool is easier to control than liquid stool. Additionally, behavior modification can be employed using bowel regimens that focus on the predictable elimination of feces. Physical therapy and biofeedback can also be useful for strengthening the continence mechanism.

Pharmacologic Approaches

Dietary Modification and Fiber

Dietary modification for treatment of fecal incontinence frequently involves avoidance of foods that precipitate loose stools and diarrhea. Common dietary irritants include spicy foods, coffee and other caffeinated beverages, beer and alcohol, and citrus fruits. Avoidance of dairy products or the addition of lactase dietary supplements is essential for those with lactose intolerance. The addition of fiber may improve fecal incontinence by functioning as a stool bulking agent to increase volume and density. The average individual in the United States consumes less than half the recommended daily fiber intake (25–35 g). Various fiber sources are listed in Table 28.9, with the highest content found in high-fiber cereals. It is difficult to consume the recommended daily amount from diet alone, and fiber supplements often are required. Although the increased stool volume and density helps many individuals maintain continence, excessive fiber with inadequate fluid intake may predispose elderly patients to fecal impaction.

Constipating Agents

**Constipating agents have the most value in patients with chronic loose stools or diarrhea.** They can also help improve symptoms in patients with fecal frequency and urgency. Loperamide (Imodium) and diphenoxylate hydrochloride with atropine (Lomotil) are the most commonly used agents. Loperamide has been shown to prolong transit time and stimulate anal sphincter function. With either of these agents, careful titration is recommended to prevent the primary side effect of constipation. It is generally preferable to begin using 2 to 4 mg of loperamide daily and then titrate up to 4 mg three to four times per day. A 4-mg dose before meals has been shown to increase anal tone and improve continence (93). Lomotil is started at a dose of one to two tablets every day or every other day and titrated up to one to two tablets three to four times a day as needed. Caution should be exercised for patients taking other anticholinergic medications. Anticholinergic side effects include dry mouth, drowsiness, lightheadedness, and tachycardia. Codeine can also be used as a constipating agent. It should be used judiciously in those with chronic disorders and in elderly patients because of side effects common to narcotics, including addiction with prolonged usage and central nervous system and respiratory depression. A study of 82 geriatric patients documented the efficacy of pharmacologic treatment for fecal incontinence (94). Patients were treated based on the underlying cause. Those with fecal impaction received lactulose and enemas, whereas those with neurogenic fecal incontinence received codeine phosphate as a constipating agent and enemas. The rate of cure for fecal incontinence was 60% in the treatment group versus 32% for controls (P <.001).

**Medications for Irritable Bowel Syndrome**

**Dietary treatment of IBS consists of avoiding foods that are associated with symptoms, including alcohol, caffeine, sorbitol, and foods that increase gas production.** Although increased dietary fiber or fiber supplementation has been shown to improve the constipation-predominant form of this illness, fiber supplementation has little effect on the diarrhea variant associated with fecal incontinence. Pharmacologic therapy is directed toward the predominant symptom. Loperamide and Lomotil tend to be useful first-line agents for treating diarrhea. Tricyclic antidepressants improve abdominal discomfort and are also valuable in diarrhea-predominant patients because of their constipating effect. The serotonin type 3 (5HT3) antagonist alosetron (Lotronex) has been approved by the U.S. Food and Drug Administration (FDA) for the treatment of severe diarrhea-predominant IBS refractory to treatment. It has shown improvement in global assessment measures, but its use is limited because of multiple isolated case reports of ischemic colitis. The recommended dose is 1 mg once or twice daily. It does not appear to be effective for the spastic-pain variant of IBS. Anticholinergics (dicyclomine, hyoscyamine) and antispasmodics (mebeverine, pinaverine[MB3]) are targeted at the pain and bloating symptoms but may also be useful for the diarrhea variant because of their constipating side effects. Studies comparing anticholinergic medications to placebo show inconclusive results with only modest benefits.
Antispasmodic agents may also be of value and are available in many countries but are not approved for use in the United States. Currently, additional 5HT3 antagonists and 5HT4 antagonists are under development and are approved for use in Europe but not in the United States. Most studies are poorly designed and difficult to interpret because of a high placebo response rate that often exceeds 30% (95,96).

Behavioral Approaches

Biofeedback

Biofeedback can be an effective therapeutic modality provided patients are motivated and comprehend instructions. The two proposed mechanisms through which biofeedback improves fecal continence are afferent and efferent training. Afferent training focuses on improving sensation in the anorectal canal through recruitment of adjacent neurons to decrease the sensory threshold of volume stimulation. The goal of this training is to enhance and restore anal sensation and the rectoanal inhibitory reflex. Efferent training enhances and restores voluntary contraction of the EAS, which permits additional recruitment of motor units and stimulates muscle hypertrophy. These two methods of training can be performed independently but are often combined for additional therapeutic benefit. The most common training method uses an intrarectal balloon. The balloon acts to stimulate rectal distention and provide pressure feedback from coordinated or synchronized contraction of the pelvic floor muscles. Other techniques focus on strength training of the EAS alone using anal pressure feedback or EMG or afferent training alone using an intrarectal balloon without pelvic floor muscle contraction in response to the stimulus.

More than 35 studies have been done to evaluate the efficacy of biofeedback for treatment of fecal incontinence, and several excellent review articles and meta-analyses have determined the effects of individual treatments and predictors of patient response to treatment (97–99). The results of all of these studies uniformly agree that biofeedback and pelvic floor exercises improve fecal incontinence and have a role in clinical practice. They also agree that the existing literature is fraught with methodologic problems and lacks validated outcomes and controls. Thus it is difficult to compare directly the study results.

Biofeedback is an ideal first-line therapy because it offers an effective, minimally invasive treatment without any reported adverse events. Biofeedback also appears to provide a higher probability of successful outcome than standard medical care for treating functional fecal incontinence (67% vs. 36%, respectively, P < .001) (97).

A Cochrane review of biofeedback and exercises for treatment of fecal incontinence found only five randomized or quasi-randomized control trials that qualified for inclusion (100). The authors concluded that there is insufficient evidence to evaluate the efficacy of exercises and biofeedback for treatment of fecal
incontinence. Specifically, they were not able to determine which patients were suitable for treatment nor which method of treatment was optimal. A meta-analysis of biofeedback techniques included a review of 13 studies using strength training alone, 4 studies with sensory training alone, and 18 with coordinated sensory and strength training (99). The authors found no advantages between coordinated training (67% improved) and strength training (70% improved). However, strength training using EMG appeared to be better than strength training with anal canal pressure biofeedback (74% vs. 64% improved, respectively, \( P < .04 \)). The limitations of this study and the literature were acknowledged.

A large randomized control trial of biofeedback for fecal incontinence in 171 patients, divided into four treatment groups, showed no significant benefit when comparing standard care to similar care with the addition of biofeedback (54% vs. 53% improvement, respectively) (101). In all groups, there was a high median rating of change of symptoms and median satisfaction with benefits relatively maintained at 1-year follow-up. All groups displayed improvement in the validated symptom surveys and quality-of-life measures as well as in anal sphincter function. The authors concluded that interactions with the therapist, patient education, and development of better coping strategies seem to be the most important factors for improvement rather than pelvic muscle exercises or biofeedback. Additional benefit may be derived with augmented biofeedback using electrical stimulation (102).

There are no clear indicators to predict which patients will benefit from biofeedback. Potential factors include age, duration and severity of incontinence, prior treatments or surgery, and severity of neurologic or physical damage. Controversy exists as to whether response to biofeedback is dependent on the presence of a structurally intact anal sphincter or normal pudendal nerve function (103–106). Similarly, there is insufficient evidence that electrical stimulation improves fecal incontinence (107). There is an obvious need for well-designed control trials using validated symptom surveys and quality-of-life instruments. More objective measures are desirable, and studies should carefully document duration of treatment and length of follow-up.

**Bowel Regimens**

The goal of bowel regimens is to achieve predictable elimination of feces. This can be accomplished by using the gastrocolic reflex as well as by dietary and pharmacologic means. Defecation immediately following meals involves the physiologic response of the gastrocolic reflex to facilitate predictable emptying. The strength of the gastrocolic reflex varies among individuals and may be hypoactive or hyperactive with certain systemic disorders, such as diabetes and multiple sclerosis. This technique can be especially useful in the morning to give the individual freedom from fecal incontinence throughout the day. The use of suppositories or enemas in the morning or at night in conjunction with the gastrocolic reflex may provide further relief of daytime symptoms. The goal is to leave the rectum empty between evacuations. Enema use, typically once or twice daily, should be titrated to the patient’s baseline colonic activity.
Toileting in elderly patients in nursing homes can improve fecal incontinence caused by overflow incontinence from fecal impaction. The use of cone-tip colostomy-irrigation catheters is reserved for patients in whom other therapeutic modalities have failed. These catheters avoid the risk of rectal perforation and provide a dam to prevent efflux of the irrigating solutions (108).
Surgical Treatment

In general, surgical treatment should be employed after conservative measures have failed. Although there may be exceptions to this principle, most surgeons follow this recommendation because of the poor long-term outcomes and high complication rates with surgery for fecal incontinence.

Overlapping Sphincteroplasty

Overlapping sphincteroplasty is the procedure of choice for fecal incontinence caused by a disrupted anal sphincter. Most authorities believe that an overlapping technique is superior to an end-to-end repair, although there are few direct comparisons in the literature. The rationale for the overlapping technique is that a more secure repair can be accomplished by placing sutures through the scarred connective tissue rather than the sphincter muscle. Sutures should be less likely to tear through or pull out of connective tissue than muscle. Therefore, the key component of the overlapping technique is preservation of the scarred ends of the ruptured EAS for suture placement.

Technique

The initial step involves wide mobilization of the ruptured EAS without excision of the scarred ends of the sphincter. This is accomplished through an inverted semilunar perineal incision or a transverse incision near the posterior vaginal fourchette with inferiolateral extension. The latter incision facilitates repair in patients with damage to the rectovaginal septum attachment to the perineal body. Patients with EAS defects have either a band of intervening fibrous scar tissue between the viable muscular ends of sphincter or a complete separation with scar tissue present only on the ruptured ends of the sphincter. In the presence of complete separation of scar tissue, perineal body reconstruction usually is indicated at the time of repair to restore normal anatomy. A Peña muscle stimulator aids in identification of the distal ends of the EAS and differentiates viable muscle tissue from scar tissue. The stimulator can be used to outline the sphincter before incision as well as during the dissection. It is important to apprise the anesthesiologist of the stimulator usage so that paralytic agents are avoided.

Excessive lateral dissection of the EAS past the 3 and 9 o'clock positions should be avoided as this is where the inferior rectal branches of the pudendal nerve innervate the EAS. Moderate bleeding often is encountered during this dissection, and the use of needlepoint electrocautery can maximize hemostasis. Controversy exists regarding the need to separate the EAS and IAS before repair. Identification of the intersphincteric groove facilitates dissection of the EAS. Dissection in this plane is relatively simple and avoids damage to either sphincter. Defects in the IAS can be more difficult to visualize because this muscle is intimately associated with the rectal mucosa. Examination with a finger in the anal canal is often helpful.

The reconstruction begins with repair of an existing IAS defect using a 3-0 delayed absorbable monofilament suture. Next, the EAS defect is repaired with the primary goal
of overlapping at least 2 to 3 cm to ensure adequate bulk of sphincter muscle encircling the anal canal. The EAS is overlapped using three to four mattress sutures of 2-0 delayed absorbable monofilament suture through the distal scar tissue. Once the sutures are tied, there should be resistance palpable with placement of a finger in the anal canal. Copious irrigation is performed throughout the procedure. Following sphincter repair, a perineal body reconstruction and rectocele repair should be undertaken, if indicated, to maximize the normal continence mechanism. Finally, the perineal skin is closed with interrupted absorbable monofilament sutures. Closure frequently requires modification of the initial incision because of changes in the perineal architecture that result from the repair. The most common approach is an inverted Y-shaped closure of the incision (Fig. 28.4).

Figure 28.4 Overlapping sphincteroplasty procedure. A: Inverted semilunar perineal incision with the distal ends of the external sphincter outlined using the Peña muscle stimulator. B: The external sphincter has been dissected, the scar divided in the midline, and the internal sphincter repaired. C: The external sphincter is overlapped using three mattress sutures of 2–0 delayed absorbable monofilament suture through the distal scar tissue. D: The sutures are tied. E: The skin is closed.
Some surgeons recommend the overlapping repair regardless of whether it is performed immediately postpartum, delayed postpartum, or several years after obstetric injury. Performance of the overlapping technique is difficult immediately postpartum and requires adequate anesthesia, exposure, and equipment. Many surgeons
believe that this can only be accomplished in the operating room. This repair lacks the theoretical advantage of using scar tissue to improve suture holding; however, it maximizes surface area for scarification of the sphincter ends. For a delayed postpartum repair, it is recommended to wait 3 to 6 months to permit complete resolution of inflammation and reinnervation.

Four randomized control trials compared end-to-end approximation to overlapping sphincteroplasty after acute obstetrical injury (109–112). Fitzpatrick et al. randomized 112 primiparous women undergoing immediate repair of a third- or fourth-degree sphincter tear (109). The authors did not detect any significant differences in objective or subjective outcomes between either of the two repairs at 3 months follow-up. Approximately one-half of the women had minor alteration in fecal continence, whereas 7 (6%) had daily soiling. Despite good symptomatic results, 74 (66%) had full-thickness EAS defects on endoanal ultrasonography. Williams et al. randomized 112 women to overlapping or end-to-end repair with either polyglactin (Vicryl) or polydioxanone (PDS) (110). They, too, found no difference in outcomes between the different methods of repair or type of suture used. Fernando et al. randomized 64 women and discovered a lower rate of fecal incontinence symptoms and fecal urgency after overlapping repair compared to end-to-end repair (111). Farrell et al. randomized 149 women to one of the two techniques and was the only study to discover higher rates of fecal incontinence of flatus in the overlapping group compared to the end-to-end group (61% vs. 39%; OR 2.44) (112). There was a trend toward overall higher rates of fecal incontinence; however, these were not statistically different (15% vs. 8%) (112). A Cochrane review that included the first three randomized controlled trials concluded that the overlapping repair technique resulted in less fecal incontinence and fecal urgency, but the data were insufficient to recommend one repair over the other (113). Another randomized controlled trial involved a delayed repair in 23 patients more than 1 year following delivery (114). The scar was preserved for each repair, and a puborectalis plication was performed. At a median follow-up of 18 months, there were no detectable differences in continence scores; however, the study was clearly underpowered. Consequently, the authors believe there is no definitive evidence to support an overlapping technique at the time of acute obstetrical injury and repair but prefer an overlapping technique as a delayed repair.

Efficacy

Despite the many large series reporting the outcomes of overlapping sphincteroplasty, almost all are retrospective in nature and lack validated measures of symptom severity and quality-of-life considerations. Several overlapping sphincteroplasty series with a total of 891 patients were evaluated from 1984 to 2001. Although the length of follow-up was variable, the results showed excellent and good outcomes in approximately two-thirds of patients (median 67%, range 52%–83%) (115). None of these studies had long-term outcomes.

More recent studies suggest poor long-term outcomes for the overlapping sphincteroplasty. In a series of 55 women who underwent overlapping sphincteroplasty
for fecal incontinence secondary to obstetric trauma, researchers contacted 47 (86%) patients by postal questionnaire and telephone interview with a median time since surgery of 77 months (range 60–96 months) (116). The investigators observed less symptomatic improvement when compared with the results at 15 months postoperative evaluation. After excluding one patient because of Crohn disease, eight (17%) failed because they required additional surgery, such as colostomy, postanal repair, and artificial bowel sphincter. Among the remaining 38 patients, 27 (71%) reported improved bowel control, 5 (13%) were unimproved, and 6 (16%) were worse. No patient was fully continent to solid and liquid stool and flatus. Only 23 (50%) patients had “good” outcomes defined as not requiring further continence surgery and fecal incontinence less than once per month.

In another study, investigators contacted 49 (69%) of 71 patients by telephone interview (117). All underwent overlapping sphincteroplasty with a median follow-up of 62.5 months (range 47–141 months). Only 6 (12%) patients were totally continent, and another 18 (37%) were continent to liquid and solid stool. More than half of the patients had incontinence to liquid or solid stool. The largest series with long-term follow-up involved contact of 130 (71%) of 191 patients using a postal or telephone questionnaire (118). The median time from surgery for respondents was 10 years (range 7–16 years). Of those who responded, 6% had no incontinence, 16% were incontinent of flatus only, 19% had soiling only, and 57% were incontinent of solid stool. These outcomes were significantly worse than the previously reported 3-year assessment (119). Despite the fact that 61% had a poor outcome defined as having fecal incontinence or requiring additional surgery for incontinence, 62% still considered their bowel control to be better than before surgery, and 74% were satisfied with the results of their surgery. Although control may be improved when compared with preoperative status, continence outcomes do not seem to be maintained at long-term follow-up.

The cause of this deterioration in long-term outcomes is unknown. Possible explanations include weakening of the muscles with normal aging, repair breakdown, and underlying nerve damage from either obstetric injury or the repair itself. A problem with most studies is the lack of a follow-up ultrasonography to determine whether the repair was still intact. The effect of pudendal nerve function on overlapping sphincteroplasty is somewhat controversial. Significantly lower success rates have been shown in a comparison of those with normal pudendal nerve terminal motor latencies to those with abnormal latencies (63% vs. 17%; P <.01) (120). Other studies have confirmed this finding (79,89,106,107,121,122), but the more recent studies fail to show a difference based on preoperative neurophysiologic testing (116,118). Other controversial factors that may affect outcome include age, duration of fecal incontinence, size of the defect, and anal manometry results.

Although there are many controversial aspects to overlapping sphincteroplasty, the literature is in agreement that diverting colostomy is not necessary; bowel confinement does not improve outcomes; clinical improvement correlates with postoperative endoanal ultrasonography results; and prior sphincteroplasty does not
affect outcomes (114,116,120,123–128).

Subsequent Deliveries
Multiple studies confirm the impact of anal sphincter laceration during the first delivery on the risk of a sphincter laceration in a second delivery (129–132). These studies have calculated odds ratios ranging between 2.5 and 5.3 for a second sphincter disruption. Two recent population-based studies revealed adjusted odds ratios of 4.2 (95% confidence interval [CI], 3.9–4.6) and 4.3 (95% CI, 3.8–4.8) (130,131). These odds ratios probably represent underestimates because they do not take into account higher cesarean delivery rates in subsequent births for women with a history of sphincter laceration. Both of these studies observed significantly increased risk of recurrent sphincter laceration associated with increased birth weight. The studies estimated that approximately 25 cesarean deliveries have to be performed to prevent one recurrent sphincter laceration. In fact, only 10% of women with anal sphincter lacerations at second delivery had a history of prior sphincter laceration. Although a history of prior sphincter laceration increases the risk of recurrent sphincter laceration, the risk remains relatively small. It is important to accurately counsel expectant mothers about their risk of sphincter laceration. Using this information, they can decide whether the risk of recurrent laceration outweighs the risk of elective cesarean birth. The risk of subsequent vaginal delivery on symptoms of fecal incontinence is unknown for women with a repaired anal sphincter. The presence or absence of preexisting fecal incontinence, as well as the estimated fetal weight, should be considered in counseling for a subsequent pregnancy.

Graciloplasty
Surgical reconstruction with a muscle flap should be considered in cases in which there is insufficient muscle to repair the EAS and all conservative measures have failed. Insufficient muscle can be caused by trauma or severe atrophy that results from denervation injury and congenital disease. Most patients considering this procedure have already undergone an overlapping sphincteroplasty that failed. Graciloplasty, first described by Pickrell et al. in 1952, is a skeletal muscle transposition procedure that uses the gracilis to create a new anal sphincter (133). There are three suitable muscles for this type of procedure: the gracilis, sartorius, and gluteus maximus. The muscle should be easily mobilized and transposed but not essential for locomotion or posture. The sartorius and gluteus maximus are suboptimal because the sartorius receives segmental vascularization, which restricts rotation, and the gluteus maximus is important in daily activities such as running, climbing stairs, and rising from a sitting position. The gracilis is a better choice because it can easily be mobilized without damage. As the most superficial adductor, it receives neurovascular supply proximally and has no important independent function.

Technique
Either one long incision or three small incisions are made in the medial thigh. The gracilis muscle is identified and mobilized toward its insertion onto the medial aspect of the tibia where the tendon is divided. Anterior and posterior perianal incisions are made approximately 1.5 cm from the anal verge. Tunnels are developed in the extrasphincteric space and from the proximal thigh to the anterior perianal incision. The gracilis muscle is then gently delivered to the anterior perianal incision, guided around the anus to the posterior perianal incision, and returned to the anterior incision encircling the anal canal. The distal tendon of the gracilis is passed behind the muscle and anchored to the contralateral periosteum of the ischium. In cases when there is inadequate length, it can be sutured to the ipsilateral ischium. This procedure can also be performed bilaterally. In patients with a large rectovaginal fistula or cloaca, a myocutaneous flap can be mobilized and used to help close the defect. Improvement of fecal incontinence is caused by passive increase of the resistance of the anal canal by the bulk of the encircling muscle (Fig. 28.5).

**Figure 28.5 Graciloplasty.** A: The gracilis muscle is identified and mobilized toward its insertion onto the medial aspect of the tibia where the tendon is divided. B: Anterior and posterior perianal incision are made approximately 1.5 cm from the anal verge. The muscle is then tunneled around the extrasphincteric space circumferentially. The distal tendon is passed behind the muscle and anchored to the contralateral periosteum of the ischium.
Experimental efforts to improve the efficacy of this procedure have focused on developing resting tone in the transposed muscle through the use of an implanted neurostimulator. The intent of the stimulated graciloplasty is to convert the fast-twitch muscle fibers into slow-twitch muscle fibers, which are more fatigue resistant. Initially, implantation of the pacemaker was performed at 6 weeks after the graciloplasty, but now most are performed concomitantly. Stimulation can be applied directly to the obturator nerve or intramuscularly to the nerve branches inside the muscle. The muscle is stimulated at a cyclic frequency, with gradual increases every 2 weeks. After 2 months, continuous stimulation is performed. Stimulation is adjusted to maintain tonic contraction around the anus, and it is interrupted or turned off to defecate.

**Efficacy**

An exhaustive review of the published literature identified 37 articles on patients undergoing dynamic graciloplasty (134). Most of these articles were case series, and
there were no randomized trials or cohort studies evaluating safety and efficacy. Mortality rate was 1% (range 0%–13%; 95% CI, 1%–3%) after excluding cancer deaths. There was a high rate of morbidity (1.12 events per patient). Most patients will have at least one adverse event, and several will have multiple complications. There is also a very high reoperation rate. The most common complications were infections (28%), stimulator and lead faults (15%), and leg pain (13%). Satisfactory continence was achieved 42% to 85% of the time, although satisfaction was not defined consistently across studies. The authors concluded that dynamic graciloplasty appeared to have equal or better efficacy than colostomy but carried a higher morbidity rate. Another review of the three largest case series found success rates ranging from 55% to 78% (135–137). Major infections were found in 13% to 29%, pain in 27% to 28%, and device or lead problems in 12% to 18%. More recent series containing large numbers of patients found similar results for efficacy, morbidity, and reoperation rate (138,139). High rates of disturbed evacuation also were reported.

Artificial Sphincter

The artificial anal sphincter is an alternative to a graciloplasty. This is a modification of the device originally designed to treat urinary incontinence. The current device is the Acticon® Neosphincter (American Medical Systems, Minnetonka, Minnesota) (Fig. 28.6). The indications for its use are similar to those for the graciloplasty.

Figure 28.6 Acticon® Neosphincter. This device includes an inflatable cuff placed around the anal canal, a balloon reservoir stored behind the pubic bone, and a pump located in the labia. (Courtesy of American Medical Systems, Inc. Minnetonka, Minnesota, www.AmericanMedicalSystems.com.)
Technique
Implantation of the artificial anal sphincter is performed, similar to the graciloplasty, through perianal tunnels. A silastic inflatable cuff is placed around the native sphincter to occlude the anal canal. A pressure-regulating balloon containing radio-opaque solution is situated in the retropubic space, and a control pump is positioned in the labia majora. Activation of the control pump deflates the cuff, permitting defecation (Fig. 28.6).

Efficacy
An extensive review of the literature summarized 13 case series and one case report from 1996 to 2003. There were no randomized trials or cohort studies (140). The largest series consisted of 112 patients (141). There was one series with 53 patients, and all others had fewer than 28 patients each (142). Explantation was required in 17% to 41% of patients. Reasons for explantation included infection, erosion, device malfunction, pain, incontinence, and dissatisfaction, with infection being the most common. Surgical revision was necessary in 13% to 50% of the reports. Almost everyone had at least one adverse event, and more than one-third of these events required surgical intervention. Reasons for surgical revision were similar to those for explantation. Rates of fecal impaction ranged from 6% to 83%. All studies recorded statistically and clinically significant improvement in continence scores for patients with a functional artificial sphincter; however, most did not report the continence status for those in whom the device was explanted. The proportion of patients with a functional device ranged from 49% to 85%. The authors concluded that there is insufficient evidence on the safety and effectiveness...
of the artificial sphincter for fecal incontinence.

One randomized control trial of 14 patients compared an artificial sphincter with a program of supportive care (143). Supportive care included all aspects of conservative management, such as physiotherapy, dietary advice, pharmacotherapy, and advice regarding skin care, odor management, anxiety reduction, and use of incontinence aids or appliances. Significant improvements in continence scores and quality-of-life measures were seen in the artificial sphincter group but not in the control group at 6 months follow-up. Explantation rate was 14% (one of seven patients). Two other patients had complications, including severe fecal impaction and perineal wound erosion requiring reoperation. The authors conclude that the artificial sphincter is safe and effective compared with supportive care alone. They anticipate perioperative and late complications, which may require explantation in up to one-third of patients. It is also remarkable that only one patient (14%) whose condition was managed conservatively had significant improvement based on continence scores, whereas the status of all others was relatively unchanged.

Another study compared the effectiveness of artificial sphincter with dynamic graciloplasty (144). Two surgeons each performed four consecutive operations with each technique to minimize the learning curve of a new operation. Each started with a different procedure to avoid discrepancies in the time of follow-up. This prospective cohort study involved eight patients in each group who had similar demographic variables. Length of follow-up was 44 months in the artificial sphincter group and 39 months in the dynamic graciloplasty group. Early postoperative complications were similar in each group at 50%, as were late complications, with both groups reporting a high reoperation rate of 63%. There were six (75%) late complications in the artificial sphincter group, of which three (38%) were nonreversible and required explantation. Postoperative continence scores were significantly lower with the artificial sphincter than with graciloplasty. The authors conclude that artificial sphincter has better efficacy and similar morbidity compared with dynamic graciloplasty. The rate of late complications for the artificial sphincter exceeded that reported in the literature, which may indicate poor long-term durability. Postoperative continence scores reflect those reported for artificial sphincter but are far worse than those for dynamic graciloplasty. The authors feel that the learning curve with the artificial sphincter is less important than that with graciloplasty.

**Sacral Nerve Root Stimulator**

Sacral neuromodulation (InterStim®, Medtronic, Minneapolis, Minnesota) was approved by the FDA for treatment of urinary urge incontinence in 1997 and for nonobstructive urinary retention and urgency in 1999. It has been employed experimentally for the treatment of fecal incontinence and is currently undergoing FDA approval for this intervention. In Europe, it was approved for treatment of both urinary and fecal incontinence in 1994. The exact mechanism of action has not been fully elucidated. The goal of sacral nerve stimulation is to recruit residual function of the continence mechanism through electrical
stimulation of its peripheral nerve supply. Initially, indications were confined to patients with deficient EAS and levator ani function without gross morphologic defects and intact neuromuscular connections. More recently, the acceptable indications have expanded to include deficiency of the IAS, limited structural defects, and functional deficits of the internal and external anal sphincter.

Technique
The device is instilled exactly the same way as for treatment of urinary incontinence. Current application is performed as a two-stage outpatient surgical procedure. The first stage involves instillation of the electrodes. The electrode is placed through the S2–4 foramen using minimally invasive surgical technique. During the test phase, multiple electrodes can be employed either bilaterally or at different levels to determine the site with the best response. Proper location is confirmed intraoperatively using fluoroscopy as well as visualization of an appropriate pelvic floor muscle response (bellows) with minimal plantar flexion of the first and second toes, which usually corresponds to S3 stimulation. An interval testing phase utilizes an external pulse generator that typically lasts 1 to 2 weeks. Those with a good response (decrease in fecal incontinence episodes of at least 50% documented by bowel-habit diary) will proceed to the second stage, implantation of the permanent pulse generator (IPG). Typically only one electrode is left in place at the end of the second stage. Once the permanent pulse generator is implanted, all adjustments are made using telemetry. The patient has a basic remote control that enables her to turn the device on or off and adjust the amplitude of the stimulation.

Efficacy
By the end of 2003, sacral nerve stimulation had been used to treat more than 1,300 patients with fecal incontinence (145). Despite this large number, the analysis of the results was limited to several small case series. In all studies, significant improvements in continence scores lasting up to 99 months occurred. Most patients experienced at least a 75% improvement in continence scores, and improvement also occurred in the frequency of incontinence episodes, the ability to postpone defecation, and bowel emptying. Intent-to-treat analysis revealed 80% to 100% therapeutic success. There also were significant improvements in quality-of-life measures using validated measurement scales. Complications occurred in 0% to 50% of patients, with the most common complications consisting of pain at the electrode or IPG site, electrode migration, infection, or worsening of bowel symptoms. No permanent sequelae occurred, however. Effects of anorectal physiology varied among the published studies, highlighting the fact that the precise mechanism of action remains unclear.

A Cochrane review of three crossover trials concluded that the limited data suggest improvement in both fecal incontinence and constipation with sacral nerve stimulation (146). Large multicenter trials have been conducted to evaluate the efficacy of sacral nerve stimulation for fecal incontinence. Wexner et al. prospectively followed 120
patients (110 female, 10 male) for a mean of 28 (2–70) months (147,148). Participants completed validated quality-of-life measures and bowel diaries. Success, defined as a 50% or greater improvement and reduction in fecal incontinence episodes per week, was achieved in 83% at 1 year and 85% at 2 years. Forty-one percent achieved total continence at 1 year, and mean incontinent episodes decreased from 9.4 to 1.9 per week. The same group reported an overall 10.8% infection rate (13/120), with nine occurring within the first month and four occurring after 1 year. Among the early infections, five responded to antibiotics, one resolved spontaneously, and three were treated surgically. For the late infections, all four had to be removed. Another large multicenter study of 200 patients revealed decreased severity scores and improved quality of life with sacral nerve stimulation (149). Loose stool consistency and low stimulation intensity were predictive of successful outcomes on multivariate analysis. Ultrasound findings, manometry, age and gender did not impact outcomes. Tjandra et al. performed a randomized controlled trial of 120 participants with 1-year follow-up comparing sacral nerve stimulation to best supportive therapy consisting of pelvic floor exercises, bulking agent, and dietary manipulation (150). Fecal incontinence outcomes improved dramatically in the stimulation group, with 47% achieving complete continence. In contrast, there were no significant improvements observed in the supportive therapy group. Thus, sacral nerve stimulation appears to be a promising new treatment for fecal incontinence with relatively limited complications. FDA approval for fecal incontinence seems likely in the near future, and the minimally invasive nature of this procedure makes it a desirable first-line surgical option.
Therapeutic Approach to Constipation

As with fecal incontinence, it is imperative to attempt conservative management of constipation and defecatory dysfunction before performing surgery. Initial evaluation should focus on identifying any underlying systemic conditions (Table 28.1) associated with disordered defecation and optimizing treatment for these conditions. In the absence of systemic etiologies, it is reasonable to proceed with empiric, nonsurgical management, such as diet, fiber supplementation, and toileting behavior changes. Biofeedback and laxatives can be used in more severe cases. Initially, disimpaction with regular enemas or laxatives is essential if the patient has fecal impaction. Symptoms that persist despite a trial of conservative management indicate the need for further evaluation of colonic and anorectal function. A diagnostic algorithm for idiopathic (nonsystemic) constipation is given in Figure 28.7. Treatment should then be tailored to the underlying cause. Some conditions associated with disordered defecation are best treated using nonsurgical techniques, whereas others may benefit from surgery once conservative management has failed. As with fecal incontinence, the lack of consistent outcome measures in the published literature makes it difficult to compare efficacy among treatments.

Figure 28.7 Diagnostic Algorithm for Idiopathic Constipation. (From Ellerkmann MR, Kaufman H. Defecatory dysfunction. In: Bent AE, Ostergard DR, Cundiff GW, et al., eds. Ostergard’s urogynecology and pelvic floor dysfunction. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2002:358, with permission.)
Nonsurgical Treatment

Nonsurgical management focuses on maximizing anorectal function through alteration of stool characteristics or behavioral modification. Stool consistency and volume can be manipulated by dietary and pharmacologic means to achieve passage of one stool every day or every other day. Additionally, behavior modification can be employed using regular toileting to prevent fecal impaction. Physical therapy and biofeedback can also be useful for coordinating pelvic floor and anal sphincter relaxation with defecation.

Pharmacologic Approaches

Dietary Modification and Fiber

The role of increased fluid and fiber intake for the treatment of constipation is controversial. It has been a commonly accepted belief that constipation is caused by low fluid intake and can be improved by increasing consumption. Several studies showed no association between fluid intake and constipation (151–153). However, one large study of 21,012 nursing home residents found a weak association between decreased fluid intake and constipation with an odds ratio of 1.49 (154). In one interventional study, increased fluid intake failed to improve stool frequency, consistency, or defecatory dysfunction in children (155). Another interventional study using fiber and mineral water displayed an increase in stool frequency and a decrease in laxative use in adults with constipation (156). This study lacked baseline data collection resulting in recall bias, and the use of mineral water containing magnesium may confound the results because of its mild laxative effect. Overall, the existing data do not support increased fluid intake to treat constipation unless there is evidence of dehydration (151).

The addition of fiber may decrease constipation through several mechanisms. Fiber acts as a stool bulking agent and improves stool consistency through water absorption. It can also act as a substrate for bacterial proliferation and gas production. These mechanisms of action are believed to result in increased colonic motility, decreased transit time, and increased stool frequency.

Fiber therapy appears to have a beneficial effect in the treatment of diverticular disease, constipation of pregnancy, and possibly IBS (19,157,158). Its efficacy for idiopathic (nonsystemic) constipation remains uncertain. Dietary fiber intake for patients with constipation was similar to that of controls in several studies (152,153). A meta-analysis of 36 randomized trials using laxatives or fiber therapy for the treatment of constipation showed that the use of fiber or laxatives resulted in increased stool frequency and improved symptoms without the presence of severe side effects (159). Conversely, another meta-analysis showed an inability to restore transit time and stool weight in constipated patients using dietary fiber (158). Approximately half of the patients in another study responded to fiber treatment, but a much better response occurred in patients without an identifiable structural or motility disorder (160).
Consequently, a low-fiber diet may be a contributing factor in chronic constipation, and an empiric trial of fiber therapy can be expected to help some patients. Side effects of increased gas production may limit compliance with treatment, so doses should be slowly titrated. Fiber therapy should be avoided in patients with impaction, megacolon or megarectum, or obstructive gastrointestinal lesions. Fiber therapy should also be used with caution in patients with cognitive dysfunction (dementia), difficulty with ambulation, and underlying neurogenic disease for fear of worsening the condition. There is no evidence to substantiate the recommendation for extra water intake with fiber supplements (161).

Laxatives

Laxatives are commonly used to treat constipation and disordered defecation. Many classes of laxatives are available over the counter.

Bulk-Forming Laxatives
These come in natural forms (psyllium) as well as synthetic form (Metamucil, Konsyl, Citrucel) and are felt to be the safest laxatives. They have mechanisms of action and side effects similar to that of fiber (162).

Hyperosmolar Laxatives
These consist of poorly absorbed substances that increase intraluminal osmolarity and water absorption. This action results in greater stool volume with decreased consistency. Examples include nonabsorbable sugars (lactulose and sorbitol), glycerin, and polyethylene glycol (GoLytely, MiraLAX). Polyethylene glycol is a common preoperative bowel preparation. Side effects are diarrhea, increased flatus, and abdominal cramping (162).

Emollient Laxatives
These agents are divided into two subsets: docusate salts and mineral oil. The docusate salts have hydrophilic and hydrophobic properties similar to detergents. They soften stool and decrease surface tension by increasing stool water and lipid content. Examples include docusate calcium (Surfak), docusate potassium (Dialose, Kasof), and docusate sodium (Colace, Comfolax). They also improve the absorption of other laxatives and are combined in preparations with stimulant laxatives such as Correctol, Peri-Colace, and Feen-a-Mint. The limited absorption of mineral oil allows it to penetrate and soften the stool. It can be used orally or rectally. Prolonged daily use can lead to decreased absorption of the fat-soluble vitamins A, D, E, and K. Use of mineral oil should be avoided in elderly and debilitated patients, as well as in those with esophageal motility disorders because of the potential for aspiration pneumonia. Side effects include diarrhea, anal leakage, and pruritus ani (162–164).

Saline Laxatives
These usually contain magnesium cations and phosphate anions that are relatively nonabsorbable and produce an osmotic gradient with increased water absorption. They also stimulate intestinal motility by increasing cholecystokinin release. Fast-acting effects can be seen with both oral (2–6 hours) and rectal (15 minutes) preparations. Examples include magnesium citrate, magnesium hydroxide (Milk of Magnesia), magnesium sulfate, sodium phosphate, and biphosphate (Phospho-soda, Fleet enema). Although generally well tolerated, electrolyte abnormalities can occur. These side effects should be avoided in patients with renal insufficiency because of the potential for magnesium toxicity (162–164).

**Stimulant Laxatives**

These are found in three basic types: castor oil, anthraquinones, and diphenylmethanes. A metabolite of castor oil, ricinoleic acid, increases intestinal motility and secretion. Anthraquinones (cascara sagrada, senna [Senokot], casanthranol [aloe], and danthron) are absorbed by the small intestine and stimulate motility by increasing intraluminal fluid and electrolyte content. Diphenylmethanes (phenolphthaleins [Feen-a-Mint, Correctol] and bisacodyl [Dulcolax]) have a mechanism of action similar to anthraquinones. These agents are potent and are intended for short-term use in cases refractory to bulk or osmotic laxatives. It has been a long-standing belief that prolonged use can lead to a dilated atonic colon known as cathartic colon syndrome, melanosis coli, or neuronal degeneration. A recent article refutes the theory that stimulant laxatives damage the autonomic nervous system when used at recommended doses (151). Other side effects include cramping, nausea, and abdominal pain (162–164).

**Prokinetic Agents**

Medications that stimulate gastrointestinal motility primarily through neuromodulation of acetylcholine levels include metoclopramide, cisapride, cholinergic agonists (bethanechol), cholinesterase inhibitors (neostigmine), and serotonin agonists. Their efficacy in the treatment of chronic idiopathic constipation is uncertain. Metoclopramide is better for upper gastrointestinal motility disorders, whereas cisapride appears to exert its effect at the level of the colon (162–164).

**Behavioral Approaches**

Behavioral techniques such as biofeedback and bowel regimens may have a role in certain conditions associated with constipation and defecatory dysfunction. Overall, these approaches have far less application to disordered defecation than to fecal incontinence. Biofeedback is important in the treatment of dyssynergic defecation. Relaxation techniques and behavioral modification may be helpful for IBS. Bowel regimens in conjunction with laxatives, suppositories, and enemas can facilitate emptying by optimizing the gastrocolic reflex and increased peristaltic activity.
Efficacy of Nonsurgical Treatment

Irritable Bowel Syndrome

The most commonly used first-line treatment for the constipation variant of IBS is fiber supplementation and osmotic laxatives. The efficacy of bulking agents for this condition is controversial, and many studies, including meta-analyses, exhibit an effect similar to placebo. There may be benefit to the use of fiber because of the high placebo effect with IBS treatment and lack of serious adverse events associated with its use. However, patients may experience exacerbation of bloating and abdominal discomfort with fiber therapy. Randomized trials and meta-analysis revealed a beneficial effect of polyethylene glycol (MiraLAX) over placebo for the treatment of chronic constipation. In addition, polyethylene glycol was better than tegaserod and lactulose for chronic constipation (165–167). They can be useful as adjunctive treatment options, but can also exacerbate abdominal pain and discomfort. A newer class of drugs, serotonin 5HT4 agonist tegaserod (Zelnorm), stimulates peristalsis, increases colonic motility, decreases intestinal transit times, and reduces visceral hypersensitivity. The recommended dose is 6 mg twice daily. Randomized trials have consistently shown an approximately 10% greater improvement in global IBS symptoms when compared with placebo. Improvement in the bloating and pain symptoms also occurred. No episodes of ischemic colitis or cardiac toxicity have been reported with the use of this medication, and the most common side effects are diarrhea and headache. Cisapride, a 5HT4 agonist with partial 5HT3 antagonist actions, has been withdrawn from use secondary to rare cardiac toxicity. Additional 5HT4 agonists, 5HT3 agonists, and cholecystokinin antagonists are in development (95,96).

Colonic Inertia and Slow-Transit Constipation

Patients with slow-transit constipation tend to respond poorly to fiber supplementation, although most have already tried an empiric trial of fiber before testing to confirm the diagnosis (160). Some patients may benefit from regular toileting, either in the morning or after meals when there is increased colonic motor activity. Biofeedback may have modest short-term benefits, but the long-term effect is questionable (168). Enemas and suppositories can be used in conjunction with bowel regimens. It is also reasonable to attempt a trial of any of the laxatives listed in Table 28.10. Stimulant laxatives are commonly used, but questions remain about the development of neuronal degeneration with prolonged usage. It is imperative that patients adhere to and not exceed the recommended dosages. Data regarding laxative use for this condition have failed to show a significantly better response than placebo. Prokinetic agents are intuitively the ideal choice to stimulate colonic motility. Currently there is only one available prokinetic agent, tegaserod, approved for the treatment of constipation that improves colonic transit. Its data are almost entirely based on treatment of IBS, and there is a lack of information for its use in slow-transit constipation. Other prokinetic agents in various stages of testing include bethanechol, neostigmine,
cholecystokinin antagonists, misoprostol, colchicine, neurotrophin-3, and other 5HT4 agonists such as prucalopride and mosapride (49).

**Dyssynergic Defecation**

As with slow-transit constipation, initial management using bowel regimens, laxatives, enemas, suppositories, and fiber supplementation is appropriate for patients with dyssynergic defecation, yet many will have already tried conservative management before undergoing testing to confirm the diagnosis. These treatments are relatively well tolerated with few serious side effects. They have not been shown to have greater efficacy when compared with placebo, and their role in the treatment of dyssynergic defecation remains uncertain. Specific treatment for this condition tends to focus on biofeedback because of studies indicating that this is an
acquired behavioral disorder of defecation. Modalities such as diaphragmatic muscle training, simulated defecation, and manometric or electromyography-guided anal sphincter and pelvic muscle relaxation have been employed independently or combined with other techniques. These techniques have yielded symptomatic improvement in approximately 60% to 80% of patients. Many patients with dyssynergic defecation also have abnormal rectal sensation, so rectal sensory conditioning may provide additional benefit (33,49,169,170). Others have tried botulinum toxin injections to paralyze the puborectalis and anal sphincter muscle. Small case series have shown modest early improvement, but the results do not appear to be long lasting (171,172). A recent randomized trial of 48 participants comparing botulinum toxin to biofeedback retraining found better initial improvement with the botulinum toxin (70% vs. 50%) but no difference at 1 year (33% vs. 25%) (173).

**Pessary for Treatment of Pelvic Organ Prolapse**

Pessaries of various shapes and sizes have been used for centuries to treat pelvic organ prolapse (174). They are a safe alternative to surgery, with the most common complications being increased vaginal discharge and erosion or ulceration of the vaginal wall. Although pessaries represent a common therapeutic modality, there are limited data regarding fitting and management (175). Even less is known about which type of pessary is better for enteroceles and rectoceles, although the site of prolapse does not appear to affect the ability to retain a pessary (176). Pessaries can be divided into subtypes of supportive and space occupying (177). Some of the space-occupying pessaries, such as the Gellhorn and cube, use a suction mechanism to maintain vaginal retention, whereas others, like the donut, do not. In theory, space-occupying pessaries and those that exert forces against the posterior wall and vaginal apex (donut, inverted Gehrung) should aid in treatment of rectoceles and enteroceles. However, there are few data regarding the efficacy of pessaries for relieving symptoms of disordered defecation. One prospective study found that stage III or IV posterior vaginal wall prolapse was an independent predictor for discontinuation of pessary use in favor of surgical repair (178). The only randomized crossover trial comparing different types of pessaries (ring and Gelhorn) found improvement in quality-of-life measures with each pessary that did not differ. Protrusion and voiding dysfunction symptoms were most improved (179). More research is needed to determine the role of pessaries for treatment of rectoceles and enteroceles as well as symptoms that are likely to be improved using a pessary.
Surgical Treatment
Following is a review of the efficacy of various surgical treatments for specific conditions associated with constipation and disordered defecation.

Slow Transit/Colonic Inertia
Subtotal colectomy with ileosigmoid or ileorectal anastomosis is considered by many to be the surgical treatment of choice for slow-transit constipation refractory to medical management. Most surgeons restrict the use of this surgical procedure to the most extreme cases and typically operate on fewer than 10% of patients. Strict criteria for surgery include the following: chronic, severe, disabling symptoms unresponsive to medical therapy; slow transit in the proximal colon; no evidence of pseudo-obstruction; and normal anorectal function (162). Success rates are variable and depend on several factors. An extensive review of colectomy for slow-transit constipation analyzed 32 studies from 1981 to 1988 and found satisfaction rates ranged from 39% to 100% (180). Higher success rates occurred in studies in the United States (n = 11, median 94%, range 75%–100%) and prospective studies (n = 16, median 90%, range 50%–100%). Superior outcomes occurred in those who had a complete physiologic evaluation and proven slow-transit constipation. Patients with anismus had higher rates of recurrent symptoms and lower satisfaction levels (181). Poorer outcomes occurred with ileosigmoid and cecorectal anastomosis than with ileorectal anastomosis. Those with segmental resection (hemicolectomy) had the worst outcome. None of the studies had a comparison group, and outcomes were variable and lacking validated measures. Morbidity associated with the operation included small bowel obstruction (median 18%, range 2%–71%), need for reoperation (median 14%, range 0%–50%), diarrhea (median 14%, range 0%–46%), fecal incontinence (median 14%, range 0%–52%), recurrent constipation (median 9%, range 0%–33%), persistent abdominal pain (median 41%, range 0%–90%), and permanent ileostomy (median 5%, range 0%–28%). Mortality ranged from 0%–6% (182). A quality-of-life study revealed that the score correlated poorly with frequency of bowel movements. However, a lower score was seen in those patients who had persistent abdominal pain, diarrhea, fecal incontinence, and permanent ileostomies. Overall satisfaction with the procedure was very high and correlated with the quality-of-life score (183).

Surgical alternatives to subtotal colectomy include ileostomy, cecostomy with antegrade continence enemas, and sacral nerve stimulation. Subtotal colectomy has never been directly compared with ileostomy, but those who had a permanent diversion after subtotal colectomy had lower quality-of-life scores. Patients undergoing cecostomy with antegrade continence enemas can expect to have satisfactory function approximately half of the time, with most requiring additional revision procedures secondary to stomal complications (184). Although sacral nerve stimulation has primarily been used for fecal incontinence, the results of a few small studies evoke optimism for its use in chronic constipation and slow-transit constipation (146,185–187).
Pelvic Organ Prolapse

The variety of surgical treatment techniques for the repair of rectocele include posterior colporrhaphy, defect-directed repair, posterior fascial replacement, transanal repair, and abdominal repair with sacral colpexy. When an enterocele is present, a culdoplasty is usually performed. In cases of perineal descent, abdominal sacral colpoperineopexy is the procedure of choice. Suture rectopexy can be performed in conjunction with sacral colpoperineopexy if rectal prolapse is present. Despite the routine use of these procedures, data are limited regarding symptomatic improvement of disordered defecation. Greater detail regarding the specific techniques for many of these procedures is provided in Chapter 27. This section will focus on surgical outcomes, including anatomic cure of prolapse, improvement of defecatory dysfunction symptoms, and morbidity associated with the procedure.

Posterior Colporrhaphy

Posterior colporrhaphy has been the surgical procedure for rectocele repair preferred by gynecologic surgeons for more than 100 years. Traditional posterior colporrhaphy narrows the vaginal caliber through plication of the rectovaginal septum and usually includes a perineorrhaphy, which narrows the introitus. Despite its broad use, there are few data regarding long-term anatomic success, symptomatic improvement, and sexual function following the procedure. The outcomes of several studies are summarized in Table 28.11 (189–207). Anatomic cure and relief of vaginal bulge occurred in 76% to 96% of patients. In these studies, the procedure was ineffective at treating constipation, vaginal digitations (splinting), and fecal incontinence. Dyspareunia developed in 8% to 26% of patients with and without levator plication (188–192,207). As early as 1961, high rates of dyspareunia have been reported with this procedure in as many as 50% of patients (208).

</table>
Many feel that the successful anatomic support obtained with this procedure is offset by the modest relief of functional symptoms and high rate of de novo dyspareunia. However, a recent prospective case series of 38 women undergoing posterior colporrhaphy along with concomitant procedures for rectocele and obstructed defecation revealed markedly different results (209). Fascial plication was performed without levator plication, and perineal body reconstruction rather than routine perineorrhaphy was employed when indicated. Anatomic cure rate was 87% at 12 months and 79% at 24 months. Subjective cure rate was 97% at 12 months and 89% at 24 months. There was significant improvement in preoperative and postoperative symptoms for constipation (76% vs. 24%), digitations (100% vs. 16%), awareness of prolapse (100% vs. 5%), obstructed defecation (100% vs. 13%), and dyspareunia (37% vs. 5%). There was no difference in fecal incontinence and only one case of de novo dyspareunia. The authors attribute their improved anatomic and functional outcomes and combined improvement in dyspareunia to exclusion of levator plication, perineorrhaphy, and excision of vaginal epithelium. An additional benefit may be derived during mobilization of the vaginal epithelium, when scar tissue from prior episiotomy or surgery is divided. They also found that preoperative defecating proctography was of limited value and have stopped its routine use as part of the preoperative evaluation for women with symptomatic rectoceles and obstructive defecation.

### Defect-Directed Repair

The goal of a defect-directed repair or site-specific repair is to restore normal anatomy (36). This procedure can be combined with a perineal body reconstruction, if necessary, but usually does not routinely involve perineorrhaphy. Table 28.11 lists the anatomic and functional outcomes for this type of repair. **Anatomic cure rates range from 82% to 100%, which are similar to those for posterior colporrhaphy.** This procedure also resulted in modest improvement for symptoms of difficult evacuation, vaginal bulge, and vaginal digitations, which appear to be slightly better than for posterior colporrhaphy (193–197,207). Constipation symptoms significantly

decreased in only one study (193). All studies reported low rates of de novo dyspareunia with good functional and anatomic outcomes, but the long-term durability of the procedure is unknown. All but one of these studies included concomitant prolapse and urinary incontinence procedures.

A randomized clinical trial of 106 women with stage II or greater posterior vaginal wall prolapse compared posterior colporrhaphy, defect-directed rectocele repair, and defect-directed repair augmented with a porcine small intestinal submucosal (210). Participants completed validated pelvic floor instruments at baseline and 6 months, 1 year, and 2 years after surgery. Anatomic failure was defined as POP-Q system point Bp greater than or equal to −2 at 1 year. There was a significant improvement in prolapse and colorectal scales in all groups with no differences between groups. The proportion of subjects with functional failures was 15% overall and not significantly different between groups. Posterior colporrhaphy and defect-directed repairs resulted in similar anatomic and functional outcomes, although the addition of a porcine-derived graft did not improve anatomic outcomes. On average, all bowel symptoms evaluated were significantly improved 1 year after surgery, with no differences between treatment groups. The development of new “bothersome” bowel symptoms after surgery was uncommon (11%). After controlling for age, treatment group, comorbidities, and preoperative bowel symptoms, corrected postoperative vaginal support (stage 0 or I) was associated with a reduced risk of postoperative straining (adjusted OR 0.17; 95% CI, 0.03–0.9) and feeling of incomplete emptying (adjusted OR 0.1; 95% CI, 0.01–0.52). This led the authors to conclude that resolution or improvement in bowel symptoms can be expected in the majority of women after rectocele repair (211).

Transanal Repair

Transanal repair involves repair of the rectocele through a transanal incision with excision of redundant rectal mucosa and plication of the rectovaginal septum and rectal wall. The procedure was developed and is primarily used by colorectal surgeons to treat constipation or obstructed defecation associated with “low” or distal rectoceles. The advantages of this approach include excision of redundant rectal mucosa and the ability to treat other anorectal pathology, such as hemorrhoids or anterior rectal wall prolapse (212). Disadvantages include the inability to repair higher rectoceles, enteroceles, cystoceles, uterine prolapse, and defects in the perineal body or anal sphincter (213). Major complications of infection (6%) and rectovaginal fistula (3%) are relatively rare (203). Most studies did not require vaginal bulging or protrusion symptoms as a prerequisite for surgery. The results of several studies are summarized in Table 28.11. The anatomic cure rate was 70% to 98%, and symptoms of constipation, difficult evacuation, and vaginal digitations appear to improve (202–207).

Recent reviews have compared transanal with transvaginal rectocele repair using the results of two small, randomized control trials (214–217). Women with compromised sphincter function and other symptomatic prolapse were excluded. The
results for transvaginal repair were superior to those for transanal repair with respect to subjective failure rate (relative risk [RR] 0.36; 95% CI, 0.13–1.0) and objective failure rate (RR 0.24; 95% CI, 0.09–0.64) (214). In one study, a significant decrease occurred in the depth of rectocele on postoperative defecography for the transvaginal group compared with the transanal group (2.73 vs. 4.13 cm, respectively) (217). The transvaginal group had fewer problems with bowel evacuation, but this finding was not statistically significant. In one study, researchers discovered that 38% of patients developed fecal incontinence following transanal repair (188). In the two randomized trials, no significant differences were seen in the rate of fecal incontinence or dyspareunia, but the studies were underpowered to detect a difference (216,217). Although a vaginal approach has been considered superior to a transanal approach for rectocele repair, studies are retrospective and impossible to compare because the indications for transanal repairs are generally different from those for transvaginal repairs. A prospective, randomized trial with adequate power to evaluate symptomatic outcomes of bowel and sexual function along with anatomic cure is warranted.

Posterior Fascial Reinforcement

Rectocele repair with graft augmentation is becoming more common, despite a paucity of supporting evidence indicating its benefits over standard procedures. The reason for its emergence is the theory that vaginal hernia repairs behave similar to abdominal hernia repairs, which have a documented decrease in recurrence when augmented with grafts. A variety of graft materials have been employed with posterior colporrhaphy and defect-directed repairs including autograft, allograft, xenograft, and synthetic mesh. There are no comparison data to aid in selecting the optimal graft. The purpose of the graft is debatable. It can either be intended to replace existing fascia as a permanent barrier or to provide an absorbable scaffold for collagen deposition, scar formation, and remodeling. The ideal material should have a low erosion rate, be relatively inexpensive, and decrease recurrence rates without causing bowel or sexual dysfunction. The outcomes for rectocele repair using graft materials placed either vaginally or abdominally appear in Table 28.11. High anatomic cure rates of 89% to 100% occurred, and symptoms of constipation, difficult evacuation, and vaginal bulge also appeared to improve.

One randomized trial used absorbable vaginal mesh for rectocele repair (192). Patients were randomly assigned to fascial replacement with polyglactin 910 mesh at the time of anterior and posterior colporrhaphy. There were no differences in recurrence rates when comparing 70 women with a traditional colpoperineorrhaphy with 73 women having a traditional repair plus mesh: 10% versus 8%, respectively. This study did not describe changes in bowel or sexual function, and there were no mesh-related adverse events. As previously noted, the randomized controlled trial comparing posterior colporrhaphy, defect-directed repair, and defect-directed repair with porcine small intestine submucosal graft augmentation revealed higher anatomical failure rates in the graft-augmented
group compared to the site-specific alone or the posterior colporrhaphy group (46% vs. 22% and 14%, respectively; \( P = .02 \)), with no difference in symptom outcomes (210). Importantly, the risks of vaginal mesh erosion and severe complications may be relatively low but carry significant morbidity, including rectovaginal fistula, persistent vaginal bleeding and discharge, dyspareunia, and the need for additional surgery (199,207). Nonsynthetic grafts appear to be safer, with fewer erosions compared with synthetic grafts; however, there is no evidence to suggest that the addition of a graft to the posterior compartment improves outcomes (210,218,219).

**Abdominal Rectocele Repair**

The abdominal approach to rectocele repair may be of value when a superior defect in the rectovaginal fascia occurs in a patient with accompanying enterocele, uterine prolapse, or vault prolapse. If a patient is undergoing an abdominal or laparoscopic procedure such as a sacral colpopexy, the graft can be extended along the posterior vaginal wall to correct proximal defects in the rectovaginal septum (220). There are limited data regarding the efficacy of abdominal rectocele repair. The indication for this procedure, as well as the need for additional vaginal repair of distal defects, is often determined intraoperatively. An ancillary study from the Pelvic Floor Disorders Network evaluating bowel symptoms 1 year after sacrocolpopexy found that the majority of bothersome bowel symptoms resolve after this procedure. There was no difference in postoperative bowel symptoms among those who underwent a concomitant rectocele repair and those who did not. It is important to note that the study was not developed to evaluate the impact of concomitant rectocele repair on bowel symptom resolution, and those who underwent a rectocele repair had more severe baseline bowel symptoms including worse obstructive symptom (221).

**Sacral Colpoperineopexy for Perineal Descent**

Sacral colpoperineopexy is a modification of sacral colpopexy aimed at correction of apical prolapse combined with rectocele and perineal descent (39). A continuous graft is placed from the anterior longitudinal ligament of the sacrum down to the perineal body. This procedure can be accomplished either through a total abdominal approach or a combined abdominal and vaginal procedure. If performing a total abdominal approach, the rectovaginal space is opened, and the rectum is dissected off the posterior vaginal wall and rectovaginal septum toward the perineal body. The graft is then sutured to the perineal body or as close to it as possible. A rectovaginal examination with the surgeon’s nondominant hand facilitates this attachment by supporting the perineal body. The graft is secured to additional points along the posterior vaginal wall and apex, and sacral colpopexy is completed in the usual fashion.

If performing a combined abdominal and vaginal approach, the graft is secured to the perineal body vaginally. The posterior vaginal wall is opened, and a defect-directed rectocele repair is performed. Sacral colpopexy is accomplished in the
usual fashion except that the vaginal dissection is opened superiorly, creating a window to the abdominal dissection. The graft can then be passed down from the abdominal field to the vaginal field and anchored inferiorly to the perineal body and laterally to the arcus tendineus fascia rectovaginalis (Fig. 28.8).

Figure 28.8 Abdominal sacral colpoperineopexy with sigmoid resection and suture rectopexy. This sagittal view shows the posterior graft sutured to the rectovaginal fascia and perineal body after defect-directed rectocele repair. The anterior graft is sutured to the pubocervical fascia. Both sheets will be secured to the sacral periosteum to the right of the rectum. Rectopexy sutures (left) have not yet been tied and secured. (Courtesy of Geoffrey W. Cundiff, M.D.)

Short-term outcomes for 19 patients who underwent sacral colpoperineopexy indicated good anatomic results for apical and posterior support as well as for perineal descent (39). Complete cessation of defecatory dysfunction symptoms was accomplished in 66% of patients. In a report of outcomes for a slightly different variation of the sacral colpoperineopexy, the authors' technique involved attachment of Marlex mesh to the perineal body using a needle carrier (222). The failure rate was 25% and mesh erosion rate was 5% for 205 patients with up to 10-year follow-up. A study of Mersilene mesh erosion rates related to sacral colpopexy and sacral colpoperineopexy noted similar erosion rates between sacral colpopexy and colpoperineopexy when the vagina was not opened (3.2% vs. 4.5%, respectively) (223). However, the erosion rate was 16% with vaginal suture placement and 40% when the mesh was placed vaginally. The use of nonsynthetic grafts such as dermal allograft and xenograft may help prevent high erosion rates. In a case series of 11 patients, researchers performed sigmoid resection (if indicated) and suture rectopexy in conjunction with sacral colpoperineopexy using...
AlloDerm for women with coexistent rectal prolapse, perineal descent, and defecatory dysfunction. Early follow-up (12.5 ± 7.7 months) revealed excellent improvement of defecatory dysfunction symptoms and quality-of-life considerations, with an 82% cure of perineal descent (224). A recently published retrospective cohort of 38 women revealed high satisfaction following abdominal sacral colpoperineopexy, despite the persistence of obstructed defecation symptoms 5 years after surgery (225). **Sacral colpoperineopexy may have value for a select group of patients**, but larger prospective series with long-term anatomic and symptomatic outcomes are necessary to evaluate the durability of this procedure.

### Rectal Prolapse

Numerous surgical procedures have been described for the treatment of rectal prolapse and are broadly categorized into perineal or abdominal approaches. Most surgeons prefer an abdominal procedure because of lower recurrence rates, reserving perineal procedures for more debilitated patients.

#### Abdominal Procedures

**Abdominal procedures vary with respect to the extent of rectal mobilization, method of rectal fixation, and inclusion or exclusion of bowel resection.** During abdominal rectopexy, the mesorectal plane is developed and the rectum mobilized down to the pelvic floor posteriorly, with care taken to identify and preserve the hypogastric nerves. Division of the lateral ligaments may or may not be performed. The concern is that division of the lateral ligaments will lead to rectal denervation and increased postoperative constipation. If performing a suture rectopexy, the fascia propria of the rectum is secured to the sacral periosteum from S-1 to S-3 (226). If performing a sigmoid resection with the rectopexy (Frykman-Goldberg resection rectopexy), the bowel resection is performed after mobilization and before suturing (227). The theoretical advantages of a rectosigmoid resection are creation of a dense area of fibrosis between the anastomotic suture line and the sacrum; removal of abundant rectosigmoid, avoiding torsion or volvulus; additional fixation through straightening of the left colon and decreased mobility from the phrenocolic ligament; and relief of constipation in select patients. It is typically reserved for patients with a long redundant sigmoid colon, although specific criteria have not been proposed. Mesh rectopexies are usually avoided because of concern for increased complications and infections associated with placement of a foreign body at the time of bowel resection. There are two basic types of mesh rectopexy: **posterior mesh rectopexy** and **anterior sling rectopexy (Ripstein procedure)** (228,229). A variety of materials have been used for this procedure, including absorbable and permanent mesh. The assumption is that placement of this material will provide increased support through increased fibrous tissue formation. During the Ripstein procedure, an anterior sling of fascia lata or synthetic mesh is placed in front of the rectum and sutured to the sacrum. Most surgeons avoid this procedure because of fear of obstructed defecation. Modifications using a posterolateral wrap have been
developed to resolve this problem.

In a series of more than 10 patients, there were five open series and five laparoscopic reports for suture rectopexy (230). The recurrence rates ranged between 0% and 9%. Most reports showed an improvement in fecal incontinence symptoms, but the results for constipation were variable. There were no mortalities noted and no difference between laparoscopic and open results. For posterior mesh rectopexy, there were 14 open series and five laparoscopic reports. The recurrence rates ranged between 0% and 6%. As with suture rectopexy, there was general improvement in fecal incontinence, mixed results for constipation, and no differences between laparoscopic and open outcomes. The mortality rate was between 0% and 3%, with increased rates of infection if resection rectopexy was performed. For anterior sling rectopexy (Ripstein procedure), there were eight studies with a recurrence rate between 0% and 12%. Again, there was a trend toward improvement of fecal incontinence and mixed response for constipation. Mortality ranged from 0% to 3%. For resection rectopexy (Frykman-Goldberg procedure), there were nine open series and three laparoscopic reports. Recurrence ranged between 0% and 5%. There was general improvement in continence as well as an overall reduction in constipation observed in most studies. Mortality rate was 0% for all studies but one, in which it was 6.7% (231). This study was a small, randomized trial comparing 15 patients undergoing resection rectopexy to 15 patients undergoing absorbable mesh rectopexy. The patient who died was in the resection group and had a myocardial infarction. The authors concluded that sigmoid resection did not seem to increase operative morbidity but tended to diminish postoperative constipation, possibly by causing less outlet obstruction. The study was underpowered to detect a difference in morbidity or mortality.

The laparoscopic series demonstrated similar safety and efficacy to the open techniques, and the effect on continence and constipation tended to mirror the type of rectopexy performed. In a small, randomized trial, there were significant short-term benefits with laparoscopic rectopexy compared with open rectopexy, including earlier ambulation, more rapid return to normal diet, shorter hospital stay, and lower morbidity (232). Most surgeons believe that there are no differences in recurrence rates between suture and mesh rectopexy. Consequently, the role of mesh in these procedures is suspect. The role of division of the lateral ligaments is somewhat controversial. A Cochrane review performed in 2008 concluded that division of the lateral ligaments was associated with less recurrent prolapse but more postoperative constipation (233). The authors acknowledged the limitations of their review, which consisted of very few trials with small sample sizes and methodological weakness. A review of seven open and four laparoscopic series involving division of the lateral ligaments revealed a general improvement in fecal incontinence and either no change or worsening of constipation (230). Conversely, there were 15 open and 4 laparoscopic series with preservation of the ligaments that displayed improved continence and a trend toward reduced constipation. This study suggests that preservation of the lateral ligaments is associated with an improvement in fecal incontinence and constipation symptoms.
Perineal Procedures

Perineal procedures are more easily tolerated because they avoid laparotomy. Thus, they are ideal for patients at high risk for perioperative and postoperative morbidity and mortality. There are basically two perineal procedures: the Delorme procedure and perineal rectosigmoidectomy (Altemeier operation). Perianal encirclement procedures such as the Thiersch procedure are not recommended because of poor success rates, high recurrence rates, and fecal impaction.

The Delorme procedure was first described in 1900 and involves separation of the rectal mucosa from the sphincter and muscularis propria, followed by resection of the rectal mucosa and plication of the distal rectal wall (muscularis propria) \((234)\) \((Fig. 28.9)\). A review of 10 series found a recurrence rate ranging between 4% and 38% and mortality rates of 0% to 4% \((230)\). The low mortality rates are impressive considering the higher-risk population; however, the recurrence rates make it a less desirable procedure among healthy patients. There was a general improvement in fecal incontinence and constipation. Fecal incontinence (presumably indicating anal sphincter disruption or denervation), chronic diarrhea, and severe perineal descent are associated with failure of this procedure \((235)\). The Delorme operation may be preferred in cases when the prolapsing segment is shorter than 3 to 4 cm or there is no circumferential full-thickness prolapse, making perineal rectosigmoidectomy difficult to perform \((230,236)\).

![Figure 28.9 Delorme's procedure](image)

Delorme's procedure. After mucosal stripping to the full extent of the prolapse, the circular smooth muscle or the rectum is plicated. A mucosa-to-mucosa anastomosis is then performed.

Perineal rectosigmoidectomy (Altemeier operation) has become the perineal procedure of choice \((237)\). Among 12 studies, performance of full thickness excision of the rectosigmoid was associated with recurrence rates from 0% to 16% and mortality rates of 0% to 5%. Patients generally have minimal pain and a relatively uneventful postoperative course. Recurrent prolapse probably reflects inadequate resection. Incontinence results are modest at best but seem to improve substantially with the addition of levatorplasty. The addition of levatorplasty also appears to decrease the short-term recurrence rate, but there is no significant change in constipation with this procedure \((238)\). Most agree that perineal rectosigmoidectomy with levatorplasty is the
best procedure for very elderly patients and those with profound comorbidity. This is the preferred approach for patients with incarcerated, strangulated, or even gangrenous prolapsed rectal segment who are not candidates for abdominal rectopexy. Although there is a general consensus that abdominal rectopexy is better than perineal rectosigmoidectomy, there is only one small, prospective, randomized controlled trial comparing these procedures. This study did not have the power to detect a difference in recurrence rates but found that patients undergoing abdominal resection rectopexy had less fecal incontinence and better physiological results than patients who had perineal rectosigmoidectomy (233,239).

Normal pubertal development occurs in a predictable orderly sequence over a definite time frame.
The major causes of delayed puberty include anatomic genital tract abnormalities and hypo- and hypergonadotropin amenorrhea.
When pubertal development occurs asynchronously with development of breasts in the absence of significant pubic and axillary hair, the diagnosis is usually androgen insensitivity.
The most common cause of precocious puberty is constitutional (idiopathic), but more serious causes must be ruled out and therapy geared toward optimizing adult height.
The most common cause of heterosexual development at the expected age of puberty is polycystic ovary syndrome.

Puberty is the period during which secondary sexual characteristics develop and the capability of sexual reproduction is attained. The physical changes accompanying pubertal development result directly or indirectly from maturation of the hypothalamus, stimulation of the sex organs, and secretion of sex steroids. Hormonally, puberty in humans is characterized by the resetting of the classic negative gonadal steroid feedback loop, alterations in circadian and ultradian (frequent) gonadotropin rhythms, and the acquisition in the woman of a positive estrogen feedback loop, which controls the monthly rhythm as an interdependent expression of gonadotropins and ovarian steroids.

The ability to evaluate and treat aberrations of pubertal development requires an understanding of the normal hormonal and physical changes that occur at puberty. An understanding of these changes is important in evaluating young women with amenorrhea.
Normal Pubertal Development

Factors Affecting Time of Onset

The major determinant of the timing of the onset of puberty is no doubt genetic, but a number of other factors appear to influence both the age at onset and the progression of pubertal development. Among these influences are nutritional state, general health, geographic location, exposure to light, and psychological state (1). The concordance of the age of menarche in mother–daughter pairs and between sisters and in ethnic populations illustrates the importance of genetic factors (1). Typically, the age of menarche is earlier than average in children with moderate obesity (up to 30% above normal weight for age), whereas delayed menarche is common in those with severe malnutrition. Children who live in urban settings, closer to the equator, and at lower altitudes typically begin puberty earlier than those who live in rural areas, farther from the equator, and at higher elevations. The risk of earlier onset of puberty is 10 to 20 times greater after international adoption for unclear reasons (2). Other risk factors implicated for precocious puberty include exposure to estrogenic endocrine-disrupting chemicals and the absence of a father in the home (3,4). Blind girls apparently undergo menarche earlier than sighted girls, suggesting some influence of light (5).

In Western Europe, the age of menarche declined 4 months each decade between 1850 and 1960 (1). Data suggest that the trend toward earlier pubertal development may be continuing among girls (but not boys) who live in the United States (6). It is presumed that these changes represent improved nutritional status and healthier living conditions.

One of the more controversial hypotheses centers on the role of total body weight and body composition on the age of menarche. It is argued that a girl must reach a critical body weight (47.8 kg) before menarche can occur (7). Body fat must increase to 23.5% from the typical 16% of the prepubertal state, which presumably is influenced by nutritional status (8). This hypothesis is supported by observations that menarche occurs earliest in obese girls, followed by normal-weight girls, then underweight girls, and lastly anorectic girls (Fig. 29.1). The importance of other factors is indicated by observations that menarche is often delayed in morbidly obese girls, those with diabetes, and those who exercise intensely but are of normal body weight and body fat percentage. Girls with precocious puberty may undergo menarche even if they have a low body fat percentage, and other girls show no pubertal development with a body fat percentage of 27% (9). The hypothesis linking menarche to body weight and composition does not always seem valid because menarche is a late event in pubertal development.

Figure 29.1 Normal twins at 12 years of age. The heavier twin (weighing 143 lb) is clearly more advanced in puberty than the lighter twin (weighing 87 lb). Anecdotal photographs and data such as these served to provide the basis for the theory that body fat, body mass, and menarche are linked. (From Wilkins L. The diagnosis and treatment of endocrine disorders in childhood and adolescence. 3rd ed. Springfield, IL: Charles C Thomas, 1965, with permission.)
Physical Changes during Puberty

The changes associated with puberty occur in an orderly sequence over a definite time frame. Any deviation from this sequence or time frame should be regarded as abnormal. The pubertal changes, their relationship to one another, and the ages at which they occur are distinctly different in girls than in boys. Although this chapter focuses on girls, changes in boys are considered briefly.

Tanner Stage

In girls, pubertal development typically takes place over 4.5 years (Fig. 29.2). The first sign of puberty is accelerated growth, and breast budding is usually the first recognized pubertal change, followed by the appearance of pubic hair, peak growth velocity, and menarche. The stages initially described by Marshall and Tanner are often used to describe breast and pubic hair development (10).

With regard to breast development (Fig. 29.3), **Tanner stage 1** refers to the prepubertal state and includes no palpable breast tissue, with the areolae generally less than 2 cm in diameter. The nipples may be inverted, flat, or raised. In **Tanner stage 2**, breast budding occurs, with a visible and palpable mound of breast tissue. The areolae begin to enlarge, the skin of the areolae thins, and the nipple develops to varying degrees. **Tanner stage 3** is reflected by further growth and elevation of the entire breast. When the individual is seated and viewed from the side, the nipple is generally at or above the midplane of breast tissue. In most girls, **Tanner stage 4** is defined by projection of the areola and papilla above the general breast contour in a secondary mound. Breast development is incomplete until **Tanner stage 5**, in which the breast is mature in contour and proportion. In most women, the nipple is more pigmented at this stage than earlier in development, and Montgomery’s glands are visible around the circumference of the areola. The nipple is generally below the midplane of breast tissue when the woman is seated and viewed from the side. Full breast development usually occurs over 3 to 3.5 years, but it may occur in as little as 2 years or not progress beyond stage 4 until the first pregnancy. Breast size is no indication of breast maturity.

Pubic hair staging is related both to quantity and distribution (Fig. 29.4). In **Tanner stage 1**, there is no sexually stimulated pubic hair present, but some nonsexual hair may be present in the genital area. **Tanner stage 2** is characterized by the first appearance
of coarse, long, crinkly pubic hair along the labia majora. In **Tanner stage 3**, coarse, curly hair extends onto the mons pubis. **Tanner stage 4** is characterized by adult hair in thickness and texture, but the hair is not distributed as widely as in adults and typically does not extend onto the inner aspects of the thighs. Except in certain ethnic groups, including Asians and American Indians, pubic hair extends onto the thighs in **Tanner stage 5**.

The staging of male pubertal sexual maturation is based on genital size and pubic hair development. **Tanner stage 1** is prepubertal. **Tanner stage 2** of genital growth begins when testicular enlargement is first evident. Testis length along the longitudinal axis ranges from 2.5 to 3.2 cm. The size of the penis increases. Pigmented, curly pubic hair is first visible around the base of the penis. In **Tanner stage 3**, there is further growth of the penis in both length and diameter, the scrotum develops further, and testis length increases to 3.3 to 4 cm. Thicker, curly hair extends above the penis. **Tanner stage 4** involves further growth of the genitalia, with testis length ranging from 4 to 4.5 cm. Extension of pubic hair over the genital area continues, but the volume is less than in the adult. At this stage, the prostate gland is palpable by rectal examination. In **Tanner stage 5**, the genitalia are within the adult range in size. Average flaccid penile length in adult men ranges between 8.6 and 10.5 cm from tip to base. Pubic hair spreads laterally onto the medial thighs. Hair may or may not extend from the pubic area toward the umbilicus and anus.

Figure 29.5 Patterns of circulating luteinizing hormone (LH), follicle-stimulating hormone (FSH), and
Pigmented pubic hair is often the first recognized sign of male puberty even though it typically occurs 6 months after genital growth begins. Tanner stage 3 puberty often is accompanied by symmetric or asymmetric gynecomastia, and mature sperm first can be identified with microscopic urinalysis.

**Height and Growth Rate**

Plotting height increments (i.e., growth velocity) against the phases of puberty allows one to see relationships during puberty (Fig. 29.2). Girls reach peak height velocity early in puberty before menarche. As a consequence, they have limited growth potential after menarche. In contrast, boys reach peak height velocity about 2 years later than girls. Boys grow an average of 28 cm during the growth spurt, in comparison to a mean of 25 cm for girls. Adult men eventually are an average of 13 cm taller than adult women because they are taller at the onset of the growth spurt. Hormonal control of the pubertal growth spurt is complex. Growth hormone (GH), insulinlike growth factor 1 (IGF-1), and gonadal steroids play major roles. Adrenal androgens appear to be less important. Mutations limiting conversion of androgens to estrogens in males confirmed that estrogen is the major stimulus to the pubertal growth spurt in both boys and girls (11).

During the growth spurt associated with puberty, the long bones in the body lengthen and the epiphyses ultimately close. The bone or skeletal age of any
individual can be estimated closely by comparing x-rays documenting the development of bones in the nondominant hand (most commonly), knee, or elbow to standards of maturation for the normal population. The Greulich and Pyle atlas is used most often for this purpose (12). Skeletal age is more closely correlated with pubertal stage than with chronologic age during puberty. **With height and chronologic age, an individual’s bone age can be used to predict final adult height using the Bayley-Pinneau tables** (13). Bone age determinations can be used to assess the degree of delay, monitor subsequent development, and estimate final adult height.

Another practical clinical approach to predicting adult height uses midparental height. **The adjusted midparental height is calculated by adding 13 cm to the mother’s height (for boys) or subtracting 13 cm from the father’s height (for girls) and then determining the mean of the heights of the parents, including the adjusted height of the opposite-sex parent. Adding and subtracting 8.5 cm to the calculated predicted height approximates the target range of the 3rd to the 97th percentile for the anticipated adult height of the child.** This quick calculation can be of assistance in evaluating individuals with delayed or precocious pubertal development and those with short stature.

Several changes in body composition occur during pubertal development. **Although lean body mass, skeletal mass, and body fat are equal in prepubertal boys and girls, by maturity, men have 1.5 times the lean body mass and almost 1.5 times the skeletal mass of women, whereas women have twice as much body fat as men** (1). The changes in body contour in girls, with accumulation of fat at the thighs, hips, and buttocks, occur during the pubertal growth spurt. In this regard, testosterone is a potent anabolic steroid and is responsible for the major changes in boys, whereas estrogen increases total body fat in a characteristic distribution at the thighs, buttocks, and abdomen in girls.

Other physical changes show sexual dimorphism at puberty. In boys both the membranous and cartilaginous portions of the vocal cords lengthen much more than they do in girls, accounting for deepening of the voice. Comedones, acne, and seborrhea of the scalp begin because of increased secretion of adrenal and gonadal steroids at puberty. In general, early-onset acne correlates with the development of severe acne later in puberty. **The appearance of comedones in the nasal creases and behind the pinna may be the first indications of impending pubertal development.**
Hormonal Changes

By 10 weeks of gestation, gonadotropin-releasing hormone (GnRH) is present in the hypothalamus, and luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are present in the pituitary gland (14). Gonadotropin levels are elevated in both female and male fetuses before birth; the levels of FSH are higher in females. At birth, gonadotropin and sex steroid concentrations are still high, but the levels decline during the first several weeks of life and remain low during the prepubertal years. The hypothalamic–pituitary unit appears to be suppressed by the extremely low levels of gonadal steroids present in childhood. Gonadal suppression of gonadotropin secretion is demonstrated by higher gonadotropin levels in children with gonadal dysgenesis and those who undergo gonadectomy before puberty (15).

Several of the hormonal changes associated with pubertal development begin before any of the physical changes are obvious. Early in puberty, there is increased sensitivity of LH to GnRH. Sleep-entrained increases in both LH and FSH can be documented early in puberty (16). In boys, the nocturnal increases in gonadotropin levels are accompanied by simultaneous increases in circulating testosterone levels (17). In contrast, in girls, the nighttime increases in circulating gonadotropin levels are followed by increased secretion of estradiol the next day (18) (Fig. 29.5). This delay in estradiol secretion is believed to result from the additional synthetic steps required in the aromatization of estrogens from androgens. Basal levels of both FSH and LH increase through puberty. The patterns differ in boys and girls, with LH levels (measured in mIU/mL) eventually becoming greater than FSH levels (19) (Fig. 29.6). Although it now appears that gonadotropins are always secreted in an episodic or pulsatile fashion, even before puberty, the pulsatile secretion of gonadotropins is more easily documented as puberty progresses and basal levels increase (20).

Increased adrenal androgen secretion is important in stimulating adrenarche, the appearance of pubic and axillary hair, in both boys and girls. Pubarche specifically refers to the appearance of pubic hair. Progressive increases in circulating levels of the major adrenal androgens, dehydroepiandrosterone (DHEA) and its sulfate (DHEAS), begin as early as 2 years of age, accelerate at 7 to 8 years of age, and continue until 13 to 15 years of age (21–23). The accelerated increases in adrenal androgens begin about 2 years before the increases in gonadotropin and gonadal sex steroid secretion when the hypothalamic–pituitary–gonadal unit is still functioning at a low prepubertal level.

In girls, mean levels of estradiol, secreted predominantly by the ovaries, increases steadily during puberty (19). Although, as noted, increases in estradiol first appear during the daytime hours, basal levels eventually increase during both the day and night. Estrone, which is secreted in part by the ovaries and arises in part from extraglandular conversion of estradiol and androstenedione, increases early in puberty but plateaus by midpuberty. Thus, the ratio of estrone to estradiol decreases throughout puberty, indicating that ovarian production of estradiol becomes
increasingly important and peripheral conversion of androgens to estrone becomes less important during maturation.

In boys, most of the testosterone in the circulation arises from direct secretion by the Leydig cells of the testis. Testosterone induces development of a male body habitus and voice change, whereas dihydrotestosterone (DHT), produced following 5α reduction within target cells, induces enlargement of the penis and prostate gland, beard growth, and temporal hair recession during puberty. Mean plasma testosterone levels rise progressively during puberty, with the greatest increase occurring during Tanner stage 2 (24).

Growth hormone secretion increases along with increased gonadotropin secretion at the onset of puberty. It is believed that the increase in GH is mediated by estrogen, which in boys is dependent on aromatization of testosterone to estradiol and reflects increasing sex steroid production at puberty. Nonetheless, there are profound sex differences in GH secretion during puberty. Girls have higher basal levels of GH throughout puberty, reaching maximal levels around the time of menarche and decreasing thereafter. In contrast, basal concentrations of GH remain constant throughout puberty in boys. Growth hormone secretion is highly pulsatile, with most pulses occurring during sleep and with sex steroids increasing pulse amplitude rather than altering pulse frequency.

Growth hormone stimulates production of IGF-1 in all tissues, with concentrations found in the circulation spilling over from the liver. During puberty the negative feedback effect of IGF-1 on GH secretion must be reduced because both IGF-1 and GH levels are high. GH and IGF-1 play significant roles in the changes in body composition that occur at puberty because both hormones are potent anabolic agents.

In the final stages of puberty in both boys and girls, GH secretion begins to diminish, returning to prepubertal levels in adult life, despite continued exposure to high levels of gonadal steroids.
Mechanisms Underlying Puberty

The mechanisms responsible for the numerous hormonal changes that occur during puberty are poorly understood, although it is recognized that a “central nervous system program” must be responsible for initiating puberty. It appears that the hypothalamic–pituitary–gonadal axis in girls develops in two distinct stages during puberty. First, sensitivity to the negative or inhibitory effects of the low levels of circulating sex steroids present in childhood decreases early in puberty. Second, late in puberty, there is maturation of the positive or stimulatory feedback response to estrogen, which is responsible for the ovulatory midcycle surge of LH.

Current evidence suggests that the central nervous system inhibits the onset of puberty until the appropriate time (25). Based on this theory, the neuroendocrine control of puberty is mediated by GnRH-secreting neurons in the medial basal hypothalamus, which together act as an endogenous pulse generator. At puberty, the GnRH pulse generator is reactivated (i.e., disinhibited), leading to increased amplitude and frequency of GnRH pulses. In turn, the increased GnRH secretion results in increased gonadotropin and then gonadal steroid secretion. What causes this “disinhibition” of GnRH release is unknown.

Figure 29.6 Increases (± standard error) in circulating levels of gonadotropins and adrenal and gonadal steroids through puberty in girls. DHEA, dehydroepiandrosterone; DHEAS, dehydroepiandrosterone sulfate. (From Emans SJH, Goldstein DP. The physiology of puberty. In: Emans SJH, Goldstein DP, eds. Pediatric and adolescent gynecology. 3rd ed. Boston, MA: Little, Brown, 1990:95, with permission.)
The relationship between body mass and the onset of puberty focused attention on leptin, produced by adipocytes, as a candidate for the factor initiating puberty. In the infertile leptin-deficient mouse, leptin therapy can induce sexual maturation and maintain fertility. Observations of two patients with leptin receptor mutations who failed to enter puberty suggest that leptin may have a similar role in humans (25).
Longitudinal studies of leptin secretion noted that there is increased leptin secretion around the time of pubertal onset. Leptin levels are increased throughout puberty in girls but not in boys. There is speculation that leptin is a trigger for pubertal onset, but a more widely held view is that leptin plays a more permissive role in regulating pubertal onset (25).
Aberrations of Pubertal Development

Classification

Several aberrations of pubertal development, as detailed in Table 29.1, can occur in girls. Pubertal aberrations can be classified in four broad categories:

**Table 29.1 Aberrations of Pubertal Development**

1. **Delayed or interrupted puberty**
   - **A. Anatomic abnormalities of the genital outflow tract**
     1. Müllerian dysgenesis (Rokitansky-Küster-Hauser syndrome)
     2. Distal genital tract obstruction
       - a. Imperforate hymen
       - b. Transverse vaginal septum
   - **B. Hypergonadotropic (follicle-stimulating hormone > 30 mIU/mL) hypogonadism (gonadal “failure”)**
     1. Gonadal dysgenesis with stigmata of Turner syndrome
     2. Pure gonadal dysgenesis
       - a. 46,XX
       - b. 46,XY
     3. Early gonadal “failure” with apparent normal ovarian development
   - **C. Hypogonadotropic (luteinizing hormone and follicle-stimulating hormone < 10 mIU/mL) hypogonadism**
     1. Constitutional delay
     2. Isolated gonadotropin deficiency
       - a. Associated with midline defects (Kallmann syndrome)
       - b. Independent of associated disorders
       - c. Prader-Labhart-Willi syndrome
       - d. Laurence-Moon-Bardet-Biedl syndrome
       - e. Many other rare syndromes
3. Associated with multiple hormone deficiencies
4. Neoplasms of the hypothalamic-pituitary area
   a. Cranopharyngiomas
   b. Pituitary adenomas
   c. Other
5. Infiltrative processes (Langerhans cell-type histiocytosis)
6. After irradiation of the central nervous system
7. Severe chronic illnesses with malnutrition
8. Anorexia nervosa and related disorders
9. Severe hypothalamic amenorrhea (rare)
10. Antidopaminergic and gonadotropin-releasing hormone-inhibiting drugs (especially psychotropic agents, opiates)
11. Primary hypothyroidism
12. Cushing syndrome
13. Use of chemotherapeutic (especially alkylating) agents

II. Asynchronous pubertal development
   A. Complete androgen insensitivity syndrome (testicular feminization)
   B. Incomplete androgen insensitivity syndrome

III. Precocious puberty
   A. Central (true) precocious puberty
      1. Constitutional (idiopathic) precocious puberty
      2. Hypothalamic neoplasms (most commonly hamartomas)
      3. Congenital malformations
      4. Infiltrative processes (Langerhans cell-type histiocytosis)
      5. After irradiation
      6. Trauma
      7. Infection
   B. Precocious puberty of peripheral origin (precocious pseudopuberty)
      1. Autonomous gonadal hypersecretion
         a. Cysts
         b. McCune-Albright syndrome
      2. Congenital adrenal hyperplasia
         a. 21-Hydroxylase (P450c21) deficiency
         b. 11β-Hydroxylase (P450c11) deficiency
         c. 3β-Hydroxysteroid dehydrogenase deficiency
      3. Iatrogenic ingestion/absorption of estrogens or androgens
      4. Hypothyroidism
      5. Gonadotropin-secreting neoplasms
         a. Human chorionic gonadotropin secreting
            i. Ectopic germinomas (pinealomas)
Delayed or interrupted puberty exists in girls who fail to develop any secondary sex characteristics by age 13, have not had menarche by age 15 (95th percentile is 14.5 yr), or have not attained menarche 5 or more years since the onset of pubertal development.

Asynchronous pubertal development is characterized by pubertal development that deviates from the normal pattern of puberty.

Precocious puberty is defined as pubertal development beginning before the age of 7 years in white girls and before the age of 6 years in African American girls (6). This new definition is controversial and is challenged because some feel that evaluation for breast or pubic hair development before 9 or 8 years of age in white or African American girls, respectively, may be warranted (26). It is clear that, in most cases, development nearer to the mean age of puberty is less likely to have a pathologic basis. Precocious pubertal development is characterized in several ways. In isosexual precocious puberty, the early changes are common to the phenotypic sex of the individual. In heterosexual precocious puberty, the development is characteristic of the opposite sex. Precocious puberty is sometimes termed “true” when it is of central origin with activation of the hypothalamic–pituitary unit. In precocious pseudopuberty, also known as precocious puberty of peripheral origin, secretion of hormones in the periphery (commonly by neoplasms) stimulates pubertal development.

Heterosexual puberty is characterized by a pattern of development that is typical of the opposite sex occurring at the expected age of normal puberty.

Disorders of sexual development and amenorrhea may be considered in relation to this
classification of the aberrations of puberty. It is very helpful to document the growth of the individual and to plot the individual’s height and weight on one of several commonly available growth charts (Fig. 29.7).

Figure 29.7 Growth chart showing stature by age percentiles for girls aged 2 to 18 years. Weight can be plotted in a similar fashion. Several excellent growth charts are available to clinicians, including those from Ross Laboratories (Columbus, OH), Serono Laboratories (Randolph, MA), and Genentech, Inc. (South San Francisco, CA). (From Hamill PVV, Drizd TA, Johnson CL, et al. Physical growth: National Center for Health Statistics percentiles. Am J Clin Nutr 1979;32:607–629, with permission; based on data from the National Center for Health Statistics.)
Delayed or Interrupted Puberty

The history and physical examination, with particular attention to growth, are most important in the evaluation of individuals with delayed puberty. Pubertal delay is much more common in boys than in girls. It is important to remember that puberty may be delayed in any child suffering from any severe chronic disease, including celiac disease, Crohn disease, sickle cell anemia, and cystic fibrosis. Chronic illness should be reviewed during the history and physical examination. One possible approach to evaluation is depicted in Figure 29.8.

Figure 29.8 Flow diagram for the evaluation of delayed or interrupted pubertal development, including primary amenorrhea, in phenotypic girls. Girls with asynchronous development often present because of failure to menstruate. FSH, follicle-stimulating hormone; PRL, prolactin; T4, thyroxine; TSH, thyroid-stimulating hormone; CNS, central nervous system; MRI, magnetic resonance imaging; CT, computed tomography. (From Rebar RW. Normal and abnormal sexual differentiation and pubertal development. In: Moore TR, Reiter RC, Rebar RW, et al., eds. Gynecology and obstetrics: a longitudinal approach. Counselling for women with medical problems: ovary and reproductive organs. In: Hollingsworth D, Resnik R, eds. Medical counselling before pregnancy. New York: Churchill Livingstone, 1988:213–248, with permission.)
Anatomic Abnormalities of the Genital Outflow Tract

Those girls who have mature secondary sex characteristics and any of a number of disorders of the outflow tract and uterus, often termed müllerian agenesis and dysgenesis, are most often identified on examination (Fig. 29.9). One of the most logical classification schemes that was proposed is shown in Table 29.2 (27). The incidence of these anomalies was estimated to be 0.02% of the female population several, but the incidence may have increased as a result of the maternal ingestion of diethylstilbestrol (DES) and the resultant increase in anomalies of the lumen of the uterus (class VI) (28,29). Of the disorders unrelated to drug use, the septate uterus (class V) is most common.

Table 29.2 Classification of Müllerian Anomalies
Disorders of the outflow tract and uterus often occur as a part of a syndrome of malformations that include abnormalities of the skeletal and renal systems (Mayer-Rokitansky-Küster-Hauser syndrome). Familial aggregates of the most common disorders of müllerian differentiation in girls—müllerian aplasia and incomplete müllerian fusion—are best explained on the basis of polygenic and multifactorial inheritance (30). It is clear that the HOX genes, a family of regulatory genes that encode for transcription factors, are essential for proper development of the müllerian tract in the embryonic period, and HOXA 13 is altered in hand–foot–genital syndrome (31). WNT4 may be involved in uterine development, as a WNT4 mutation was described in cases involving a Mayer-Rokitansky-Küster-Hauser-like syndrome with hyperandrogenism (32).

The most common single anatomic disorder of puberty is the imperforate hymen, which prevents the passage of endometrial tissue and blood. These products can accumulate in the vagina (hydrocolpos) or uterus (hydrometrocolpos) and result in a bulging hymen that is often bluish in color. The affected individual often has a history of vague abdominal pain with approximately monthly exacerbations. It is sometimes difficult to distinguish an imperforate hymen from a transverse vaginal septum, and in most situations, examination under anesthesia is required.

Regardless of the cause, uterine anomalies not involving segmental müllerian agenesis or hypoplasia (class I) are compatible with normal pregnancy. However, increased fetal wastage is reported in the presence of these anomalies (33).
Uterine malformations are associated with spontaneous abortion, preterm labor, abnormal presentations, and complications of labor (i.e., retained placenta). Many of these uterine anomalies can be identified with hysterosalpingography (Fig. 29.9). Hysterosalpingography, laparoscopy, and hysteroscopy are used to differentiate a septate uterus (class V) from a bicornuate uterus (class IV). Magnetic resonance imaging (MRI) and endovaginal ultrasonography (sometimes with sonohysterography) are as accurate as these invasive techniques in identifying the abnormality (34).

**Obstruction or malformation of the distal genital tract must be distinguished from androgen insensitivity.** Individuals with androgen insensitivity have breast development in the absence of significant pubic and axillary hair development; the vagina may be absent or foreshortened in these women.
Hypergonadotropic and Hypogonadotropic Hypogonadism

Basal levels of FSH and prolactin should be determined in individuals in whom secondary sex characteristics have not developed to maturity (Fig. 29.8). Bone age should be estimated from x-rays of the nondominant hand. If prolactin levels are elevated, thyroid function should be assessed to determine whether the individual has primary hypothyroidism. Paradoxically, primary hypothyroidism can result in precocious puberty. If thyroid function is normal, a hypothalamic or pituitary neoplasm is possible, and careful evaluation of the hypothalamic and pituitary area by MRI or computed tomography (CT) is indicated.

The karyotype should be determined in any individual with delayed puberty and increased basal FSH concentrations. Regardless of the karyotype, the individual with hypergonadotropic hypogonadism has some form of ovarian “failure” (i.e., primary hypogonadism).

Forms of Gonadal Failure

Turner Syndrome

The diagnosis of Turner syndrome requires the presence of characteristic features in phenotypic females coupled with complete or partial absence of the second sex chromosome, with or without cell line mosaicism. Most affected individuals have a 45,X karyotype, while others have mosaic karyotypes (i.e., 45,X/46,XX; 45,X/46,XY). Intrauterine growth restriction is common in infants with a 45,X karyotype. After birth, these patients generally grow slowly, beginning in the second or third year of life. They typically have many of the associated stigmata, including lymphedema and sometimes large cystic hygromas of the neck at birth; a webbed neck; multiple pigmented nevi; disorders of the heart, kidneys (most commonly horseshoe), and great vessels (most commonly coarctation of the aorta); and small hyperconvex fingernails (35) (Fig. 29.10). Diabetes mellitus, thyroid disorders, essential hypertension, and other autoimmune disorders are often present in individuals with 45,X karyotypes.

Figure 29.10 Typical appearance of two individuals with 45,X gonadal dysgenesis. A: This 16-year-old individual has obvious short stature, a webbed neck, shortened fourth metatarsals, and a thoracotomy scar from the repair of the coarctation of the aorta that was performed at 13 years of age. B: This 11-year-old individual also has obvious short stature and stigmata of Turner syndrome. Note that these two individuals look more like each other than they might look like any genetic siblings.
Most 45,X patients have normal intelligence, but many affected individuals have an unusual cognitive defect characterized by an inability to appreciate the shapes and relations of objects with respect to one another (i.e., space-form blindness). Patients with a small ring X chromosome have an increased risk of mental retardation (36). As they grow older, affected children typically are shorter than normal. Although they do not develop breasts at puberty, some pubic or axillary hair may develop because appropriate adrenarche can occur with failure of thelarche (i.e., breast development).

Although less severe short stature and some adolescent development may occur with chromosomal mosaicism, it is reasonable to assume that any short, slowly growing, sexually infantile girl has Turner syndrome until proved otherwise because this disorder is so prevalent (about 1 in 2,500 newborn phenotypic females). In fact, the 45,X karyotype is the single most frequent chromosomal disorder in humans, but most affected fetuses are aborted spontaneously early in pregnancy. However, trisomy is the most common chromosomal type or category of abnormality in first-trimester losses.

The short stature commonly associated with the Turner phenotype appears to result from the loss of a homeobox-containing gene (which encodes for an osteogenic gene) located on the pseudoautosomal region (PAR 1) of the short arms of the X (Xp22) and Y (Yp11.3) chromosomes (37). This gene, which is called either SHOX (short stature homeobox-containing gene) or PHOG (pseudoautosomal homeobox osteogenic gene), escapes X inactivation because of its pseudoautosomal location. The gene appears to account for
about two-thirds of the height deficit commonly associated with Turner syndrome. Even in the presence of typical Turner stigmata, a karyotype is indicated to eliminate the possibility of the presence of any portion of a Y chromosome. Analysis of pooled data suggests that the presence of Y chromosome material is associated with a 12% risk of a gonadoblastoma (38). If a Y chromosome is identified, laparoscopic prophylactic gonadectomy is recommended at the time of diagnosis to eliminate the risk of malignancy. Although gonadoblastomas are benign tumors with no metastatic potential that can arise spontaneously in gonads containing a portion of a Y chromosome, they can be precursors to germ cell malignancies, such as dysgerminomas (most commonly), teratomas, embryonal carcinomas, or endodermal sinus tumors (39). In individuals in whom there is no evidence of neoplastic dissemination, the uterus may be left in situ for donor in vitro fertilization and embryo transfer. **Individuals with Turner syndrome are at increased risk of sudden death from aortic rupture or dissection resulting from cystic medial necrosis during pregnancy, and the risk may be as great as 2% or more (40).** In addition, this may occur even if the aortic root diameter is normal. Because of their small stature, ascending aortic diameters of less than 5 cm may represent significant dilatation. Thus, the use of the aortic size index (ascending aortic diameters measured by MRI at the level of the right pulmonary artery normalized to body surface area) is preferred (41). Patients with an aortic size index greater than 2.0 cm/m² require close cardiovascular surveillance and those with an aortic size index of 2.5 cm/m² or more are at highest risk for aortic dissection. In fact, the risk of acute aortic dissection is increased by more than 100-fold in young and middle-aged women with Turner syndrome. **If pregnancy is being considered, preconception assessment must include cardiologic evaluation with MRI of the aorta.**

The evaluation of other commonly involved organ systems should include a careful physical examination, with special attention to the cardiovascular system, and thyroid function tests (including antibody assessment), fasting blood glucose, renal function tests, and intravenous pyelography or a renal ultrasonography.

**Treatment of Turner Syndrome**

To increase final adult height, commonly accepted treatment strategies include use of exogenous GH (42–44). With recombinant human GH use, the average height gain varied from 4 to 16 cm. It appears that early initiation of therapy (between 2–8 years of age), gradually increasing the dose, and continuing treatment for a mean of 7 years can lead to achievement of a final height greater than 150 cm in most patients (43). Weekly doses of GH of 0.375 mg/kg divided into seven daily doses are typical. Therapy may be continued until a satisfactory height is attained or until little growth potential remains (bone age ≥14 years and growth velocity <2 cm per year). It is not clear if a nonaromatizable anabolic steroid such as oxandrolone will provide additional growth. In girls older than 8 years of age or those with extreme short stature, consideration can be given to using
higher doses of GH and adding oxandrolone (45). The dose of oxandrolone should be 0.05 mg/kg per day or less, as higher doses will result in virilization and more rapid skeletal maturation. In addition, liver enzymes should be monitored.

**The gonadal steroid treatment of patients with Turner syndrome is as follows:**

To promote sexual maturation, therapy with exogenous estrogen should be initiated when the patient is psychologically ready, at about 12 to 13 years of age, and after GH therapy was administered for several years. Low-dose estrogen can be introduced at this time without compromising final adult height (46).

Because the intent is to mimic normal pubertal development, therapy with **low-dose estrogen alone** (such as 0.025 mg per day transdermal estradiol or 0.3–0.625 mg conjugated estrogens orally each day) **should be initiated**.

**Progestins** (5–10 mg medroxyprogesterone acetate or 200 mg micronized progesterone orally for 12 to 14 days every 1 to 2 months) **can be added to prevent endometrial hyperplasia after the patient first experiences vaginal bleeding or after 6 to 12 months of unopposed estrogen use if the patient has not yet had any bleeding.** The dose of estrogen is increased slowly over 1 to 2 years until the patient is taking about twice as much estrogen as the amount administered to postmenopausal women.

**Girls with gonadal dysgenesis must be monitored carefully for the development of hypertension with estrogen therapy.**

The patients and their parents should be counseled regarding the emotional and physical changes that will occur with therapy.

It is important to educate the patient that hormone replacement therapy is usually required until the time of normal menopause to maintain feminization and prevent osteoporosis (47).

**Mosaic Forms of Gonadal Dysgenesis**

Individuals with rare mosaic forms of gonadal dysgenesis may develop normally at puberty. The decision to initiate therapy with exogenous estrogen should be based mainly on circulating FSH levels. Levels in the normal range for the patient’s age imply the presence of functional gonads.

These individuals can become pregnant, with success rates of more than 50% using donor oocytes (48). The increased risk of sudden death during pregnancy resulting from aortic rupture should be assumed to be similar to that of other women with the Turner phenotype (40).

**Pure Gonadal Dysgenesis**

The term pure gonadal dysgenesis refers to 46,XX or 46,XY phenotypic females who have streak gonads. This condition may occur sporadically or may be inherited as an autosomal recessive trait or as an X-linked trait in XY gonadal
dysgenesis (Fig. 29.11). Affected girls typically are of average height and have none of the stigmata of Turner syndrome, but they have elevated levels of FSH because the streak gonads produce neither steroid hormones nor inhibin. When gonadal dysgenesis occurs in 46,XY individuals, it is sometimes termed Swyer syndrome. Surgical extirpation is warranted in individuals with a 46,XY karyotype to prevent development of germ cell neoplasms. Both 46,XX and 46,XY forms of gonadal dysgenesis benefit from exogenous estrogen and are potential candidates for donor oocytes.

Figure 29.11 A: A 16-year-old individual with 46,XX gonadal dysgenesis and primary amenorrhea. Circulating follicle-stimulating hormone (FSH) levels were markedly elevated. The small amount of breast development (Tanner stage 2) is unusual, but some pubertal development may occur in such patients. B: A 16-year-old individual with 46,XY gonadal dysgenesis who presented with primary amenorrhea and markedly elevated FSH levels. Most affected individuals do not present with as much pubic and axillary hair development. The right gonad contained a dysgerminoma, but there was no evidence of metastases. (From Rebar RW. Normal and abnormal sexual differentiation and pubertal development. In: Moore TR, Reiter RC, Rebar RW, et al., eds. Gynecology and obstetrics: a longitudinal approach. New York: Churchill Livingstone, 1993:97–133, with permission.) C: Clitoromegaly noted in the girl with 46,XY gonadal dysgenesis depicted in Figure 29.11B. D: The same individual as depicted in Figure 29.11B and D with 46,XY gonadal dysgenesis 1 year after gonadectomy and replacement with exogenous estrogen.
In early gonadal failure, the ovaries apparently develop normally but contain no oocytes by the expected age of puberty. These disorders are considered further in the discussion delineating the evaluation of amenorrhea (see Chapter 30).

**Hypogonadotropic Hypogonadism**

Hypothalamic–pituitary disturbances are usually associated with low levels of circulating gonadotropins (with both LH and FSH levels less than or equal to 10 mIU/mL) (49). There are both sporadic and familial causes of hypogonadotropic hypogonadism, and the differential diagnosis is extensive. Mutations in several genes cause hypogonadotropic hypogonadism in humans (50). This condition can arise from abnormalities in hypothalamic GnRH secretion, impaired release of gonadotropins from the pituitary gland, or both.

At least 17 different single-gene mutations are identified as being associated with delayed or absent puberty in humans (51). They are estimated to account for about 30%
of individuals with disorders of puberty. These genes include KAL1 (X-linked Kallmann syndrome), FGFR1 (autosomal Kallmann syndrome), DAX1 (the gene for X-linked congenital adrenal hypoplasia), GNRHR (the gene for the GnRH receptor), PC1 (the gene for prohormone convertase 1), and GPR54 (encoding a G-protein coupled receptor). Delayed puberty may result from mutations in genes affecting gonadotrophs specifically (GnRHR, LHβ, FSHβ) or in genes involved more generally in the development and functioning of the pituitary gland (LHX3, PROP1, HESX1).

**Constitutional Delay**

It is important to remember that low levels of LH and FSH are normally present in the prepubertal years; thus, girls with constitutionally delayed puberty may mistakenly be presumed to have hypogonadotropic hypogonadism. **Constitutional delay is the most common cause of delayed puberty.** In a normal population, 2% to 3% of normal children will be classified as having pubertal delay, and this finding may be considered a normal variant. **Constitutional delayed growth and adolescence can be diagnosed only after careful evaluation excludes other causes of delayed puberty and normal sexual development is documented by longitudinal follow-up.** The farther below the third percentile for height that the young girl is, the less likely it is that the cause is constitutional. Because some children are severely handicapped socially by constitutional pubertal delay, some physicians occasionally provide exogenous estrogen in low doses for 3 to 4 months to stimulate some pubertal development. However, the benefits of treatment are not well documented, and there is little evidence to support the idea that treatment improves psychosocial function.

**Kallmann Syndrome**

As originally described in 1944, Kallmann syndrome consisted of the triad of anosmia, hypogonadism, and color blindness in men (52). Women may be affected, and other associated defects may include cleft lip and palate, cerebellar ataxia, nerve deafness, and abnormalities of thirst and vasopressin release. The frequency approximates 1 in 10,000 men and 1 in 50,000 women. Sporadic cases are more common than inherited forms. Inheritance is described as being X-linked recessive, autosomal dominant, and autosomal recessive. Because autopsy studies show partial or complete agenesis of the olfactory bulb, the term olfactogenital dysplasia is used to describe the disorder. These anatomic findings coincide with embryologic studies documenting that GnRH neurons originally develop in the epithelium of the olfactory placode and normally migrate into the hypothalamus (53). In some affected individuals, gene defects were found in one protein, anosmin-1, that facilitates this neuronal migration, thus leading to an absence of GnRH neurons in the hypothalamus and olfactory bulbs and consequent hypogonadotropic hypogonadism and anosmia (Kallmann syndrome) (54). The gene defect resulting in loss of this adhesion protein is localized to the Xp22.3 locus in an X-linked form of the syndrome, and this locus is designated KAL1. Other features of X-linked Kallmann syndrome include unilateral renal agenesis, bimanual synkinesia, and sensorineural hearing loss. In some cases of autosomal dominant
Kallmann syndrome, inactivating mutations of the gene encoding the fibroblast growth factor receptor-1 (FGFR1 or KAL2) were reported. The disorder is so heterogeneous that it appears likely that it forms a structural continuum with other midline defects. Septo-optic dysplasia represents the most severe form of the disorder.

Clinically, affected individuals typically present with sexual infantilism and an eunuchoid habitus, but some degree of breast development may occur (Fig. 29.12). Primary amenorrhea is the rule. The ovaries are usually small, with follicles seldom developing beyond the primordial stage. Circulating gonadotropin levels are usually very low but almost invariably measurable. Affected individuals respond readily to pulsatile administration of exogenous GnRH, and this is the most physiologic approach to ovulation induction (48). For women not seeking pregnancy, therapy with exogenous estrogen and progestin is indicated.

Isolated gonadotropin deficiency can occur in association with the Prader-Labhart-Willi syndrome, which is characterized by obesity, short stature, hypogonadism, small hands and feet (acromicria), mental retardation, and infantile hypotonia. When the syndrome occurs in association with the Laurence-Moon-Bardet-Biedl syndrome, retinitis pigmentosa, postaxial polydactyly, obesity, and hypogonadism may be present. Prader-Labhart-Willi syndrome apparently results from rearrangements of chromosome 15q11 to q13, an imprinted region of the human genome (55). Laurence-Moon-Bardet-Biedl syndrome, inherited in an autosomal recessive manner, is apparently heterogeneous, with at least four involved gene loci having been mapped to date (56).

Multiple pituitary hormone deficiencies, which are usually hypothalamic in origin, may be congenital and either part of an inherited constellation of findings or sporadic. If GH or thyroid-stimulating hormone (TSH) concentrations are subnormal, growth and pubertal development will be affected. Thus, the condition should be diagnosed before the age of puberty. Because individuals with hypopituitarism have a high mortality rate, predominantly caused by vascular and respiratory disease, it is important to identify affected individuals. Later age at diagnosis, female sex, and above all craniopharyngioma are identified as significant independent risk factors (57). Untreated gonadotropin deficiency is an important risk factor for early mortality.

Tumors of the Hypothalamus and Pituitary

Several different tumors of the hypothalamic and pituitary regions may lead to hypogonadotropic hypogonadism (58) (Fig. 29.13A). Except for craniopharyngiomas, these tumors are relatively uncommon in children. A craniopharyngioma is a tumor of the Rathke’s pouch. It is the most common neoplasm associated with delayed puberty, and it accounts for 10% of all childhood central nervous system tumors. Craniopharyngiomas are usually suprasellar in location and may be asymptomatic well into the second decade of life. Such tumors may present as headache, visual disturbances, short stature or growth failure, delayed puberty, or diabetes insipidus. Visual field defects (including
bilateral temporal hemianopsia), optic atrophy, or papilledema may be seen on physical examination. Laboratory evaluation should document hypogonadotropism and may reveal hyperprolactinemia as a result of interruption of hypothalamic dopamine inhibition of prolactin release. Radiographically, the tumor may be either cystic or solid and may show areas of calcification. Appropriate therapy for hypothalamic–pituitary tumors may involve surgical excision or radiotherapy (with adequate pituitary hormone replacement therapy) and are best managed by a team of physicians that includes an endocrinologist, a neurosurgeon, and a radiotherapist.

Figure 29.12 Left A 21½-year-old woman with Kallmann syndrome. Note that the patient has some pubic and axillary hair. Bone age was 16 years. It is rare to see affected individuals today who were not given oral contraceptive agents to induce menses (with some consequent breast development). (From Wilkins L. The diagnosis and treatment of endocrine disorders in childhood and adolescence. 3rd ed. Springfield, IL: Charles C Thomas, 1965, with permission.)

Figure 29.13 Right A: A 16-year-old girl with delayed puberty. Breast budding began at 11 years of age, but there was no further development. During the year before presentation, her scholastic performance in school deteriorated, she gained 25 lb, she became increasingly lethargic, and nocturia and polydypsia were noted. Initial evaluation documented low follicle-stimulating hormone, elevated prolactin, and a bone age of 10.5 years. Computed tomography scanning documented a large hypothalamic neoplasm that proved to be an ectopic germinoma. The patient was also documented to be hypothyroid and hypoadrenal and to have diabetes insipidus. Despite the elevated prolactin, she had no galactorrhea because of the minimal breast development. (From Rebar RW. Normal and abnormal sexual differentiation and pubertal development. In: Moore TR, Reiter RC, Rebar RW, et al., eds. Gynecology and obstetrics: a longitudinal approach. New York: Churchill Livingstone, 1993:97–133, with permission.) B: A 16-year-old girl (frontal view) with primary amenorrhea who progressed in puberty until about 12 years of age. Breast budding occurred at about 10 years of age. The patient’s short stature is obvious. She proved to have hypopituitarism. Classic radiographic findings established the diagnosis of Langerhans cell-type histiocytosis (Hand-Schüller-Christian disease). C: Side view of girl shown in Figure 29.13B.
Other Central Nervous System Disorders

Other central nervous system disorders that may lead to delayed puberty include infiltrative diseases, such as Langerhans cell-type histiocytosis, particularly the form known previously as **Hand-Schüller-Christian disease** (Fig. 29.13B and 29.13C). Diabetes insipidus is the most common endocrinopathy (because of infiltration of the supraoptic nucleus in the hypothalamus), but short stature resulting from GH deficiency and delayed puberty caused by gonadotropin deficiency are not uncommon in this disorder (59).

Irradiation of the central nervous system for treatment of any neoplasm or leukemia may result in hypothalamic dysfunction. Although GH deficiency is the most frequent finding, partial or complete gonadotropin deficiency may develop in some patients.

**Severe chronic illnesses, often accompanied by malnutrition, may lead to slowed growth in childhood and delayed adolescence.** Regardless of the cause, weight loss to less than 80% to 85% of ideal body weight often results in hypothalamic GnRH deficiency. If adequate body weight and nutrition are maintained in chronic illnesses such as Crohn disease or chronic pulmonary or renal disease, sufficient gonadotropin secretion usually is present to initiate and maintain pubertal development.

*Figure 29.14 A: A 20-year-old college woman with anorexia nervosa. B: A 16-year-old student with anorexia nervosa.* In both cases, as is true of most such patients, pubertal development had been completed and menses initiated before anorexia led to marked weight loss.
Anorexia Nervosa and Bulimia

Significant weight loss and psychological dysfunction occur simultaneously with anorexia nervosa (60,61). Although many anorectic girls experience amenorrhea after pubertal development begins, if the disorder begins sufficiently early, pubertal development may be delayed or interrupted (Fig. 29.14). The following constellation of associated findings confirms anorexia nervosa in most individuals:

Relentless pursuit of thinness
Amenorrhea, sometimes preceding the weight loss
Extreme inanition
Obsessive-compulsive personality often characterized by overachievement
Distorted and bizarre attitude toward eating, food, or weight
Distorted body image

Because normal body weight is commonly maintained in bulimia, it is unusual for bulimic patients to experience either delayed development or amenorrhea. Girls with anorexia nervosa may have, in addition to hypogonadotrophic hypogonadism, partial diabetes insipidus, abnormal temperature regulation, hypotension, chemical hypothyroidism with low serum triiodothyronine (T_3) and high reverse T_3 levels, and elevated circulating cortisol levels in the absence of evidence of hypercortisolism (62). Other common features include
hypokalemia, anemia, hypoalbuminemia, high β-carotene levels, and high cholesterol levels. All features of anorexia nervosa are reversible with weight gain, except for amenorrhea (which persists in 30% to 47%) and osteopenia (i.e., it now seems that any bone lost cannot be fully recovered). **Management of patients with anorexia nervosa is notoriously difficult.** A team approach involving the primary clinician, psychiatrist, and nutritionist is most effective. In fact, anorexia nervosa has the highest mortality of any psychiatric disorder. Deaths are often sudden and unexpected. Cause of death (often unknown) can include hypoglycemia and electrolyte imbalance.

**Fear of obesity**, a syndrome of self-induced malnutrition common among teenage gymnasts and ballet dancers, may slow growth and delay pubertal development (63). These children voluntarily reduce their caloric intake as much as 40%, leading to nutritional growth retardation. An additive role for endurance training in the delayed development is possible, but the mechanisms are unclear at this point. These conditions are essentially severe forms of hypothalamic amenorrhea. Inevitably delayed puberty will occur unless adequate caloric intake is provided.

**Hyperprolactinemia**

**Low levels of LH and FSH may be associated with hyperprolactinemia.** As noted, galactorrhea cannot occur in the absence of complete breast development. Pituitary prolactinomas are rare during adolescence but must be considered when certain signs and symptoms are present. **Many individuals with prolactinomas have a history of delayed menarche.** The association between the ingestion of certain drugs (most often psychotropic agents and opiates in this age group) is well established. Primary hypothyroidism is associated with hyperprolactinemia because increased levels of thyrotropin-releasing hormone (TRH) stimulate secretion of prolactin. The empty sella syndrome, in which the sella turcica is enlarged but is replaced by cerebrospinal fluid, may be associated with hyperprolactinemia.

**Use of Chemotherapeutic Agents**

As survival rates following treatment for childhood malignancy improve, the effects of cancer therapy become more important. Both radiation therapy to the abdomen and systemic chemotherapeutic agents, particularly alkylating agents, have toxic effects on germ cells. Although prepubertal gonads appear less vulnerable than those of adults, ovarian failure is common. An argument can be made for endocrine assessment as early as 1 year following completion of therapy to identify children who will suffer from hypogonadism. Spontaneous ovarian activity can resume even years after therapy.
Asynchronous Puberty

Asynchronous pubertal development is characteristic of androgen insensitivity (i.e., testicular feminization). Affected individuals typically present with breast development (usually only to Tanner stage 3) out of proportion with the amount of pubic and axillary hair present (Fig. 29.15). In this disorder, 46,XY individuals have bilateral testes, female external genitalia, a blindly ending vagina (often foreshortened and sometimes absent), and no müllerian derivatives (i.e., uterus and fallopian tubes) (64). Infrequently, patients may have clitoral enlargement and labioscrotal fusion at puberty, which is referred to as incomplete androgen insensitivity.

Asynchronous puberty is heterogeneous but is always related to some abnormality of the androgen receptor or of androgen action (65). In perhaps 60% to 70% of cases, androgen receptors cannot be detected (i.e., the patient is receptor negative). In the remaining cases, androgen receptors are present (i.e., receptor positive), but mutations in the androgen receptor are detected or there is a defect at a more distal step in androgen action (i.e., a postreceptor defect). Receptor-positive individuals are indistinguishable clinically from receptor-negative individuals. Several different mutations in the androgen receptor gene, most of which occur within the androgen-binding domain of the receptor, are identified in affected individuals who are receptor positive. Severe X-linked androgen receptor gene mutations cause complete androgen insensitivity, whereas mild mutations impair virilization with or without infertility, and moderate mutations result in a wide phenotypic spectrum of expression among siblings (66).

Because the Sertoli cells of the testes make antimüllerian hormone (AMH), müllerian derivatives are absent in this disorder; thus, müllerian regression occurs normally. The testes are often normal in size and may be located anywhere along the path of embryonic testicular descent—in the abdomen, inguinal canal, or labia. Half of all individuals with androgen insensitivity develop inguinal hernias. Recognizing that most such girls will be 46,XX, it is important to determine the karyotype in prepubertal girls with inguinal hernias, especially if a uterus cannot be detected with certainty by ultrasound.

The risk of germ cell malignancy is 2% in complete androgen insensitivity syndrome (67). Most clinicians believe the risk for gonadal neoplasia is low before 25 years of age; thus, the testes should be left in place until after pubertal feminization, especially because the risk of neoplasia appears to increase with age. Exogenous estrogen should be provided after gonadectomy.

The diagnosis is often suspected by the typical physical findings and strongly suggested by normal (or even somewhat elevated) male levels of testosterone, normal or somewhat elevated levels of LH, and normal levels of FSH. The diagnosis is confirmed by a 46,XY karyotype.

Interacting with the patient and family requires sensitivity and care. It may be
inadvisable to begin by informing the patient of the karyotype; the psychological implications may be devastating because the patient was reared as a girl. Family members should be informed initially that müllerian aplasia occurred and that the risk for neoplasia mandates gonadectomy after puberty. Because the disorder can be inherited in an X-linked recessive fashion, families should undergo appropriate genetic counseling and screening to identify the possible existence of other affected family members.

Figure 29.15 A: This 17-year-old individual presented with primary amenorrhea and was found to have a blind-ending vagina and bilateral inguinal masses. Circulating levels of testosterone were at the upper limits of the normal range for men and the karyotype was 46,XY, confirming androgen insensitivity. B: Two inguinal testes were found at surgery. (From Simpson JL, Rebar RW. Normal and abnormal sexual differentiation and development. In: Becker KL, ed. Principles and practice of endocrinology and metabolism. 2nd ed. Philadelphia, PA: JB Lippincott, 1995:788–822, with permission.)
Precocious Puberty

Although precocious pubertal development may be classified in several ways, it is perhaps simplest to think of the development as gonadotropin dependent (in which case it is almost invariably of central origin) or gonadotropin independent (of peripheral origin). Precocious puberty is 20 times more common in girls than in boys. In fully 90% of girls, the precocious development is idiopathic, whereas this appears to be true for only 10% of boys. Family history, the rapidity with which secondary sexual characteristics are developing, the rate of growth, and the presence or absence of central nervous system disease should all be considered in deciding whether to pursue evaluation of a girl for precocious puberty. The evaluation of precocious puberty is as follows:

Measurement of basal gonadotropin levels is the first step in the evaluation of a child with sexual precocity (Fig. 29.16).

Figure 29.16 Flow diagram for the evaluation of precocious puberty in phenotypic females. LH, luteinizing hormone; FSH, follicle-stimulating hormone; TSH, thyroid-stimulating hormone; T4, thyroxine; T, testosterone; DHEAS, dehydroepiandrosterone sulfate; 17OHP, 17-hydroxyprogesterone; CNS, central nervous system. (From Rebar RW. Normal and abnormal sexual differentiation and pubertal development. In: Moore TR, Reiter RC, Rebar RW, et al., eds. Gynecology and obstetrics: a longitudinal approach. New York: Churchill Livingstone, 1993:97–133, with permission.)

Thyroid function should be evaluated to rule out primary hypothyroidism as the cause of precocious development.

High levels of LH (which really may be human chorionic gonadotropin detected because of cross-reactivity with LH in immunoassays) suggest a gonadotropin-producing neoplasm, most often a pinealoma (ectopic germinoma) or
Choriocarcinoma or, less often, a hepatoblastoma. (Gonadotropin-producing neoplasms are the only causes of precocious puberty in which the gonadotropin dependence does not equate with central precocious puberty.)

Low or pubertal levels of gonadotropins indicate the need to determine circulating estradiol concentrations in girls with isosexual development and to assess androgen levels, specifically testosterone, DHEAS, and 17α-hydroxyprogesterone in girls with heterosexual development.

Increased estradiol levels suggest an estrogen-secreting neoplasm, probably of ovarian origin.

Increased testosterone levels suggest an androgen-producing neoplasm of the ovary or the adrenal gland. Such neoplasms may be palpable on abdominal or rectal examination. Increased 17α-hydroxyprogesterone levels are diagnostic of 21-hydroxylase deficiency (i.e., congenital adrenal hyperplasia [CAH]). Levels of DHEAS are elevated in various forms of CAH.

If the estradiol levels are compatible with the degree of pubertal development observed, evaluation of the central nervous system by MRI or CT scanning is warranted.

Bone age should always be assessed in evaluating an individual with sexual precocity.

A GnRH stimulation test can be used to confirm central precocious puberty. After 100 μg GnRH, an LH peak of greater than 15 mIU/mL is suggestive of gonadotropin-dependent precocious puberty (68).

Perhaps the most difficult decision for the gynecologist is determining how much evaluation is warranted for the young girl brought in by her mother for precocious breast budding only (precocious thelarche) or the appearance of pubic or axillary hair alone (precocious pubarche or adrenarche) (Fig. 29.17). In such cases, it is acceptable to many clinicians to follow the patient at frequent intervals and to proceed with evaluation if there is evidence of pubertal progression. The feasibility of this approach may depend on the concerns of the parents.

**Figure 29.17** Five-year-old girl with development of pubic hair (A) as shown more closely in (B) (precocious adrenarche). Gonadotropin levels were prepubertal, and bone age was appropriate for age. No further development occurred until breast budding at approximately age 9.
Premature Thelarche

Premature thelarche is unilateral or bilateral breast enlargement without other signs of sexual maturation. There is no significant nipple or areola development. It usually occurs by 2 years of age and rarely after age 4. It may be caused by increased sensitivity of the breasts to low levels of estrogen or to increased estradiol secretion by follicular cysts. It is a benign self-limited disorder and thus only reassurance and follow-up are required. In most cases, onset of puberty, adult height, and adult reproductive function are normal.
Rarely, premature thelarche can be a harbinger of progressive gonadarche. It is suggested that measurement of uterine volume (anteroposterior diameter × longitudinal diameter × transverse diameter × 0.523) may be the most sensitive and specific discriminator between premature thelarche and early true precocious puberty. If needed, breast ultrasound can help distinguish unilateral premature thelarche from fibroadenomas, cysts, neurofibromas, or other lesions.

**Premature Adrenarche**

Premature adrenarche or pubarche may be caused by increased sensitivity to low levels of androgens and must be distinguished from late-onset (nonclassic) CAH. If there is no evidence of breast development or of progression, these conditions are virtually always benign.

Girls with premature adrenarche are at increased risk of developing polycystic ovary syndrome (PCOS), hyperinsulinemia, acanthosis nigricans, and dyslipidemia in adolescence and adult life, especially if fetal growth was reduced and birth weight was low. Although mean androgen levels are within the normal range, a significant minority have an exaggerated response to corticotropin stimulation. The magnitude of this response is inversely related to insulin sensitivity. Thus, premature adrenarche may be the first sign of insulin resistance or PCOS in some individuals. Treatment of coexisting obesity and long-term follow-up are indicated to address potential complications of PCOS and insulin resistance.

**Isolated Premature Menarche**

Isolated premature menarche is vaginal bleeding at age 1 to 9 years in the absence of other signs of puberty. The bleeding is usually limited to a few days. It can recur for 1 to 6 years and then cease. The etiology is uncertain. Most cases are associated with subsequent normal pubertal development and fertility. The differential diagnosis includes vaginal foreign bodies, trauma, sexual abuse, vaginal infection, or neoplasms such as rhabdomyosarcoma, McCune-Albright syndrome (in which menarche may occur before other manifestations of sexual precocity), and primary hypothyroidism.
In central precocious puberty, GnRH prematurely stimulates increased gonadotropin secretion. Central precocious puberty may occur in children in whom there is no structural abnormality, in which case it is termed constitutional or idiopathic. Constitutional (idiopathic) sexual precocity is the most common cause of precocious puberty. It is often familial and represents the so-called tail of the Gaussian curve (i.e., the early 2.5% for the age distribution for the onset of puberty). In many of these girls, puberty is slowly progressive, but in a few, development progresses rapidly. The major complication of sexual precocity is limitation of height. Thus, therapy may be warranted to prevent this consequence.

Alternatively, central precocious puberty may result from a tumor, infection, congenital abnormality, or traumatic injury affecting the hypothalamus. A number of congenital malformations, including hydrocephalus, craniostenosis, arachnoid cysts, and septo-optic dysplasia, can be associated with precocious puberty (and with sexual infantilism).

A common etiology (2% to 28%) of central precocious puberty is a hypothalamic hamartoma. It is a congenital malformation composed of a heterotopic mass of nerve tissue containing GnRH neurosecretory neurons, fiber bundles, and glial cells. It is not a true neoplasm and it generally does not change over time based on long-term follow-up studies with periodic CT or MRI scans. Hamartomas appear as isodense, abnormal fullnesses that do not enhance with contrast material. Extreme precocity (usually before 3
years of age) and the absence of tumor markers, such as β-human chorionic gonadotropin and α-fetoprotein, suggest a hamartoma (72). Hamartomas can be associated with laughing (gelastic) seizures, behavioral disturbances, mental retardation, and dysmorphic syndromes. It appears that hamartomas produce GnRH in a pulsatile manner and thus stimulate gonadotropin secretion (Fig. 29.18) (73). Precocious pubertal development can be controlled with GnRH-agonist therapy (74). Because deaths were reported after neurosurgical extirpation, the latter should be reserved for management of hamartomas associated with intractable seizures or hydrocephalus (75).

The efficacy of gonadotropin-releasing hormone analogues (GnRHa) in increasing adult height is undisputed only in early-onset (girls less than 6 years old) central precocious puberty (76). Concerns of weight gain and long-term decrease in bone mineral density with the use of GnRHa do not seem to be warranted. The most important clinical criterion for initiating GnRHa treatment is documented progression of pubertal development over a 3- to 6-month period. This observational period may not be necessary if the child is at or past Tanner stage 3, particularly with advanced skeletal maturation. It appears that discontinuation of GnRHa at a chronological age of about 11 years and a bone age of about 12 years is associated with maximum adult height (77–79). There are a variety of GnRHa formulations, and the choice of a particular agent depends on patient and physician preference.

Precocious Puberty of Peripheral Origin

In gonadotropin-independent precocious puberty, production of estrogens or androgens from the ovaries, adrenals, or rare steroid-secreting neoplasms leads to early pubertal development. Small functional ovarian cysts, typically asymptomatic, are common in children and may cause transient sexual precocity (80). Simple cysts (with a benign ultrasonographic appearance) can be observed and usually resolve over time. Of the various ovarian neoplasms that can secrete estrogens, granulosa-theca cell tumors occur most frequently but are still rare (81). Although such tumors may grow rapidly, more than two-thirds are benign.

Exposure to exogenous estrogens can mimic gonadotropin-independent precocious puberty. Ingestion of oral contraceptives, other estrogen-containing pharmaceutical agents, and estrogen-contaminated foods, and the topical use of estrogens, are implicated in cases of precocious development in infants and children. Ingestion of exogenous steroids over a considerable length of time is required to induce changes typical of complete precocious development.

McCune-Albright Syndrome

The McCune-Albright syndrome is characterized by the classic triad of polyostotic fibrous dysplasia of bone, irregular café-au-lait spots on the skin, and GnRH-independent sexual precocity. The café-au-lait spots are usually large, do not cross the midline, and have irregular “coast of Maine” margins. They are often
located on the same side as the bony lesions. Sexual precocity often begins in the first 2 years and usually presents with menstrual bleeding. Girls develop sexual precocity as a result of functioning ovarian cysts. Serum estradiol is elevated. Other endocrinopathies may include hyperthyroidism, hypercortisolism, hyperprolactinemia, acromegaly, and hyperparathyroidism. Osteomalacia, hepatic abnormalities, and cardiac arrhythmia may occur. Mutations of the $G_{\alpha}$ subunit of the G protein, which couples extracellular hormonal signals to the activation of adenylate cyclase, are responsible for the autonomous hyperfunction of the endocrine glands and, presumably, for the other defects present in this disorder (82). Treatment with a GnRH agonist is not effective because the precocious pubertal development is GnRH independent. Treatment with aromatase inhibitors, such as testolactone and fadrozole, has mixed results. A multicenter trial showed that tamoxifen decreases vaginal bleeding, growth rate, and the rate of bone age advancement (83).

**Primary Hypothyroidism**

**Longstanding primary hypothyroidism is associated with sexual precocity.** It can present with premature breast development or isolated vaginal bleeding. If serum prolactin is elevated, galactorrhea may be present. On pelvic ultrasound, solitary or multiple ovarian cysts may be found. Primary hypothyroidism is the only cause of precocious puberty that is associated with a delayed bone age. These features return to normal within a few months of initiation of levothyroxine therapy.

**Congenital Adrenal Hyperplasia**

**Heterosexual precocious puberty is always of peripheral origin and is most often caused by CAH.** In most untreated or poorly treated adolescent girls and in some adolescent boys, spontaneous true isosexual pubertal development does not occur until proper treatment is instituted. In most patients treated satisfactorily from early life, the onset of puberty occurs at the expected chronological age. Three adrenal enzyme defects—21-hydroxylase deficiency, 11β-hydroxylase deficiency, and 3β-hydroxysteroid dehydrogenase deficiency—can lead to heterosexual precocity and to virilization of the external genitalia because of increased androgen production beginning in utero (84). The clinical presentation of the various forms of CAH depends on the following factors: (i) the affected enzyme, (ii) the extent of residual enzymatic activity, and (iii) the physiologic consequences of deficiencies in the end products and excesses of precursor steroids.

**21-Hydroxylase Deficiency**

**Most patients with classic CAH have 21-hydroxylase deficiency** (Fig. 29.19). All forms of 21-hydroxylase deficiency are caused by homozygous or compound heterozygous mutations in the human CYP21A2 gene, which encodes the 21-hydroxylase enzyme; in the carrier, heterozygote state, only one allele is mutated (85). Two CYP21A2 genes, a 3′ CYP21A2B gene encoding the functional enzyme and a pseudogene termed CYP21A2A, are situated very close to each other within the major histocompatibility locus on the
short arm of chromosome 6. At least one-fourth of cases of 21-hydroxylase deficiency result from unequal crossover and genetic recombination between the two genes during meiosis. Severe mutations do not correlate with severe phenotype, and phenotypic variability likely depends on the activity of other interacting genes.

Neonatal screening suggests an incidence of about 1 in 15,000 births. Because of the location of the gene within the major histocompatibility locus, siblings with 21-hydroxylase deficiency usually have identical human leukocyte antigen (HLA) types. There are various forms of 21-hydroxylase deficiency, including simple virilizing (typically identified at birth because of genital ambiguity), salt-wasting (in which there is impairment of mineralocorticoid and glucocorticoid secretion), and late-onset or nonclassic (in which heterosexual development occurs at the expected age of puberty). The so-called classic form includes the simple virilizing and salt-wasting forms. The nonclassic form is discussed in the following section on heterosexual pubertal development.

Deficiency of 21-hydroxylase results in the impairment of the conversion of $17\alpha$-hydroxyprogesterone to 11-deoxycortisol and of progesterone to deoxycorticosterone (Fig. 29.20). As a consequence, precursors accumulate, and there is increased conversion to adrenal androgens. Because the development of the external genitalia is controlled by androgens, in the classic form of this disorder, girls are born with ambiguous genitalia, including an enlarged clitoris and fusion of the labioscrotal folds and the urogenital sinus. The internal female organs (including the uterus, fallopian tubes, and ovaries) develop normally because they are not affected by the increased androgen levels. In three-quarters of cases with classic 21-hydroxylase deficiency, salt-wasting occurs, as defined by hyponatremia, hyperkalemia, and hypotension. It is important to recognize that the extent of virilization may be the same in simple virilizing and salt-wasting CAH. Thus, even a mildly virilized newborn with 21-hydroxylase deficiency should be observed for signs of a potentially life-threatening crisis within the first weeks of life. During childhood, untreated girls with the classic form grow rapidly but have advanced bone ages, enter puberty early, experience early closure of their epiphyses, and ultimately are short in stature as adults. CAH, with appropriate therapy, is the only inherited disorder of sexual differentiation in which normal pregnancy and childbearing are possible. The classic forms of 21-hydroxylase deficiency are easily diagnosed based on the presence of genital ambiguity and markedly elevated levels of $17\alpha$-hydroxyprogesterone. Some states in the US initiated neonatal screening programs to detect 21-hydroxylase deficiency at birth.

3β-Hydroxysteroid Dehydrogenase

Deficiency of 3β-hydroxysteroid dehydrogenase (3β-HSD), caused by mutations in the HSD3B2 gene that encodes the 3β-HSDDII enzyme, affects the synthesis of glucocorticoids, mineralocorticoids, and sex steroids. Typically, levels of $17\alpha$-hydroxypregnenolone and DHEA are elevated (Fig. 29.20). The classic form of the disorder, detectable at birth, is quite rare, and affected girls may be masculinized only slightly. In severe cases, salt
A nonclassic form of this disorder may be associated with heterosexual precocious pubertal development (as is the classic form if untreated), but postpubertal hyperandrogenism occurs more often. The androgen excess in individuals with nonclassic 3β-HSD deficiency appears to result from androgens derived from the peripheral conversion of increased serum concentrations of DHEA. This disorder is inherited in autosomal recessive fashion, with allelism at the 3β-HSD gene on chromosome 1 believed to be responsible for the varying degrees of enzyme deficiency.

11-Hydroxylase Deficiency

The classic form of 11-hydroxylase deficiency is believed to constitute 5% to 8% of all cases of CAH. Deficiency in 11-hydroxylase, caused by mutations in the CYP11B1 gene, results in the inability to convert 11-deoxycortisol to cortisol and the consequent accumulation of androgen precursors (Fig. 29.20). Markedly elevated levels of 11-deoxycortisol and deoxycorticosterone are present in the disorder. Because deoxycorticosterone acts as a mineralocorticoid, many individuals with this disorder become hypertensive. A mild

nonclassic form of 11-hydroxylase deficiency was reported but apparently is very uncommon (84).

**Treatment of Congenital Adrenal Hyperplasia**

The treatment of CAH involves providing replacement doses of the deficient steroid hormones. Hydrocortisone (10 to 20 mg/m² body surface area) or its equivalent is given daily in divided doses to suppress the elevated levels of pituitary corticotropin present and thus suppress the elevated androgen levels. With such treatment, signs of androgen excess should regress. In children, growth velocity, bone age, and hormone levels should be monitored carefully because both overreplacement and underreplacement can result in premature closure of the epiphyses and short stature. Data now indicate that early diagnosis and compliance with therapy lead to adult height within 1 standard deviation of the anticipated target height in girls with 21-hydroxylase deficiency (86).

Mineralocorticoid replacement is generally required in individuals with 21-hydroxylase deficiency whether or not they are salt losing. The intent of
glucocorticoid therapy should be to suppress morning 17α-hydroxyprogesterone levels to between 300 and 900 ng/dL. Sufficient fludrocortisone should be given daily to suppress plasma renin activity to less than 5 mg/mL per hour.

It is possible to diagnose 21-hydroxylase deficiency prenatally in patients known to be at risk (84). The diagnosis is established by documenting elevated levels of 17α-hydroxyprogesterone or 21-deoxycortisol in amniotic fluid. Genetic diagnosis using specific probes and cells obtained by chorionic villus sampling or amniocentesis is possible. Dexamethasone (20 μg/kg/day in three divided doses) can be administered to the pregnant women beginning before the ninth week of gestation because the urogenital sinus begins to form at nine weeks of gestation. If the fetus is determined to be a male or an unaffected female upon DNA analysis, treatment is discontinued. Otherwise, treatment is continued to term. Human studies found that this treatment regimen is effective in reducing virilization in the genetic female so that genitoplasty was not needed in the majority of cases (87,88). The majority of studies proved that this management scheme is effective for both mother and the child. Maternal complications, including hypertension, massive weight gain, and overt Cushing syndrome, were noted in about 1% of pregnancies in which the mothers are given low doses of dexamethasone. All maternal complications disappear after delivery. The long-term effects of this treatment strategy on the physical and neurodevelopmental health of the offspring remains unclear. A recent systematic review concluded that dexamethasone seems to reduce virilization without significant adverse maternal or fetal effects, though the available data allow merely weak inferences to be made (89). Despite the risks and the nonuniformity of beneficial outcome to affected female fetuses, many parents may choose prenatal medical treatment because of the psychological impact of ambiguous genitalia.

**Girls with ambiguous genitalia may require reconstructive surgery, including clitoral recession and vaginoplasty.** Timing of such surgery is debated, but the girl must be of appropriate size to ensure the surgery is as simple as possible.
Heterosexual Pubertal Development

The most common cause of heterosexual development at the expected age of puberty is PCOS (Fig. 29.21). Because the syndrome is heterogeneous and poorly defined, clinical difficulties result in diagnosis and management (90). For the sake of simplicity, **PCOS may be defined as LH-dependent hyperandrogenism** (91). The Rotterdam criteria are commonly used to identify individuals with PCOS and require the presence of at least two of the following: oligo- or anovulation, clinical and/or biochemical signs of hyperandrogenism, and polycystic ovaries, with exclusion of other etiologies (CAH, androgen-secreting tumors, Cushing syndrome) (92). Polycystic ovaries ultrasonically are defined as the presence of 12 or more follicles in each ovary measuring 2 to 9 mm in diameter and/or increased ovarian volume (>10 mL). Most clinical manifestations arise as a consequence of the hyperandrogenism and often include hirsutism beginning at or near puberty and irregular menses from the age of menarche because of oligo-ovulation or anovulation. **Clinical manifestations are as follows:**

Figure 29.21 Typical facial hirsutism in three women with polycystic ovarian syndrome. A: 25-year-old. B: 21-year-old C: 17-year-old.
Affected girls may be but are not necessarily somewhat overweight. In rare instances, menarche may be delayed, and primary amenorrhea may occur. Basal levels of LH tend to be elevated in most affected individuals, and androgen production is invariably increased, even though circulating levels of androgens may be near the upper limits of the normal range in many affected women. In anovulatory women, estrone levels are typically greater than estradiol levels. Because circulating levels of estrogens are not diminished in PCOS and androgen levels are only mildly elevated, affected girls become both feminized and masculinized at puberty. This is an important feature because girls with classic forms of CAH who do not experience precocious puberty (and even those who do) only become masculinized at puberty (i.e., they do not develop breasts). Some degree of insulin resistance may be present, even in the absence of
overt glucose intolerance (93). Polycystic ovaries are frequently, but not always present in ultrasound examination.

Differential Diagnosis and Evaluation

Distinguishing PCOS from the nonclassic forms of CAH is problematic and controversial (94,95). The evaluation is as follows:

Some clinicians advocate measurement of 17α-hydroxyprogesterone in all women who develop hirsutism. Although values of 17α-hydroxyprogesterone are commonly elevated more than 100-fold in individuals with classic 21-hydroxylase deficiency, they may or may not be elevated in nonclassic late-onset forms of the disorder.

Measurement of 17α-hydroxyprogesterone can identify women with various forms of 11-hydroxylase deficiency.

Basal levels of DHEAS and 17α-hydroxyprogesterone may be moderately elevated in patients with PCOS, making the diagnosis even more difficult. To screen for CAH, 17α-hydroxyprogesterone should be measured in early morning.

In women with regular cyclic menses, it is important to measure 17α-hydroxyprogesterone only in the follicular phase because basal levels increase at midcycle and in the luteal phase.

Measurements of 17α-hydroxyprogesterone appear to be of value in populations at high risk for nonclassic late-onset 21-hydroxylase deficiency. In the white population, the gene occurs in only about 1 in 1,000 individuals, but it occurs in 1 in 27 Ashkenazi Jews, 1 in 40 Hispanics, 1 in 50 Yugoslavs, and 1 in 300 Italians (84). The incidence is increased among Eskimos and French Canadians. Alternatively, screening might be restricted to hirsute teenagers presenting with the more “typical” features of nonclassic 21-hydroxylase deficiency, including severe hirsutism beginning at puberty, “flattening” of the breasts (i.e., defeminization), shorter stature than other family members, and increased DHEAS levels (between 5,000 and 7,000 ng/mL). Women with a strong family history of hirsutism or hypertension might be screened (49) (Fig. 29.22).

Figure 29.22 Left: A 19-year-old girl with secondary amenorrhea and severe acne and hirsutism beginning at the normal age of puberty. Stimulatory testing with corticotropin documented nonclassic 21-hydroxylase deficiency. Flattening of the breasts is apparent. She was shorter than her one sister and her mother. Right: Newborn girl with 46,XX karyotype and genital ambiguity. There is obvious clitoral hypertrophy, paired frenula, so-called scrotalization of the labia, and a common urogenital sinus (shown by the probe). She had 21-hydroxylase deficiency. (From Rebar RW. Normal and abnormal sexual differentiation and pubertal development. In: Moore TR, Reiter RC, Rebar RW, et al., eds. Gynecology and obstetrics: a longitudinal approach. New York: Churchill Livingstone, 1993:97–133, with permission.)
Basal Levels of 17α-Hydroxyprogesterone

Basal levels of 17α-hydroxyprogesterone higher than 800 ng/dL are virtually diagnostic of CAH. Levels between 300 and 800 ng/dL require stimulatory testing with corticotropin to distinguish between PCOS and CAH. To complicate the situation even further, nonclassic 21-hydroxylase deficiency may occur even when basal levels of 17α-hydroxyprogesterone are below 300 ng/dL, thus requiring stimulatory testing in those cases.

Cosyntropin Stimulation Test

The most commonly used stimulatory test involves measurement of 17α-hydroxyprogesterone 30 minutes after administration of a bolus of 0.25 mg of synthetic cosyntropin (Cortrosyn) (96). In normal women, this value seldom exceeds 400 ng/dL. Patients with classic 21-hydroxylase deficiency achieve peak levels of 3,000 ng/dL or higher. Patients with nonclassic 21-hydroxylase deficiency commonly achieve levels of 1,500 ng/dL or more. Heterozygous carriers achieve peak levels up to about 1,000 ng/dL. In hirsute women with hypertension, 11-deoxycortisol levels can be determined during the test. If both 11-deoxycortisol and 17α-hydroxyprogesterone levels are increased, the rare 11-hydroxylase deficiency is present. Only measurements of several steroid precursors after corticotropin stimulation can identify individuals with nonclassic forms of 3β-HSD deficiency.

The elevated levels of 17α-hydroxyprogesterone present in all forms of 21-hydroxylase deficiency are rapidly suppressed by administration of exogenous corticoids. Even a single dose of a glucocorticoid such as dexamethasone will suppress 17α-hydroxyprogesterone in CAH but not in virilizing ovarian and adrenal neoplasms.

Hirsutism

It is suggested that androgen-receptor blockade may be preferable to glucocorticoids as
primary treatment of nonclassic 21-hydroxylase deficiency (97). Although menses usually (but not always) become regular shortly after beginning therapy with glucocorticoids, the hirsutism in this disorder is remarkably refractory to glucocorticoids.

Distinguishing nonclassic forms of CAH from idiopathic hirsutism may be problematic. Individuals with idiopathic hirsutism have regular ovulatory menses, thus effectively eliminating PCOS from consideration. Confusion can be created by the fact that some women with nonclassic CAH may continue to ovulate. Basal levels of 17α-hydroxyprogesterone are normal in idiopathic hirsutism, as is the response to adrenocorticotropic hormone stimulation. Idiopathic hirsutism represents enhanced androgen action at the hair follicle (98).

Mixed Gonadal Dysgenesis

The term mixed gonadal dysgenesis is used to designate those individuals with asymmetric gonadal development, with a germ cell tumor or a testis on one side and an undifferentiated streak, rudimentary gonad, or no gonad on the other side. Most individuals with this rare disorder have a mosaic karyotype of 45,X/46,XY and are raised as girls who experience virilization at puberty. Gonadectomy is indicated to remove the source of androgens and eliminate any risk for neoplasia.

Rare Forms of Male Pseudohermaphroditism

Individuals who have rare forms of male pseudohermaphroditism, especially 5α-reductase deficiency (the so-called penis at 12 syndrome) and the Reifenstein syndrome, generally have ambiguous female genitalia with variable virilization at puberty. Cushing syndrome may occur rarely during the pubertal years, as may adrenal or ovarian androgen-secreting neoplasms.
Genital Ambiguity at Birth

Ambiguous external genitalia in a newborn constitutes a major diagnostic challenge. Prompt evaluation is of critical importance to identify a possible life-threatening disorder and to assign the appropriate gender. The prime diagnosis until ruled out is CAH because it is the only condition that is life-threatening. Extreme sensitivity is required in interacting with the family, and no attempt should be made to guess the sex of the baby. The incidence of genital ambiguity is 1 in 4,500, although some degree of male undervirilization, or female virilization may be present in as many as 2% of live births (99,100).
Physical Signs

During the 3 to 4 days required for evaluation, it is important to be supportive of the parents. Many clinicians believe that it is important not to attach any unusual significance to the genital ambiguity and to treat the abnormality as just another “birth defect.” Physicians should emphasize that the child should undergo normal psychosexual development regardless of the sex-of-rearing selected. Either a name compatible with either sex should be chosen or the naming of the infant should be delayed until the studies are completed.

Although the diagnosis is not usually obvious on examination, there are some helpful distinguishing features (Fig. 29.23). In normal boys, there is only a single midline frenulum on the ventral side of the phallus; in normal girls, there are two frenula lateral to the midline. A girl with clitoral enlargement still has two frenula, and a boy with hypospadias has a single midline frenulum or several irregular fibrous bands (chordee). It is important to determine whether any müllerian derivatives are present. Studies suggest that MRI may be the most effective way of evaluating the infant for the presence of müllerian tissue (101).

The location or consistency of the gonad may be helpful in deducing its composition. A gonad located in the labial or inguinal regions almost always contains testicular tissue. A testis is generally softer than an ovary or a streak gonad and is more apt to be surrounded by blood vessels imparting a reddish cast. An ovary is more often white, fibrous, and convoluted. A gonad that varies in consistency may be an ovotestis or a testis or a streak gonad that underwent neoplastic transformation. If a well-differentiated fallopian tube is absent on only one side, the side without the tube probably contains a testis or ovotestis.
Diagnosis and Management

The fact that there is uncertainty about the sex of one’s baby is devastating and incomprehensible for most parents. Parents require reassurance that either a male or female gender will be assigned ultimately. Optimum clinical management should comprise of the following (67):

Gender assignment must be avoided before expert evaluation of newborns. Evaluation and long-term management must be performed at a center with an experienced multidisciplinary team (pediatric endocrinologist, pediatric urologist, geneticist, clinical psychologist, and gynecologist). All individuals should receive a gender assignment after appropriate assessment.

Open communication with patients and families is essential, and participation in decision making should be encouraged. Patient and family concerns should be respected and addressed in strict confidence.

First-line testing in newborns includes:

- Karyotyping with X- and Y-specific probe detection (even when prenatal karyotype is available)
- Measurement of serum 17-hydroprogesterone, testosterone, gonadotropins, antimüllerian hormone, and electrolytes
- Abdominopelvic ultrasound (to assess anatomy of the vagina, uterus, or urogenital sinus, exclude renal anomalies, and locate any inguinal gonads)
- Urinalysis (to check for protein as a screen for any associated renal anomaly)

The results of these investigations are generally available within 48 hours and sufficient to develop a working diagnosis. If needed, additional testing may include (102):

- Human chorionic gonadotropin- and adrenocorticotropin-stimulation tests to assess testicular and adrenal steroid biosynthesis
- Urinary steroid analysis by gas chromatography mass spectroscopy
- Imaging studies
- Biopsies of gonadal material
- Genetic testing

Although genital ambiguity is usually identified at birth, it may not be recognized for several years. Questions about changing the sex-of-rearing may arise. It was believed that sex-of-rearing may be changed before 2 years of age without psychologically damaging the child, but experience with individuals with 5α-reductase deficiency suggests that gender changes may be made after 2 years of age in certain instances (103). In any case, surgery for genital ambiguity to make the external genitalia (and development) as compatible with the sex-of-rearing of the child
is warranted but was not always successful. Clitoral recession and clitorectomy are the most frequently performed surgical procedures.

Masculinized external genitalia can be classified into five “Prader” stages. Excessive androgen exposure results in virilization to varying degrees, including clitoral enlargement, labial fold fusion, and rostral migration of the urethral/vaginal perineal orifice. Prader stage V defines virilization resulting in complete labioscrotal fusion, a penile phallus with the urethra opening on the glans. Clitoroplasty is required at an early stage after it is established that a Prader stage V “male” has CAH and needs to be reassigned to the female sex (104).
Teratogens
It is important to recognize that ambiguous genitalia can result from the maternal ingestion of various teratogens, most of which are synthetic steroids (Table 29.3). Exposure to the teratogen must occur early in pregnancy, during genital organogenesis. Not all exposed fetuses manifest the same anomalies or even the presence of any anomalies. In principle, most synthetic steroids with androgenic properties, including weakly androgenic progestins, can affect female genital differentiation. The doses required to produce genital ambiguity are generally so great that the concern is only theoretical. The one agent that can lead to genital ambiguity when ingested in clinically used quantities is danazol. There is no evidence that inadvertent ingestion of oral contraceptives, which contain relatively low doses of either mestranol or ethinyl estradiol and a 19-nor-steroid, results in virilization (105,106).

aThose agents proved to cause genital ambiguity do so only when administered in relatively high doses. Insufficient data exist regarding effects of dimethisterone and norgestrel. In low doses (e.g., as in oral contraceptives), progestins, even including norethindrone, seem unlikely to virilize a female fetus.
References

Girls experienced menarche at increasingly younger ages during the past century. Primary amenorrhea is defined as absence of menses at age 13 years when there is no visible development of secondary sexual characteristics or age 15 years in the presence of normal secondary sexual characteristics. Absent or irregular menses may be an indication that a woman has a medical condition that can affect her overall health. The health implications can vary depending on the etiology of the amenorrhea. Therefore, a cause for amenorrhea should be established whenever possible.

When gonadal failure occurs in conjunction with primary amenorrhea, it is associated with a high incidence of abnormal karyotype. The anatomic causes of amenorrhea are relatively few, and the majority may be diagnosed by history and physical examination. The most important elements in the diagnosis of amenorrhea include physical examination for secondary sexual characteristics and anatomic abnormalities, measurement of human chorionic gonadotropin (hCG) to rule out pregnancy, serum prolactin and thyroid stimulating hormone (TSH) levels, and assessment of follicle-stimulating hormone (FSH) levels to differentiate between hypergonadotropic and hypogonadotropic forms of hypogonadism.

Therapeutic measures may include specific therapies (medical or surgical) aimed at correcting the primary cause of amenorrhea, hormone therapy to initiate and maintain secondary sexual characteristics and provide symptomatic relief, treatments to maximize and maintain peak bone mass including hormone therapy, calcium, and vitamin D for cases where circulating estrogen levels are low, and ovulation induction for patients desiring pregnancy.
A complex hormonal interaction must take place in order for normal menstruation to occur. The hypothalamus must secrete gonadotropin-releasing hormone (GnRH) in a pulsatile fashion, which is modulated by neurotransmitters and hormones. The GnRH stimulates secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the pituitary, which promotes ovarian follicular development and ovulation. A normally functioning ovarian follicle secretes estrogen; after ovulation, the follicle is converted to corpus luteum, and progesterone is secreted in addition to estrogen. These hormones stimulate endometrial development. If pregnancy does not occur, estrogen and progesterone secretion decrease and withdrawal bleeding begins. If any of the components (hypothalamus, pituitary, ovary, uterus, and outflow tract) are nonfunctional, bleeding cannot occur.

The mean age of menarche became younger during this century. Therefore, the definition of primary amenorrhea changed: Primary amenorrhea is defined as the absence of menses by 13 years of age when there is no visible development of secondary sexual characteristics or by 15 years of age in the presence of normal secondary sexual characteristics. The ages defining primary amenorrhea were decreased by 1 year to continue to represent two standard deviations above the mean age of developing secondary sexual characteristics and menses (1). Failure to begin breast development by age 13 warrants investigation. A woman who previously menstruated can develop secondary amenorrhea, which is defined as absence of menstruation for three normal menstrual cycles (2). A woman with regular cycles and a delay of menses of even a week may warrant assessment with a pregnancy test. It is reasonable to evaluate a woman who has fewer than nine cycles per year. With a few exceptions, the causes of primary amenorrhea are similar to the causes of secondary amenorrhea.

Patients may develop slight alterations in the hypothalamic–pituitary–ovarian axis that are not severe enough to cause amenorrhea but instead cause irregular menses (oligomenorrhea) associated with absent or infrequent ovulation. These patients may bleed excessively during menstruation because estrogen is unopposed. The etiologies of oligomenorrhea overlap with the etiologies of amenorrhea, with the exception that certain anatomic (e.g., absent uterine development) and karyotypic abnormalities (e.g., Turner syndrome), are largely associated with primary amenorrhea.

The World Health Organization (WHO) described three classes of amenorrhea. WHO Group I includes women with no evidence of endogenous estrogen production, normal or low FSH levels, normal prolactin levels, and no lesion in the hypothalamic-pituitary region. WHO Group II is associated with evidence of estrogen production and normal levels of prolactin and FSH. WHO Group III includes individuals with elevated serum FSH indicating gonadal insufficiency or failure.

To detect the cause of amenorrhea, it is useful to determine whether secondary sexual characteristics are present (Fig. 30.1). The absence of
secondary sexual characteristics indicates that a woman was never exposed to estrogen.

Amenorrhea without Secondary Sexual Characteristics

Although the diagnosis and treatment of disorders associated with hypogonadism were discussed in another chapter (see Chapter 29), they will be mentioned here because these conditions may present as primary amenorrhea. **Because breast development is the first sign of estrogen exposure in puberty, patients without secondary sexual characteristics typically have primary, not secondary, amenorrhea** (Fig 30.1). It is helpful to categorize the causes of amenorrhea in the absence of breast development on the basis of gonadotropin status.
Causes of Primary Amenorrhea

Hypergonadotropic Hypogonadism Associated with Absence of Secondary Sexual Characteristics

Gonadal dysgenesis is a term typically used to describe abnormal development of the gonads, typically resulting in streak gonads. Gonadal dysgenesis is associated with high levels of LH and FSH because the gonad fails to produce the steroids and inhibin that would normally feed back to the pituitary gland to suppress pituitary production of LH and FSH. Karyotypic abnormalities are common in women with primary amenorrhea associated with gonadal failure (Table 30.1). In one series, approximately 30% of patients with primary amenorrhea had an associated karyotypic abnormality (3). Turner syndrome (45,X) and its variants represent the most common form of hypergonadotropic hypogonadism in women with primary amenorrhea. Other disorders associated with primary amenorrhea include structurally abnormal X chromosomes, mosaicism (e.g., 45,X in some cells and another karyotype such as 46,XX or 46,XXX in other cells), pure gonadal dysgenesis (46,XX and 46,XY individuals with gonadal streaks resulting from lack of gonad development), enzyme deficiencies that prevent normal estrogen production, and gonadotropin-receptor inactivating mutations. Individuals with these conditions have gonadal failure and cannot synthesize ovarian steroids. Therefore, gonadotropin levels are elevated because of the lack of negative estrogen feedback on the hypothalamic–pituitary axis. Most patients with these conditions have primary amenorrhea and lack secondary sexual characteristics. Occasionally patients with a partial deletion of the X chromosome, mosaicism, or pure gonadal dysgenesis (46,XX) may synthesize enough estrogen in early puberty to induce breast development and a few episodes of uterine bleeding and thus have secondary amenorrhea. Ovulation and, occasionally, pregnancy are possible.

Hypothalamic/pituitary dysfunction

**Genetic Disorders**

**Turner Syndrome**

*Turner syndrome (45,X) is the most common karyotypic abnormality causing gonadal failure and primary amenorrhea* *(3,4).* It appears that patients with Turner syndrome initially have normal ovarian development in utero. Amenorrhea is the result of accelerated atresia of the follicles. The fibrotic ovaries are called streak ovaries.

*In addition to gonadal failure, there are associated stigmata with Turner syndrome that include short stature, webbed neck, shield chest, cubitus valgus (increased carrying angle of the arms), low hair line, high arched palate, multiple pigmented nevi, and short fourth metacarpals* *(4).* X inactivation is a process that inactivates most of the genes on one X chromosome. Of the genes on the X chromosome, 20% escape X inactivation, and it is believed that loss of the second copy of these genes in a 45,X patient causes the stigmata associated with Turner syndrome *(5).*

*After the diagnosis of Turner syndrome is confirmed by karyotype, studies should be performed to ensure that cardiac (30% have coarctation of the aorta), renal (especially horseshoe kidney), and autoimmune (thyroiditis) abnormalities are diagnosed and treated.* Cardiac magnetic resonance imaging (MRI) should be used in addition to echocardiography *(6).* Evaluation should be performed in childhood to identify potential attention-deficit or nonverbal learning disorders. **Women with Turner syndrome should be screened for diabetes mellitus, aortic enlargement, hypertension, and hearing loss throughout their lives** *(6).*

**Abnormal X Chromosome**

*Those 46,XX individuals with partial deletions of the X chromosome have variable phenotypes depending on the amount and location of the missing genetic material.* Patients with a deletion of the long arm of the X chromosome (Xq−) from Xq13 to Xq26 have sexual infantilism, normal stature, no somatic abnormalities, and streak gonads *(7).* Some patients may be eunuchoid in appearance and have delayed epiphyseal closure. Patients with a deletion of the short arm of the X chromosome (Xp)
usually are phenotypically similar to individuals with Turner syndrome (8). Many genes on the Xp chromosome escape X inactivation and act similarly to genes on autosomes. The effective monosomy created by the deletion results in the phenotypic features of Turner syndrome (5). Most patients with a ring X have ovarian failure and phenotypes similar to Turner syndrome, although some are able to reproduce successfully. These patients differ from those with Turner syndrome in that they are more likely to have intellectual disability and have syndactyly. Patients with isochrome of the long arm of the X chromosome (i[Xq]) are similar to XO patients, with the exception that autoimmune disorders are more common. Half of the women with balanced translocations of the X chromosome to an autosome have gonadal failure. Typically, the normal X is inactivated to preserve the balance of autosomal genes. The gonadal failure can be caused by the chromosomal break occurring in a gene that is required for ovarian function, abnormal meiosis, or X inactivation of the translocated X and adjacent autosomal genes (5,9).

**Mosaicism**

**Primary amenorrhea is associated with various mosaic states, the most common of which is 45,X/46,XX (10).** The clinical findings in 45,X/47,XXX and 45,X/46,XX/47,XXX are similar to those in 45,X/46,XX and vary in estrogen and gonadotropin production, depending on the number of follicles in the gonads. When compared with the pure 45,X cell line, individuals with 45,X/46,XX are taller and have fewer abnormalities, although 80% of those with 45,X/46,XX mosaics are shorter than their peers, and 66% have some somatic abnormalities. Spontaneous menstruation occurs in approximately 20% of these patients (10).

**Pure Gonadal Dysgenesis**

**Individuals who are phenotypically female with sexual infantilism, primary amenorrhea, normal stature, and no karyotypic abnormalities (46,XX or 46,XY) have pure gonadal dysgenesis.** The gonads are usually streaks, but there may be some development of secondary sexual characteristics, and a few episodes of uterine bleeding. Pure gonadal dysgenesis in a 46,XY individual (previously known as Swyer syndrome) can occur when mutations in the SRY (sex-determining region gene on the Y chromosome) located at Yp11 result in XY females without proper gonad development (11,12).

Mutations in many other genes such as SOX9, DAX1, WT-1, and SF1, which affect testicular differentiation and inhibit antimüllerian hormone production, result in XY pure gonadal dysgenesis (13). The SOX9 gene located at 17q24 has a role in testis differentiation and promotes antimüllerian hormone secretion. Some but not all mutations in the SOX9 gene cause XY sex reversal, along with camptomelic dysplasia (severe skeletal abnormalities) (14,15). Duplications of the DAX1 gene at Xp21 cause dose-sensitive XY sex reversal (16). DAX1 is hypothesized to antagonize the SRY gene, preventing testis development. Transgenic XY mice with overexpression of the DAX1 gene develop as phenotypic females, supporting this hypothesis (17). Mutation in the
WT1 gene (Wilms' tumor suppressor gene 1) located at 11p13 causes several different syndromes, depending on where the mutation in the gene occurs. In Frasier syndrome, there is alternative splicing, which causes the protein product to lack a highly conserved KTS triplet repeat. The normal +KTS isoform of the protein is believed to synergize with SF1 (steroidogenic factor 1) to promote the expression of antimüllerian hormone (AMH). Lack of the +KTS isoform in an XY patient results in normal female internal and external genitalia, streak gonads, and progressive glomerulopathy. These women frequently develop gonadoblastomas but rarely develop Wilms' tumor, which is associated with mutations in other locations in the WT1 gene. XX patients with the mutation that prevents the +KTS isoform have similar kidney abnormalities but develop normal ovaries and genitalia (17–19). One XY patient with a heterozygous mutation of the SF1 gene had adrenal failure and sex reversal (20). SF1 is an orphan nuclear receptor that regulates AMH expression and regulates all the cytochrome P450 steroid hydroxylase enzymes (19). Duplication of 1p, which encodes the WNT4 gene, causes XY sex reversal. WNT4 may upregulate DAX1 transcripts. A TRX mutation causes XY sex reversal. Other genes that cause XY gonadal dysgenesis are likely to be identified. Mutations at 9p24 and 10q cause XY sex reversal, but the exact genes causing the defects are not elucidated (17,19,21).

XX pure gonadal dysgenesis can be caused by the presence of small Y chromosome fragments in the genome. It is estimated that 5% to 40% of patients with Ullrich-Turner syndrome have Y sequences by polymerase chain reaction (PCR), depending on the DNA sequences targeted for testing (22,23). If Y sequences are present, gonadectomy is advised because of the risk of gonadoblastoma (22).

In other patients with XX gonadal dysgenesis, the condition is likely to be caused by gene mutations that lead to ovarian insufficiency before pubertal development or after the development of secondary sexual characteristics, as discussed later in this chapter.

**Mixed Gonadal Dysgenesis**

Most patients with mixed gonadal dysgenesis are XY and have ambiguous genitalia with a streak gonad on one side and a malformed testis on the opposite. A small proportion of these patients have mutations in the SRY gene (17).

**Rare Enzyme Deficiencies**

**Congenital Lipoid Adrenal Hyperplasia**

Patients with this autosomal recessive disorder are unable to convert cholesterol to pregnenolone, which is the first step in steroid hormone biosynthesis. A defect was not found in the P450scC gene, which is the conversion enzyme responsible for this step in the pathway. Instead, 15 different mutations were identified in the steroidogenic acute regulatory protein (StAR), which facilitates the transport of cholesterol from the outer to the inner mitochondrial membrane. This protein
appears to be the rate-limiting step for steroid hormone biosynthesis stimulated by tropic hormones. These patients present in infancy with hyponatremia, hyperkalemia, and acidosis. Both XX and XY individuals are phenotypically female. Genetic clusters of the disorder are found in the Japanese, Korean, and Palestinian Arab populations. With appropriate mineralocorticoid and glucocorticoid replacement, these patients can survive into adulthood. Most patients are XY and do not have a uterus. Without hormone replacement, they remain sexually infantile. XX patients may acquire secondary sexual characteristics at puberty but develop large ovarian cysts and early ovarian failure (24,25).

17α-Hydroxylase and 17,20-lyase Deficiency

Mutations in the CYP17 gene cause abnormalities in both the 17α-hydroxylase and 17,20-lyase functions of the protein that is active in the adrenal and gonadal steroidogenic pathways. More than 20 mutations that alter the reading frame of the gene are identified, even though very few people have the disorder (26). Patients have either 46,XX or 46,XY karyotypes. The uterus is absent in individuals with 46,XY karyotype, a feature distinguishing them from individuals with the 46,XX karyotype. Individuals with CYP17 mutations have primary amenorrhea, no secondary sexual characteristics, female phenotype, hypertension, and hypokalemia (27). The diminished levels of 17α-hydroxylase that characterize this disorder lead to a reduction in cortisol production, which in turn causes an increase in adrenocorticotropic hormone (ACTH). 17α-hydroxylase is not required for production of mineralocorticoids; thus, excessive amounts of mineralocorticoid are produced, resulting in sodium retention, loss of potassium, and hypertension. Patients with 17α-hydroxylase deficiency have primordial follicles, but gonadotropin levels are elevated because the enzyme deficiency prevents synthesis of sex steroids.

Aromatase Deficiency

This very rare autosomal recessive abnormality prevents the affected individual from aromatizing androgens to estrogen (28). This syndrome may be suspected even before birth because most mothers of affected children become virilized during pregnancy. This occurs because the placenta cannot convert the fetal androgens to estrogen and they diffuse into the maternal circulation. At birth, a female child has clitoromegaly and posterior labioscrotal fusion (ambiguous genitalia). At puberty, there is no breast development, primary amenorrhea, worsening virilization, absent growth spurt, delayed bone age, and multicystic ovaries. The diagnostic hormonal pattern consists of an elevation of FSH, LH, testosterone, and dehydroepiandrosterone sulfate (DHEAS) levels, and undetectable levels of estradiol. Estrogen therapy improves the ovarian and skeletal abnormalities but must be titrated to mimic normal estrogen levels. Estrogen administration should be minimal during childhood and increased at puberty (29,30).

Galactosemia
In girls, galactosemia often is associated with ovarian failure, but this condition usually is detected by newborn screening programs. A galactose-1-phosphate uridyl transferase level can be measured to assess the patient for galactosemia or carrier status.

**Rare Gonadotropin Receptor Mutations**

**Luteinizing Hormone Receptor Mutation**

Inactivation of LH receptors is identified in XY pseudohermaphrodites with primary amenorrhea in the absence of secondary sexual characteristics caused by homozygous premature stop codon, deletions, and missense mutations in the LHR gene located on chromosome 2. The Leydig cells in these individuals are unable to respond to LH, causing Leydig cell hypoplasia. This leads to early testicular failure and prevents masculinization. XX siblings with the same mutations develop normal secondary sexual characteristics but are amenorrheic with elevated LH levels, normal FSH levels, and cystic ovaries (31,32).

**Follicle-Stimulating Hormone Receptor Mutation**

An autosomal recessive single amino acid substitution in the extracellular domain of the FSH receptor, which prevents FSH binding, was identified in six families in Finland. This condition leads to primary or early secondary amenorrhea, variable development of secondary sexual characteristics, and high levels of FSH and LH (33).

**Other Causes of Primary Ovarian Failure without Secondary Sexual Characteristics**

Severe damage to the ovaries before the onset of puberty can lead to ovarian insufficiency and failure to develop secondary sexual characteristics. Ovarian dysfunction can occur in association with irradiation of the ovaries, chemotherapy with alkylating agents (e.g., cyclophosphamide), or combinations of radiation and other chemotherapeutic agents (34,35). Other causes of premature ovarian failure (also known as primary ovarian insufficiency) are more commonly associated with amenorrhea after the development of secondary sexual characteristics, as described below.

**Hypogonadotropic Hypogonadism Associated with the Absence of Secondary Sex Characteristics**

Primary amenorrhea resulting from hypogonadotropic hypogonadism occurs when the hypothalamus fails to secrete adequate amounts of GnRH or when a pituitary disorder associated with inadequate production or release of pituitary gonadotropins is present.

**Physiologic Delay**
Physiologic or constitutional delay of puberty is the most common manifestation of hypogonadotropic hypogonadism. Amenorrhea may result from the lack of physical development caused by delayed reactivation of the GnRH pulse generator. Levels of GnRH are functionally deficient in relation to chronologic age but normal in terms of physiologic development.

Kallmann Syndrome

The second most common hypothalamic cause of primary amenorrhea associated with hypogonadotropic hypogonadism is insufficient pulsatile secretion of GnRH (Kallmann syndrome), which has varied modes of genetic transmission. Insufficient pulsatile secretion of GnRH leads to deficiencies in FSH and LH. Kallmann syndrome is often associated with anosmia (inability to perceive odors), although a woman may not be aware of her impaired sense of smell. The hypogonadism and anosmia arise because of failure of proper neuronal migration during fetal development.

Other Causes of Gonadotropin-Releasing Hormone Deficiency

Deficiencies in GnRH may be caused by developmental or genetic defects, inflammatory processes, tumors, vascular lesions, or trauma. Central nervous system tumors that lead to primary amenorrhea, the most common of which is craniopharyngioma, are usually extracellular masses that interfere with the synthesis and secretion of GnRH or stimulation of pituitary gonadotropins. Virtually all of these patients have disorders in the production of other pituitary hormones and LH and FSH. Prolactin-secreting pituitary adenomas are rare in childhood and more commonly occur after development of secondary sexual characteristics.

Genetic Disorders

5α-Reductase Deficiency

5α-Reductase deficiency should be considered a cause of amenorrhea. Patients with this disorder are genotypically XY, frequently experience virilization at puberty, have testes (because of functioning Y chromosomes), and have no müllerian structures as a result of functioning AMH. 5α-Reductase converts testosterone to its more potent form, dihydrotestosterone. Patients with 5α-reductase deficiency differ from patients with androgen insensitivity because they do not develop breasts at puberty. These patients have low gonadotropin levels as a result of testosterone levels that are sufficient to suppress breast development and allow normal feedback mechanisms to remain intact. Normal male differentiation of the urogenital sinus and external genitalia do not occur because dihydrotestosterone is required for this development. Normal internal male genitalia derived from the wolffian ducts are present because this development requires only testosterone. Male pattern hair growth, muscle mass, and voice deepening are testosterone dependent.
Gonadotropin-Releasing Hormone Receptor Mutations

Several mutations are identified in the GnRH receptor gene that causes abnormal GnRH function. Most affected patients are compound heterozygotes, but homozygous autosomal recessive mutations are identified. The GnRH receptor is a G-protein-coupled receptor. Functional studies show that the mutations cause marked decrease in binding of GnRH to its receptor or prevent second-messenger signal transduction. Without a functional signal transduction, FSH and LH are not stimulated and are unable to promote follicular growth (40). All patients are normosomic. Receptor mutations in GnRH cause 17% of sporadic cases of idiopathic hypogonadotropic hypogonadism with normal olfaction (41).

Follicle-Stimulating Hormone Deficiency

Patients with FSH deficiency usually seek treatment for delayed puberty and primary amenorrhea associated with hypoestrogenism. They are distinguished from other hypoestrogenic patients by having decreased FSH levels and increased LH levels. These patients have low serum androgen levels despite the abnormal LH-to-FSH ratio, indicating that FSH-stimulated follicular development is a prerequisite for thecal cell androgen production. In some of these patients, autosomal recessive mutations in the FSHβ subunit, which impair dimerization of α and β subunits and prevent binding to the FSH receptor, are identified (42). Pregnancy was achieved in one patient after induction of ovulation with injectable gonadotropins (43).

Other Hypothalamic/ Pituitary Dysfunctions

Functional gonadotropin deficiency results from malnutrition, malabsorption, weight loss or anorexia nervosa, excessive exercise, chronic disease, neoplasias, and marijuana use, although these conditions are more commonly associated with amenorrhea accompanied by secondary sexual characteristics that developed before the onset of the problem, which is discussed in detail below (44–48). Hypothyroidism, polycystic ovarian syndrome (PCOS), Cushing syndrome, hyperprolactinemia, and infiltrative disorders of the central nervous system are more commonly associated with amenorrhea in the presence of development of secondary sexual characteristics, but can lead to amenorrhea accompanied by delayed puberty (49,50). Constitutional delay without underlying causes is less common in girls than in boys, and the reason for lack of development should be vigorously pursued (51).
Evaluation of Women with Amenorrhea Associated with the Absence of Secondary Sexual Characteristics

A careful history and physical examination are necessary to appropriately diagnose and treat primary amenorrhea associated with hypogonadism. The physical examination may be particularly helpful in patients with Turner syndrome. A history of short stature but consistent growth rate, a family history of delayed puberty, and normal physical findings (including assessment of smell, optic discs, and visual fields) may suggest physiologic delay. Headaches, visual disturbances, short stature, symptoms of diabetes insipidus, and weakness of one or more limbs suggest central nervous system lesions (38). Galactorrhea may be seen with prolactinomas, a condition more commonly associated with secondary amenorrhea in the presence of normal secondary sexual characteristics.

The diagnostic workup is summarized as follows:

**The initial laboratory test should be assessment of serum FSH and LH levels unless the history and physical examination suggest otherwise in order to differentiate hypergonadotropic and hypogonadotropic forms of hypogonadism.** If the FSH level is elevated, a karyotype should be obtained. An elevated FSH level in combination with a 45,X karyotype confirms the diagnosis of Turner syndrome. Partial deletion of the X chromosome, mosaicism, pure gonadal dysgenesis, and mixed gonadal dysgenesis are diagnosed by obtaining a karyotype.

**Because of the association with coarctation of the aorta (up to 30%) and thyroid dysfunction, patients with Turner syndrome should undergo echocardiography every 3 to 5 years and thyroid function studies yearly.** Cardiac MRI is considered an important component of the cardiac evaluation (6). Patients with Turner syndrome should be evaluated for hearing loss, renal malformations, diabetes, and hypertension.

If the karyotype is abnormal and contains the Y chromosome, as in gonadal dysgenesis, the gonads should be removed to prevent tumors (13).

If the karyotype is normal and the FSH level is elevated, it is important to consider the diagnosis of 17α-hydroxylase deficiency because it may be a life-threatening disease if untreated. This diagnosis should be considered when testing indicates elevated serum progesterone (>3.0 ng/mL) level, a low 17α-hydroxyprogesterone (0.2 ng/mL) level, and an elevated serum deoxycorticosterone level (52). The diagnosis is confirmed with an ACTH stimulation test. After ACTH bolus administration, affected individuals have markedly increased levels of serum progesterone compared with baseline levels and no change in serum 17α-hydroxyprogesterone levels.

If the screening FSH level is low, the diagnosis of hypogonadotropic hypogonadism is established. Central nervous system lesions should be ruled out by imaging using computed tomography (CT) or MRI, especially if galactorrhea, headaches, or visual field defects are identified. Suprasellar or
intrasellar calcification in an abnormal sella is found in approximately 70% of patients with craniopharyngioma (38).

**Physiologic delay is a diagnosis of exclusion that is difficult to distinguish from insufficient GnRH secretion.** The diagnosis can be supported by a history suggesting physiologic delay, an x-ray showing delayed bone age, and the absence of a central nervous system lesion on CT or MRI scanning.
Treatment of Amenorrhea Associated with the Absence of Secondary Sexual Characteristics

Individuals with primary amenorrhea associated with all forms of gonadal failure and hypergonadotropic hypogonadism need cyclic estrogen and progestogen therapy to initiate, mature, and maintain secondary sexual characteristics. Prevention of osteoporosis is an additional benefit of estrogen therapy:

Therapy is usually initiated with 0.3 to 0.625 mg per day of conjugated estrogens or 0.5 to 1 mg per day of estradiol.

If the patient is short in stature, higher doses should not be used because premature closure of the epiphyses should be avoided. Most of these patients are of normal height, and higher estrogen doses may be used initially and reduced to the maintenance doses after several months.

Estrogen can be given daily in combination with progestogen (medroxyprogesterone acetate or progesterone) to prevent hyperplasia that could result from unopposed estrogen stimulation of the endometrium in patients with a uterus. Medroxyprogesterone acetate may be administered at a dose of 2.5 mg daily every day of the month or 5 to 10 mg for 12 to 14 days per month. Oral micronized progesterone may be administered at a daily dose 100 mg every day of the month or 200 mg daily for 12 to 14 days per month. Cyclic hormone therapy (with 12 to 14 days of progestogen per month) more closely mimics the natural menstrual cycle. Progesterone suppositories may be administered at a dose of 50 mg daily or 100 mg for 12 to 14 days monthly.

Occasionally, individuals with mosaicism and gonadal streaks may ovulate and be able to conceive either spontaneously or after the institution of estrogen therapy.

If 17α-hydroxylase deficiency is confirmed, treatment is instituted with corticosteroid replacement and estrogen. Progestogen should be added to protect the endometrium from hyperplasia.

If possible, therapeutic measures are aimed at correcting the primary cause of amenorrhea:

Craniopharyngiomas may be resected with a transsphenoidal approach or during craniotomy, depending on the size of the tumor. Some studies show improved prognosis with radiation therapy used in combination with limited tumor removal (38,53). Germinomas are highly radiosensitive, and surgery is rarely indicated (54). Prolactinomas and hyperprolactinemia often may respond to dopamine agonists (bromocriptine or cabergoline) (55). Specific therapies are directed toward malnutrition, malabsorption, weight loss, anorexia nervosa, exercise amenorrhea, neoplasia, and chronic diseases. Logically, it would appear that patients with hypogonadotropic hypogonadism of hypothalamic origin should be treated with long-term administration of pulsatile GnRH.
This form of therapy is impractical because it requires the use of an indwelling catheter and a portable pump for prolonged periods and the lack of availability of this equipment in the United States. The primary focus of treatment should be to correct the underlying problem that is causing the menstrual dysfunction (e.g., malnutrition). If a patient is unable to correct the underlying condition, she may be treated with cyclic estrogen and progestogen therapy at least until sexual maturity is achieved. Once sexual maturation is achieved, hormone therapy can be continued to treat hypoestrogenic symptoms until the underlying disorder leading to amenorrhea can be adequately treated.

Patients with Kallmann syndrome, and patients with other etiologies for hypothalamic amenorrhea, can be treated with hormone replacement, as described above. For individuals with anorexia, intensive treatment to achieve weight gain and emotional well-being is preferable to long-term treatment with hormone therapy (56).

If the patient has physiologic delay of puberty, the only management required is reassurance that the anticipated development will occur eventually.

Individuals whose karyotypes contain a Y cell line (45,X/46,XY mosaicism, or pure gonadal dysgenesis 46,XY) are predisposed to gonadal ridge tumors, such as gonadoblastomas, dysgerminomas, and yolk sac tumors. The gonads of these individuals should be removed when the condition is diagnosed to prevent malignant transformation. There is some evidence that hirsute individuals without Y chromosomes should undergo gonad removal. One patient with hirsutism and the karyotype 45,X was noted to have a streak gonad; the contralateral gonad was dysgenic and contained developing follicles, well-differentiated seminiferous tubules, and Leydig cells. This patient was found to be HY antigen–positive (57).

Clomiphene citrate is most often ineffective for inducing ovulation in patients with hypogonadism who desire pregnancy because such patients are hypoestrogenic. In patients with hypogonadism, ovulation induction with injectable gonadotropins is generally successful. In patients without ovarian function, oocyte donation may be appropriate. There are reports of deaths in pregnant patients with Turner syndrome resulting from aortic dissection and rupture (58). Careful counseling and investigation should be undertaken in patients with Turner syndrome before treating them with donated oocytes.
Amenorrhea with Secondary Sexual Characteristics and Abnormalities of Pelvic Anatomy

Causes

Outflow and Müllerian Anomalies

Amenorrhea occurs if there is blockage of the outflow tract, if the outflow tract is missing, or if there is no functioning uterus (Table 30.2) In order for menses to occur, the endometrium must be functional and there must be patency of the cervix and vagina. Most women with müllerian abnormalities will have normal ovarian function and thus will have normal secondary sexual characteristic development.

Table 30.2 Anatomic Causes of Amenorrhea

Secondary sexual characteristics present

- Müllerian anomalies
- Imperforate hymen
- Transverse vaginal septum
- Mayer-Rokitansky-Küster-Hauser syndrome
- Androgen insensitivity
- True hermaphrodism
- Absent endometrium
- Asherman syndrome
  - Secondary to prior uterine or cervical surgery
    - Curettage, especially postpartum
    - Cone biopsy
    - Loop electroexcision procedure
- Secondary to infections
  - Pelvic inflammatory disease
  - Intrauterine devise–related
  - Tuberculosis
  - Schistosomiasis

Transverse Blockages

Any transverse blockage of the müllerian system will cause amenorrhea (59). Such outflow obstructions include imperforate hymen, transverse vaginal septum, and absence of the cervix or vagina. Transverse blockage of the outflow tract with an intact endometrium frequently causes cyclic pain without menstrual bleeding in adolescents. The blockage of blood flow can cause hematocolpos, hematometra, or
hemoperitoneum, and endometriosis.

Müllerian Anomalies

Mayer-Rokitansky-Küster-Hauser syndrome includes vaginal agenesis with variable müllerian duct abnormalities accompanied in some cases by renal, skeletal, and auditory abnormalities (60). Müllerian agenesis accounts for approximately 10% of cases of primary amenorrhea (2). Of the patients with this syndrome, 15% have an absent, pelvic, or horseshoe kidney, 40% have a double urinary collecting system, and 5% to 12% have skeletal abnormalities (61–63). Mayer-Rokitansky-Küster-Hauser syndrome is associated with abnormal galactose metabolism (64).

Absence of Functioning Endometrium

Amenorrhea may occur if there is no functioning endometrium. When the findings of the physical examination are normal, anatomic abnormalities of the uterine cavity should be considered. A congenitally absent endometrium is a rare finding in patients with primary amenorrhea. Asherman syndrome, which is more common with secondary amenorrhea or hypomenorrhea, may occur in patients with risk factors for endometrial or cervical scarring (Fig. 30.3). Such risk factors include a history of uterine or cervical surgery, infections related to use of an intrauterine device, and severe pelvic inflammatory disease. Asherman syndrome is found in 39% of patients undergoing hysterosalpingography who previously underwent postpartum curettage (65). Infections such as tuberculosis and schistosomiasis may cause Asherman syndrome but are not common for women who have lived their whole lives in the United States. Cervical stenosis resulting from surgical removal of dysplasia (cone biopsy, loop electroexcision procedure) may lead to amenorrhea.

Figure 30.2 A: A well-developed patient with complete androgen insensitivity. Note the characteristic paucity of pubic hair and well-developed breasts. (From Yen SSC, Jaffe RB. Reproductive endocrinology. 3rd ed. Philadelphia, PA: WB Saunders, 1991:497, with permission.) B: Another patient with androgen insensitivity syndrome with a contrasting thin body hiatus. This is a 17-year-old twin 46,XY. (From Jones HW Jr, Scott WW. Hermaphroditism, genital anomalies, and related endocrine disorders. 2nd ed. Baltimore, MD: Williams & Wilkins, 1971, with permission.)
Androgen Insensitivity
Phenotypic females with complete congenital androgen insensitivity
Defects in the androgen receptor gene located on the X chromosome include absence of the gene that encodes for the androgen receptor and abnormalities in the binding domains of the receptor. Androgen receptor deficits are diverse and may result from diminished receptor function or concentration. The diversity of androgen receptor mutations may be related to diversity in phenotype. More than 250 extremely diverse mutations are described, with amino acid substitution being by far the most common. Postreceptor defects can exist. Total serum testosterone concentration is in the range of normal males. Because antimüllerian hormone is present and functions normally in these patients, internal female (müllerian) structures such as a uterus, vagina, and fallopian tubes are absent. Testes rather than ovaries are present in the abdomen or in inguinal hernias because of the presence of normally functioning genes on the Y chromosome. Patients have a blind vaginal pouch and scant or absent axillary and pubic hair. These patients experience abundant breast development at puberty; however, the nipples are immature and the areolae are pale. Testosterone is not present during development to suppress the formation of breast tissues; at puberty, the conversion of testosterone to estrogen stimulates breast growth. Patients are unusually tall with eunuchoidal tendency (long arms with big hands and feet).

**True Hermaphroditism**

True hermaphroditism is a rare condition that should be considered as a possible cause of amenorrhea. Both male and female gonadal tissues are present in these patients, in whom XX, XY, and mosaic genotypes are found. Two-thirds of the patients menstruate, but menstruation was never reported in XY genotypes. The external genitalia usually are ambiguous, and breast development frequently occurs in these individuals. Fifteen percent of XX true hermaphrodites have SRY translocations, and another 10% have Y chromosomal mosaicism within the gonad.
Evaluation of Women with Amenorrhea, Normal Secondary Sexual Characteristics, and Suspected Anatomic Abnormalities

Most congenital abnormalities can be diagnosed by physical examination:

An imperforate hymen is diagnosed by the presence of a bulging membrane that distends during Valsalva maneuver. Ultrasonography or MRI is useful to identify the müllerian anomaly when the abnormality cannot be found by physical examination. The patient should be examined for skeletal malformations and assessed with intravenous pyelography or renal ultrasound to detect concomitant renal abnormalities. These abnormalities occur less frequently than in müllerian agenesis (63).

It is difficult to differentiate a transverse septum or complete absence of the cervix and uterus in a female from a blind vaginal pouch in a male pseudohermaphrodite by examination alone. Androgen insensitivity is likely when pubic and axillary hair is absent. To confirm the diagnosis, a karyotype determination should be performed to see whether a Y chromosome is present. In some patients, the defect in the androgen receptor is not complete and virilization occurs.

An absent endometrium is an outflow tract abnormality that cannot be diagnosed by physical examination in a patient with primary amenorrhea. This abnormality is so rare that in a patient with normal physical findings (normal vagina, cervix, and uterus), it may be advisable to proceed with evaluation of endocrine abnormalities. Although in most cases performance of the progestogen challenge test is not recommended, this test may be of value to confirm the rare diagnosis of congenitally absent endometrium. In this case, progestogen can be administered to a woman who appears to have normal estrogen production (or if estrogen status is questioned, 2.5 mg conjugated estrogen or 2 mg micronized estradiol can be given for 25 days with 5 to 10 mg of medroxyprogesterone acetate added for the last 10 days). Congenital absence of the endometrium is confirmed if no bleeding occurs with this regimen in a patient with primary amenorrhea and no physical abnormalities. This is a very rare diagnosis and routine performance of progestogen challenge is not recommended. Transvaginal ultrasound to assess endometrial thickness may be helpful, with a thickened endometrial lining indicating endometrial response to estrogen.

Asherman syndrome cannot be diagnosed by physical examination. It is diagnosed by performing hysterosalpingography, saline infusion sonography (also known as saline hysteroagram), or hysteroscopy. These tests will show either complete obliteration or multiple filling defects caused by synechiae. If tuberculosis or schistosomiasis is suspected, endometrial cultures should be performed.
Treatment of Women with Amenorrhea, Normal Secondary Sexual Characteristics, and Abnormalities of Pelvic Anatomy

The treatment of congenital anomalies can be summarized as follows:

Treatment of an imperforate hymen involves making a cruciate incision to open the vaginal orifice. Most imperforate hymens are not diagnosed until a hematocolpos forms. It is unwise to place a needle into a hematocolpos without completely removing the obstruction because a pyocolpos may occur.

If a transverse septum is present, surgical removal is required. Forty-six percent of transverse septa occur in the upper third of the vagina, and 40% occur in the middle third of the vagina (69). Frank dilators should be used to distend the vagina until it is healed to prevent vaginal adhesions (70). Patients have a fully functional reproductive system after surgery; however, patients with repaired high transverse septa may have lower pregnancy rates (71).

Hypoplasia or absence of the cervix in the presence of a functioning uterus is more difficult to treat than other outflow obstructions. Surgery to repair the cervix is rarely successful, and hysterectomy is typically required (72). Endometriosis is a common finding, and it is questionable whether this condition should be treated initially with surgery or if it will resolve spontaneously after surgical repair of the obstruction. The ovaries should be retained to provide the benefits of estrogen and to allow for the possibility of future childbearing by removing mature oocytes for in vitro fertilization and transfer of embryos to a gestational carrier.

If the vagina is absent or short, progressive dilation is usually successful in making it functional (70,73). If dilation fails or the patient is unable to perform dilation, the McIndoe split thickness graft technique may be performed (62,74,75). Controversy exists as to the best technique (60). The initial use of vaginal dilators is required to maintain a functional vagina.

In patients with complete androgen insensitivity, the testes should be removed after pubertal development is complete to prevent malignant degeneration (76). In patients with testes, 52% develop a neoplasia, most often a gonadoblastoma. Almost one-half of the testicular neoplasms are malignant (dysgerminomas), but transformation usually does not occur until after puberty (77). In patients who develop virilization and have an XY karyotype, the testes should be removed immediately to preserve the female phenotype and to promote female gender identity. Bilateral laparoscopic gonadectomy is the preferred procedure for removal of intra-abdominal testes.

Adhesions in the cervix and uterus (Asherman syndrome) can be removed using hysteroscopic resection with scissors or electrocautery. It is reasonable to place a pediatric Foley catheter in the uterine cavity for 7 to 10 days postoperatively (along with systemic administration of broad-spectrum antibiotic therapy). A 2-month course of high-dose estrogen therapy with monthly progestogen withdrawal is used to prevent reformation of adhesions. Eighty percent of patients thus treated achieve pregnancy, but complications including miscarriage, preterm labor, placenta previa, and
placenta accreta can occur (78). Cervical stenosis can be treated by cervical dilation.
Amenorrhea with Secondary Sexual Characteristics and Normal Pelvic Anatomy

Although the complete list of potential causes is long, as noted below, the most common causes of amenorrhea in women with normal secondary sexual characteristics and normal pelvic are pregnancy, polycystic ovarian syndrome, hyperprolactinemia, primary ovarian insufficiency (also known as premature ovarian failure), and hypothalamic dysfunction. Pregnancy must be considered in all women of reproductive age with amenorrhea.
Causes

Polycystic Ovarian Syndrome

PCOS is a medical condition associated with hyperandrogenism, ovulatory dysfunction, and polycystic ovaries (79). All definitions of PCOS exclude patients with significantly elevated prolactin, significant thyroid dysfunction, adult-onset congenital adrenal hyperplasia, and androgen-secreting neoplasms from being classified as PCOS. The National Institutes of Health (NIH) 1990 criteria included hyperandrogenism and oligomenorrhea or amenorrhea as required for PCOS diagnosis. The Rotterdam 2003 criteria required two of three of the following for PCOS diagnosis: hyperandrogenism, oligomenorrhea or amenorrhea, polycystic ovaries by ultrasound (80). Although insulin resistance is noted among women with PCOS, it is not included in any of the diagnostic criteria. Obesity is common, but approximately 20% of women with PCOS are not obese. Women with PCOS are often subfertile caused by infrequent or absent ovulation. PCOS can have other general health implications, including increased risk for endometrial hyperplasia and cancer, diabetes, and possibly cardiovascular disease.

Even though PCOS usually causes irregular bleeding rather than amenorrhea, it remains one of the most common causes of amenorrhea (2). The etiology of PCOS remains largely unknown.

In patients who are hirsute and amenorrheic and appear to have PCOS, androgen-secreting adrenal tumors and congenital adrenal hyperplasia should be considered. Elevations in androgens (e.g., Sertoli-Leydig, hilus, and lipoid cell tumors) and estrogens (e.g., granulosa cell tumors) by ovarian tumors may lead to abnormal menstrual patterns, including amenorrhea. A history of rapid onset of hirsutism is suggestive of a tumor.

Hyperprolactinemia

Hyperprolactinemia is a common cause of anovulation in women. Elevation of prolactin produces abnormal GnRH secretion, which can lead to menstrual disturbances (81). Prolactin levels rise in pregnancy, but typically return to normal within 6 months after delivery in nursing mothers and within weeks in nonnursing mothers. Dopamine release suppresses prolactin secretion. Levels of prolactin can be increased by pituitary adenomas that produce prolactin, by other central nervous system (CNS) lesions that disrupt the normal transport of dopamine down the pituitary stalk, and by medications that interfere with normal dopamine secretion (such as antidepressants, antipsychotics including risperidone, metoclopramide, some antihypertensives, opiates, and H₂-receptor blockers).

If elevated TSH and elevated prolactin levels are found together, the hypothyroidism should be treated before hyperprolactinemia is treated. Often, the prolactin level will normalize with treatment of hypothyroidism because thyroid-
releasing hormone, which is elevated in hypothyroidism, stimulates prolactin secretion.

**Primary Ovarian Insufficiency (Premature Ovarian Failure)**

Primary ovarian insufficiency is suggested as the preferred term for the condition that otherwise was referred to as premature ovarian failure or premature menopause (82,83). Overt primary ovarian insufficiency (POI) is defined as the presence of amenorrhea for 4 months or more accompanied by two serum FSH levels in the menopausal range for a woman who is less than 40 years of age. Ovarian “insufficiency” is suggested to be more appropriate than “failure” in part because ovarian function can wax and wane, and function can resume even after it appears that a woman transitioned into menopause. Ovarian insufficiency may be caused by decreased follicular endowment or accelerated follicular atresia (82). Over 75% of women with POI will have at least intermittent symptoms including hot flushes, night sweats, and emotional lability (84). Symptoms are uncommon among women with primary amenorrhea who never received estrogen.

**If the ovary does not develop or stops its hormone production before puberty, the patient will not develop secondary sexual characteristics without exogenous hormone therapy.** If ovarian insufficiency begins later in life, the woman will have normal secondary sexual characteristics.

POI clearly compromises the chance of a woman conceiving with autologous oocytes. However, 5% to 10% of women with a diagnosis of premature ovarian failure achieve pregnancy, with approximately 80% of these pregnancies resulting in the delivery of a healthy child (85). It can be difficult to determine which women will be able to conceive. Published studies of testing for ovarian reserve have not specifically focused on the POI populations, and pregnancies may occur despite very unfavorable results for tests of ovarian reserve such as serum FSH, estradiol, and AMH.

**POI is a heterogenous disorder with many potential causes.** POI may be caused by sex chromosome disorders, mutations of single genes, and by FMR1 premutations. Radiation or chemotherapy may lead to POI. The cause of POI may be autoimmune. **The cause remains unknown in a majority of cases** (Table 30.3).

**Table 30.3 Causes of Ovarian Insufficiency or Failure after Development of Secondary Sexual Characteristics**

- Chromosomal etiology (e.g., Turner mosaic)
- FMR1 premutation
- Iatrogenic causes: radiation, chemotherapy, surgical damage to ovarian blood supply
  - or ovary
- Infections
- Autoimmune-lymphocytic autoimmune oophoritis
Infections
Galactosemia
Perrault syndrome
Idiopathic (80%–90% of cases)

Sex Chromosome and Single Gene Disorders Associated with Primary Ovarian Insufficiency

Deletion of the X chromosome (Turner syndrome) is associated with primary ovarian insufficiency, despite normal development of the ovaries, because of accelerated atresia of the follicles (86). Although Turner syndrome may often be associated with primary amenorrhea with absence of secondary sexual characteristics, breast development may occur if ovarian function is initially present. Mosaicism of an XO or XY cell line may cause ovarian insufficiency. Individuals with a 47,XXX karyotype may develop ovarian failure (87). The most common physical features of 47,XXX are tall stature, epicanthal folds, hypotonia, and clinodactyly.

A deletion of a portion of the X chromosome may be present in patients with POI. The Xq21-28 region is critical (7,88). Several genes in this region are identified as the cause of early ovarian insufficiency in humans. Examples include the POF1B gene located at Xq21, the DIAPH2 gene located at distal Xq21, and the XPNPEP2 gene located at Xq25 (89,90). The specific functions of these genes require further investigation. In addition, a mutation of the BMP15 gene located at Xp11.2 is identified in patients with premature ovarian failure (91).

An autosomal recessive form of premature ovarian failure is associated with hearing loss in Perrault syndrome (92). Mutations in FOXL2 causes ovarian failure and ptosis (93). Familial ovarian failure is inherited by dominant Mendelian inheritance in rare cases (94). Numerous genetic mutations leading to ovarian insufficiency are identified and many more are likely to be discovered (95,96). Other than the FMR1 premutation described next, no one mutation is particularly common.

Fragile X Carriers

Fragile X syndrome, the most common cause of inherited (X-linked) intellectual disability, is caused by inactivation of the FMR1 (fragile X mental retardation 1) gene located on Xq27.3. This inactivation occurs as a result of expansion of a cytosine-guanine-guanine (CGG) triplet repeat of more than 200 copies (97). FMR1 premutation carriers (typically defined as greater than 55 but under 200 CGG repeats) may have primary ovarian insufficiency and impaired fertility. The prevalence of POI in women who carry the FMR1 premutation is estimated to be between 13% and 26%. The risk of having POI appears to increase with increasing premutation repeat size between 59 and 99. It is possible that there is an increased risk of POI among women who carry intermediate-size allele (approximately 41 to 58 repeats), but this is not conclusively proven. The risk plateaus or decreases for
women with repeat sizes of 100. Interestingly, women with full mutations (200 or more CGG repeats) are not at higher risk for POI. It is hypothesized that expression of abnormal FMR1 mRNA produced by patients with the premutation causes dysfunction in the ovary, which does not occur when the FMR1 gene is inactivated and not transcribed. The incidence of having a premutation is 0.8% to 7.5% of women with sporadic POI and up to 13% of women with familial POI.

**FMR1 premutations carried by women are unstable and can expand in the next generation to transmit fragile X syndrome to male offspring,** especially if women have more than 100 repeats. The smallest repeat to expand to the full mutation in one generation is approximately 59. In contrast to potential expansion in women, the repeat sequence is transmitted from fathers to daughters in a relatively stable manner.

**Iatrogenic Causes of Primary Ovarian Insufficiency**

Radiation, chemotherapy (especially alkylating agents such as cyclophosphamide) (98), surgical interference with ovarian blood supply, and infections can cause ovarian failure from early loss of follicles. A radiation dose of 800 cGy causes sterility in most individuals. Ovarian failure can be caused by as little as 150 cGy in some patients, especially if they are older than 40 years of age with limited ovarian reserve. In an evaluation of ovarian function in 100 childhood cancer survivors, 17 had premature ovarian failure. Those with spontaneous menses had smaller ovarian volume, fewer antral follicles, and lower inhibin B levels when compared with controls (99). Ovarian suppression with GnRH agonists and oral contraceptives to reduce the risk of ovarian failure was attempted with limited success (100,101). Cigarette smoking decreases the age at which menopause will occur. But smoking would not be expected to be the primary cause of amenorrhea occurring before the age of 40.

**Infections**

In rare cases, mumps was associated with premature ovarian failure (102). Women with human immunodeficiency virus (HIV) infection may prematurely lose ovarian function compared to women without HIV infection (103). Cytomegalovirus was shown postmortem to cause oophoritis, but premature ovarian failure had not yet developed clinically in the patient, so the relationship of cytomegalovirus to ovarian failure remains unclear (104).

**Autoimmune Disorders**

In one series, 4% of women with POI were noted to have steroidogenic cell immunity with lymphocytic oophoritis as the mechanism for follicle dysfunction (105). Autoimmune lymphocytic oophoritis is associated with a theca cell infiltrate that spares granulosa cells (106). Ultrasound examination reveals the presence of numerous ovarian follicles, despite elevated serum FSH levels and hypoestrogenism (82). Ovarian antibody testing is not clinically reliable for
diagnosing the disorder, as women with biopsy-proven autoimmune oophoritis may have a negative test for ovarian antibody. However, women with autoimmune lymphocytic oophoritis appear to reliably test positive for adrenal antibodies. The most readily available antibody is the 21-hydroxylase antibody (by immunoprecipitation). Ideally, antibody to the adrenal gland itself, as assessed by indirect immunofluorescence, is reasonable to test if available. Testing for 21-hydroxylase antibody is strongly recommended for women who are determined to have POI because women who test positive for this antibody are at risk for potentially fatal hypoadrenalism. Signs that suggest a risk for potentially fatal adrenal insufficiency include hyperpigmentation, weakness, nausea, vomiting, diarrhea, and weight loss.

**POI may be part of a polyglandular autoimmune syndrome. Antibodies are present in a variable number of patients with POI,** depending on the autoimmune studies performed. One study showed that 92% of patients with premature ovarian failure had autoantibodies (107). Only 20% of these patients exhibited signs of immunologic dysfunction, most frequently in the form of a thyroid disorder that is common in the general population of women who do not have POI. **Presence of antithyroid antibodies does not confirm that there is an autoimmune cause for POI.** Rarely, POI is associated with myasthenia gravis, idiopathic thrombocytopenia purpura, rheumatoid arthritis, vitiligo, autoimmune hemolytic anemia, diabetes mellitus, and other autoimmune disorders (108–110).

**Galactosemia**

Galactosemia is caused by a lack of functional galactose-1-phosphate uridyl transferase. Galactosemia is a rare cause of POI and is typically diagnosed in childhood prior to presentation with amenorrhea. Galactose metabolites appear to have toxic effects on ovarian follicles, causing their premature destruction (111). Cataracts and mental retardation are associated with galactosemia. There is evidence that heterozygote carriers of this disorder may have suboptimal ovarian function (112). Early dietary modification may delay but not prevent the ovarian failure (26).

**Pituitary and Hypothalamic Lesions**

**Hypothalamic Tumors**

For normal menstruation to occur, the hypothalamus must be able to secrete GnRH, and the pituitary must be able to respond with production and release of FSH and LH. Tumors of the hypothalamus or pituitary, such as craniopharyngiomas, germinomas, tubercular or sarcoid granulomas, or dermoid cysts, may prevent appropriate hormonal secretion. Patients with these disorders may have neurologic abnormalities, and secretion of other hypothalamic and pituitary hormones may be abnormal. Craniopharyngiomas are the most common tumors. They are located in the suprasellar region and frequently cause headaches and visual changes. The surgical and radiologic treatment of tumors may in itself cause further
abnormalities in hormone secretion (Table 30.4).

### Table 30.4 Pituitary and Hypothalamic Lesions

#### Pituitary and hypothalamic
- Craniopharyngioma
- Germinoma
- Tubercular granuloma
- Sarcoid granuloma
- Dermoid cyst

#### Pituitary
- Nonfunctioning adenomas
- Hormone-secreting adenomas
  - Prolactinoma
  - Cushing’s disease
  - Acromegaly
- Infarction
- Lymphocytic hypophysitis
- Surgical or radiologic ablations
- Sheehan’s syndrome
- Diabetic vasculitis

#### Pituitary Lesions

**Hypopituitarism** is rare because a large portion of the gland must be destroyed before decreased hormonal secretion affects the patient clinically. The pituitary gland may be destroyed by tumors (nonfunctioning or hormone secreting), infarction, or infiltrating lesions such as lymphocytic hypophysitis, granulomatous lesions, and surgical or radiologic ablations. **Sheehan syndrome is associated with postpartum necrosis of the pituitary resulting from a hypotensive episode that, in its severe form (pituitary apoplexy), presents with the patient in shock.** The patient may develop a localized, severe, retro-orbital headache or abnormalities in visual fields and visual acuity. Patients with a mild form of postpartum pituitary necrosis cannot lactate, lose pubic and axillary hair, and do not menstruate after delivery.

Diabetic vasculitis and sickle cell anemia rarely manifest as pituitary failure. **Hypopituitarism is associated with hyposecretion of ACTH and thyroid-stimulating hormone (TSH) and gonadotropins; therefore, thyroid and adrenal function must be evaluated. If hypopituitarism occurs before puberty, menses and secondary sexual characteristics will not develop.**

Growth hormone (GH), TSH, ACTH, and prolactin are secreted by the pituitary, and the excess production of each by pituitary tumors causes menstrual abnormalities. The
Menstrual abnormalities are caused by adverse effects of these hormones on the GnRH pulse generator and not by direct effects on the ovary. Prolactinomas are the most common hormone-secreting tumors in the pituitary, as described above.

### Altered Hypothalamic Gonadotropin-Releasing Hormone Secretion

Abnormal secretion of GnRH accounts for one-third of patients with amenorrhea (113). Chronic disease, malnutrition, stress, psychiatric disorders, eating disorders, and exercise inhibit GnRH pulses, thus altering the menstrual cycle (Table 30.5). Other hormonal systems that produce excess or insufficient hormones can cause abnormal feedback and adversely affect GnRH secretion. In hyperprolactinemia, Cushing disease (excess ACTH), and acromegaly (excess GH), excess pituitary hormones are secreted that inhibit GnRH secretion. It is uncommon to have functional hypothalamic amenorrhea without a secondary cause. Prognosis for recovery is better if the precipitating cause of the amenorrhea can be reversed (114).

Androgen-secreting ovarian tumors
Granulosa cell tumor
Idiopathic

Severity of the condition determines estrogen status—the more severe, the more likely to manifest as hypoestrogenism.

**When the decrease in GnRH pulsatility is severe, amenorrhea results. With less severe alterations in GnRH pulsatility, anovulation and oligomenorrhea can occur.** The pulsatile secretion of GnRH is modulated by interactions with neurotransmitters and peripheral gonadal steroids. Endogenous opioids, corticotropin-releasing hormones (CRH), melatonin, and α-aminobutyric acid (GABA) inhibit the release of GnRH, whereas catecholamines, acetylcholine, and vasoactive intestinal peptide stimulate GnRH pulses. Dopamine and serotonin have variable effects (115).

Decreased leptin levels are associated with hypothalamic amenorrhea, regardless of whether it is caused by exercise, eating disorders, or idiopathic factors (116,117). Leptin is a hormone secreted by adipocytes that is involved in energy hemostasis. Receptors are found in the hypothalamus and bone, making it an excellent candidate for a modulator of menstrual function and bone mass. Levels correlate with nutritional changes and body mass index. Administration of leptin to women with hypothalamic amenorrhea increased levels of LH, estradiol, insulinlike growth factor-1 (IGF-1), and thyroid hormone. Ovulation and increased bone mass occurred in these patients (117). Weight loss occurring with leptin administration limits the utility of using leptin as a therapeutic agent.

**Eating Disorders**

**Anorexia nervosa is an eating disorder that affects 5% to 10% of adolescent women in the United States.** The criteria for diagnosis of anorexia nervosa are refusal to maintain body weight above 15% below normal, an intense fear of becoming fat, altered perception of one’s body image (i.e., patients see themselves as fat despite being underweight), and amenorrhea. Patients attempt to maintain their low body weight by food restriction, laxative abuse, and intense exercise. **This is a life-threatening disorder with a mortality rate as high as 9%**. Amenorrhea may precede, coincide, or follow the weight loss. Multiple hormonal patterns are altered. The 24-hour patterns of FSH and LH may show constantly low levels as seen in childhood or increased LH pulsatility during sleep consistent with the pattern seen in early puberty. Hypercortisolism is present despite normal ACTH levels, and the ACTH response to CRH administration is blunted. Circulating triiodothyronine (T₃) is low, yet circulating inactive reverse T₃ concentrations are high (118). Patients may develop cold and heat intolerance, lanugo hair, hypotension, bradycardia, and diabetes insipidus. They may have yellowish discoloration of the skin resulting from elevated levels of serum carotene caused by altered vitamin A metabolism.
Binge eating is associated with bulimia consisting of vomiting, laxative abuse, and diuretics to control weight. Signs of bulimia include tooth decay, parotid gland hypertrophy (chipmunk jowls), hypokalemia, and metabolic alkalosis (119).

Weight Loss and Dieting

Weight loss can cause amenorrhea even if weight does not decrease below normal. Loss of 10% body mass in 1 year is associated with amenorrhea. Some but not all of these women have an underlying eating disorder. Prognosis is good for the return of menses if the patients recover from the weight loss. Dieting without weight loss and changes in diet can lead to amenorrhea (114).

Exercise

In patients with exercise-induced amenorrhea, there is a decrease in the frequency of GnRH pulses, which is assessed by measuring a decreased frequency of LH pulses. These patients are usually hypoestrogenic, but less severe alterations may cause minimal menstrual dysfunction (anovulation or luteal phase defect). The decrease in GnRH pulsatility can be caused by hormonal alterations, such as low levels of leptin or high levels of ghrelin, neuropeptide Y and corticotrophin-releasing hormone (120). Runners and ballet dancers are at higher risk for amenorrhea than swimmers (121). It was previously suggested that a minimum of 17% body fat is required for the initiation of menses and 22% body fat for the maintenance of menses (122). Studies suggest that inappropriately low caloric intake during strenuous exercise is more important than body fat (123). Higher-intensity training, poor nutrition, stress of competition, and associated eating disorders increase an athlete’s risk for menstrual dysfunction (124). Osteoporosis may result in stress fractures during training and lifelong increased fracture risk. Stress fractures most commonly occur in the weight-bearing cortical bone such as the tibia, metatarsal, fibula, and femur. These athletes may fail to reach peak bone mass and have abnormal bone mineralization.

Stress

Stress-related amenorrhea can be caused by abnormalities in neuromodulation in hypothalamic GnRH secretion, similar to those that occur with exercise and anorexia nervosa. Excess endogenous opioids and elevations in CRH secretion inhibit the secretion of GnRH (115). These mechanisms are not fully understood but appear to be the common link between amenorrhea and chronic diseases, pseudocyesis, and malnutrition.

Obesity

Most obese patients have normal menstrual cycles, but the percentage of women with menstrual disorders increases for women with obesity compared with women of normal
weight. The menstrual disorder is more often irregular uterine bleeding with anovulation rather than amenorrhea. **Obese women have an excess number of fat cells in which extraglandular aromatization of androgen to estrogen occurs. They have lower circulating levels of sex hormone–binding globulin, which allows a larger proportion of free androgens to be converted to estrone. Excess estrogen creates a higher risk for endometrial cancer for these women.** The decrease in sex hormone–binding globulin allows an increase in free androgen levels, which initially are eliminated by an increased rate of metabolic clearance. This compensatory mechanism diminishes over time, and hirsutism can develop. Frequently, these patients are classified as having PCOS. Alterations in the secretion of endorphins, cortisol, insulin, growth hormone, and IGF-1 may interact with the abnormal estrogen and androgen feedback to the GnRH pulse generator to cause menstrual abnormalities.

**Other Hormonal Factors**

The secretion of hypothalamic neuromodulators can be altered by feedback from abnormal levels of peripheral hormones. Excesses or deficiencies of thyroid hormone, glucocorticoids, androgens, and estrogens can cause menstrual dysfunction. Excess secretion of GH, TSH, ACTH, and prolactin from the pituitary gland can cause abnormal feedback inhibition of GnRH secretion, leading to amenorrhea. **Growth hormone excess causes acromegaly, which may be associated with anovulation, hirsutism, and polycystic-appearing ovaries as a result of stimulation of the ovary by IGF-1.** More commonly, GH excess is accompanied by amenorrhea, low gonadotropin levels, and elevated prolactin levels. Acromegaly is recognized by enlargement of facial features, hands, and feet; hyperhidrosis; visceral organ enlargement; and multiple skin tags. **Cushing disease is caused by an ACTH-secreting pituitary tumor, which is manifested by truncal obesity, moon facies, hirsutism, proximal weakness, depression, and menstrual dysfunction.**
Evaluation for Women with Amenorrhea in the Presence of Normal Pelvic Anatomy and Normal Secondary Sexual Characteristics

A pregnancy test (urine or serum human chorionic gonadotropin [hCG]) should be performed in a reproductive-age woman who has amenorrhea with normal secondary sexual characteristics and a normal pelvic examination. If the results of the pregnancy test are negative, the evaluation of amenorrhea is as follows:

Clinical assessment of estrogen status
Serum TSH
Serum prolactin
Serum FSH level
Vaginal ultrasound for assessment of antral follicle count in the ovaries can be considered (may help establish the diagnosis of PCOS or suggest POI)
Imaging of the pituitary and hypothalamic assessment if prolactin is elevated or if hypothalamic amenorrhea is suspected (particularly if CNS symptoms are present or there is no clear explanation for hypothalamic amenorrhea).

Assessment of Estrogen Status
The presence of vaginal dryness or hot flashes increases the likelihood of a diagnosis of hypoestrogenism. A sample of vaginal secretions can be obtained during the physical examination, and mucosal estrogen response can be demonstrated by the presence of superficial cells. A serum estradiol level higher than 40 pg/mL is considered indicative of significant estrogen production, but interassay discrepancies often exist and serum estrogen levels can vary greatly on a day-to-day basis for a given woman. Vaginal ultrasound demonstrating a thin endometrium suggests that a patient is hypoestrogenic, unless there is reason to suspect that the patient lacks functional endometrium. A DEXA (dual-energy x-ray absorptiometry) scan to determine bone mineral density should be considered for a patient in whom long-term hypoestrogenism is suspected.

There is little utility in routine performance of a progestogen challenge test to determine the patient’s estrogen status. False positives and false negatives are common.

Thyroid and Prolactin Disorders
Consideration should be given to thyroid disorders and hyperprolactinemia in women with amenorrhea because of the relatively common incidence of these conditions.

Sensitive TSH assays can be used to evaluate hypothyroidism and hyperthyroidism. Further evaluation of a thyroid disorder is required if abnormalities in TSH levels are found. Mild degrees of thyroid dysfunction are unlikely to cause amenorrhea. Given the general health implications of thyroid dysfunction and readily
available treatments, routine assessment of TSH is reasonable for women with amenorrhea.

Prolactin is most accurately obtained in a patient who is fasting and who has not had any recent breast stimulation to avoid concluding that a patient is hyperprolactinemic on the basis of a transient prolactin elevation. If a patient still has some menstrual cycles, it is advisable to obtain the prolactin level in the follicular phase.

**Follicle-Stimulating Hormone Levels**

Assessment of serum FSH levels is required to determine whether the patient has hypergonadotropic, hypogonadotropic, or eugonadotropic amenorrhea. A circulating FSH level of greater than 25 to 40 mIU/mL indicated on at least two blood samples is indicative of hypergonadotropic amenorrhea. Hypergonadotropism implies that the cause of amenorrhea is ovarian insufficiency. The history should establish whether the cause of ovarian insufficiency is chemotherapy or radiation therapy.

One test that is likely to be performed increasingly frequently is serum AMH. AMH is a product of the granulosa cells. **AMH levels are low in women with POI and high in women with PCOS.** AMH may be used more commonly in the evaluation of amenorrhea, but its assessment is not yet part of routine evaluation.

**If the diagnosis of POI is confirmed, the patient should be tested for:**

**FMR1 premutation**

**Karyotype**

**21-hydroxylase antibody.**

FMR1 premutation testing will reveal women at risk for bearing a child with fragile X syndrome, which may be important information for other family members. The goal of the peripheral blood karyotype is to identify an absent or abnormal X chromosome and to identify whether or not any portion of a Y chromosome is present. In situ hybridization studies may prove the existence of Y chromosomal material with a Y-specific probe when the karyotype is normal and should be assessed if there are clinical signs to suggest that a Y-bearing cell line is present despite normal routine peripheral blood karyotype (125). It is important to identify Y chromosomal material so it may be removed to prevent malignant degeneration. Although commonly suggested that karyotype only be performed if the patient is under age 30, it should be noted that rare patients with Turner syndrome developed amenorrhea after age 35. In addition, some patients who present over the age of 30 may have actually had the onset of POI at a younger age but were unaware because of the use of oral contraceptives. Therefore, consideration should be given to performance of karyotype, regardless of the patient’s age. Testing for 21-hydroxylase antibody will identify women at risk for adrenal crisis.

**If a diagnosis of PCOS is suspected, the patient should have:**

Documentation of hyperandrogenism (either by serum total testosterone and sex
Serum 17-hydroxyprogesterone to exclude congenital adrenal hyperplasia resulting from 21-hydroxylase deficiency, particularly if the patient is at increased risk (highest prevalence is among Ashkenazi Jews, Hispanics, Yugoslavs, Native American Inuits in Alaska, and Italians) (79),

If the diagnosis of PCOS is made, the patient should undergo a 2-hour oral glucose tolerance test and a fasting lipid profile.

**Assessment of the Pituitary and Hypothalamus**

*If the patient is hypoestrogenic and the FSH level is not high, pituitary and hypothalamic lesions should be excluded.*

A complete neurologic examination may help localize a lesion. **Either CT or MRI scanning should be performed** to confirm the presence or absence of a tumor. MRI will identify smaller lesions than CT; if a lesion is too small for identification by CT, it may be clinically insignificant. MRI offers the advantage of avoiding exposure to x-ray.

The patient’s history of weight changes, exercise, eating habits, and body image is an important factor in determining whether anorexia nervosa, malnutrition, obesity, exercise, or stress may be responsible for amenorrhea.

Patients with certain specific clinical findings should undergo screening for other hormonal alterations:

- **Androgen levels should be assessed** in any hirsute patient to ensure that adrenal and ovarian tumors are not present and to aid in the diagnosis of PCOS.

- **Acromegaly** is suggested by coarse facial features, large doughy hands, and hyperhidrosis and **may be confirmed by measuring IGF-1 levels.**

- In patients with truncal obesity, hirsutism, hypertension, and erythematous striae, **Cushing syndrome should be ruled out** by assessing 24-hour urinary cortisol levels or performing a 1-mg overnight dexamethasone suppression test or late night salivary cortisol (126). It is important to confirm that the patient is not taking exogenous glucocorticoid.
Treatment for Women with Amenorrhea in the Presence of Normal Pelvic Anatomy and Normal Secondary Sexual Characteristics

The treatment of nonanatomic causes of amenorrhea associated with normal secondary sexual characteristics varies widely according to the cause. The underlying disorder should be treated whenever possible. Patients who are pregnant may be counseled regarding the options for continued care. When thyroid abnormalities are detected, thyroid hormone, radioactive iodine, or antithyroid drugs may be administered as appropriate. When hyperprolactinemia is present, treatment may include discontinuation of contributing medications, treatment with dopamine agonists such as bromocriptine or cabergoline, and, rarely, surgery for particularly large pituitary tumors. When POI causes amenorrhea, hormone replacement may be considered to diminish symptoms and to prevent osteoporosis. Counseling regarding the risks and benefits of hormone replacement therapy is indicated. Gonadectomy is required when a Y cell line is present.

Surgical removal, radiation therapy, or a combination of both is advocated for treatment of CNS tumors other than prolactinomas. It may be necessary to treat individuals who have panhypopituitarism with various replacement regimens after all the deficits are elucidated. These regimens include estrogen and progestogen replacement for lack of gonadotropins, corticosteroid replacement for lack of ACTH, thyroid hormone for lack of TSH, and desmopressin acetate ([1-deamino-8-D-AVP [DDAVP]]) to replace vasopressin.

The treatment of amenorrhea associated with hypothalamic dysfunction depends on the underlying cause:

- **Hormonally active ovarian tumors are surgically removed (rare).**
- **Obesity, malnutrition or chronic disease, Cushing syndrome, and acromegaly should be specifically treated.**
- **Stress-induced amenorrhea may respond to psychotherapy.**
- **Exercise-induced amenorrhea may improve with moderation of activity and weight gain, when appropriate.** If hypoestrogenism persists, higher doses of estrogen may be needed in these women than in older menopausal women to maintain bone density. In addition, 1,200 to 1,500 mg of calcium and 400 to 800 IU of vitamin D daily are advised. Bisphosphonates do not improve bone density in amenorrheic athletes because it is lack of bone formation rather than increased resorption that causes the osteopenia. In addition, the use of bisphosphonates is not advised because they can be deposited into the bone, and long-term effects, especially during pregnancy, are unknown.

**Treatment of eating disorders such as anorexia nervosa generally demands a multidisciplinary approach, with severe cases requiring hospitalization (127).**

**Chronic anovulation associated with PCOS may be treated after identifying the desires of the patient.** Patients may be concerned about their lack of menstruation, not hirsutism, or infertility. **The endometrium of these individuals should be protected**...
from the environment of unopposed estrogen that accompanies the anovulatory state. Oral contraceptives are a good alternative for those patients who require contraception. For those patients who are not candidates for oral contraceptive use, cyclic administration of progestogen is advised. Progestogen withdrawal will occur if there is an adequate estrogenic environment to induce proliferation of the endometrium, and it is not sufficient to cause withdrawal bleeding in patients who are hypoestrogenic (e.g., those who have amenorrhea associated with anorexia nervosa). Women with PCOS may require treatment for insulin resistance, dyslipidemia, and obesity. Regular periodic screening with an oral glucose load test and lipid panel is recommended for women with PCOS. Reduction in weight in obese women with PCOS leads to improved pregnancy rates, decreases hirsutism, and improves glucose and lipid levels (79). Insulin-sensitizing medications such as metformin and cholesterol-lowering medications such as statins can be considered. Ovulation induction is performed if pregnancy is desired, as described below.

A common progestogen used to induce withdrawal bleeding and thus protect the endometrium from hyperplastic transformation is medroxyprogesterone acetate (10 mg for 12 to 14 days per month). Occasionally, ovulation may occur; therefore, patients should be made aware that pregnancy is possible, and appropriate contraceptive measures should be used. Because there is theoretical concern that medroxyprogesterone acetate used in early pregnancy may increase the incidence of pseudohermaphroditism, a pregnancy test should be obtained if a woman fails to have a withdrawal bleed (128). Alternatively, progesterone suppositories (50 to 100 mg) or oral micronized progesterone (200 mg) can be given for 12 to 14 days per month to protect the endometrium from hyperplasia and induce withdrawal bleeding. No increased incidence of birth defects is associated with the use of natural progesterone (129).

In hypoestrogenic individuals such as those with POI, estrogen replacement must be added to the progestogen for successful menstrual regulation and prevention of osteoporosis. The doses of estrogen needed for relief of symptoms in young women with POI are often higher than those that are used for older menopausal women (130). Women with POI (who would normally still be making hormone if the ovaries were functioning normally) are different from those reaching menopause at a median age of 51. Therefore, data regarding hormone therapy that were collected from women reaching menopause at the median age should not be extrapolated to younger women. Although there are no comparative data and no long-term prospectively collected data regarding hormone therapy for women with POI, the risks of hormone therapy are likely to be lower and the benefits potentially greater for younger women than for older women reaching menopause after the age of 50 (131).

When chronic anovulation is caused by congenital adrenal hyperplasia, glucocorticoid administration (i.e., dexamethasone 0.5 mg at bedtime) is sometimes successful in restoring the normal feedback mechanisms, thereby permitting regular menstruation and ovulation.
Hirsutism

Patients who have oligomenorrhea or amenorrhea resulting from chronic anovulation may have hirsutism. The most common cause of hirsutism and oligo-ovulation is PCOS. After ruling out androgen-secreting tumors and congenital adrenal hyperplasia, treatment may be aimed at decreasing coarse hair growth.

Oral Contraceptives

Oral contraceptives may be effective for hirsutism by decreasing ovarian androgen production and increasing circulating levels of sex hormone–binding globulin, leading to decreased free androgen in the circulation.

Antiandrogens

Spironolactone decreases androgen production and competes with androgens at the androgen receptor. Side effects include diuresis and dysfunctional uterine bleeding. The use of spironolactone is typically combined with oral contraceptives to avoid irregular bleeding and to prevent pregnancy from occurring while on spironolactone. Flutamide is approved by the U.S. Food and Drug Administration (FDA) for adjuvant therapy in prostatic cancer and for treatment of hirsutism. Its effects are similar to those of spironolactone (132). Liver function should be monitored because of the rare complication of hepatotoxicity. Cyproterone acetate, a strong progestin and antiandrogen, is used abroad but is not available in the United States. It is usually administered in combination with ethinyl estradiol in an oral contraceptive. By decreasing circulating androgen and LH levels, and by inducing antagonism of androgen effects at the peripheral level, cyproterone acetate is effective in treating hirsutism (133). Finasteride, a 5α-reductase inhibitor, is approved by the FDA for the treatment of benign prostatic hypertrophy (Proscar) and male pattern baldness (Propecia). It is effective in treating hirsutism, although perhaps is no more effective than other available agents (134,135). Its major advantage is that it is exceptionally well tolerated and may be used when side effects preclude the use of other therapeutic options for hirsutism.

All antiandrogens are teratogenic as they may lead to feminization of the external genitalia of a male fetus (ambiguous genitalia) if the patient should conceive while taking the medication. Therefore, antiandrogens are typically used in combination with oral contraceptives.

GnRH Agonist

Administration of GnRH agonist agents virtually eliminates ovarian steroid production, and estrogen-progestogen add-back therapy allows long-term administration and protection against osteoporosis.

Eflornithine Hydrochloride
Eflornithine hydrochloride is a topical cream that is approved by the FDA for use on the face and chin. Improvements in facial hirsutism may be seen in 4 to 8 weeks of twice-daily applications.

**Ovulation Induction**

A large subset of patients with amenorrhea or oligomenorrhea and chronic anovulation seek care because they are unable to conceive (see Chapter 32). Ovulation induction therapy is generally the treatment of choice for such patients, but pretreatment counseling should be provided in sufficient detail to ensure realistic expectations. The patient should be provided with information regarding the chances of a successful pregnancy (considering age of the patient and treatment modality), potential complications (hyperstimulation and multiple gestation), expense, time, and psychological impact involved in completing the course of therapy. Treatment should be individualized (136).

Earlier studies raised the possibility of a relationship between ovulation induction and the risk of ovarian cancer (137,138). Ongoing studies are attempting to address this issue conclusively, but data support an increase of approximately 2.5-fold in ovarian cancer in patients with infertility, which appears unrelated to the use of ovulation-inducing drugs (139140). There is no conclusive evidence to link fertility drug use and ovarian cancer; thus, no change in current ovulation induction practices seems warranted at present (141). Pregnancy and use of oral contraceptives before or after childbearing may protect against ovarian cancer.

Clomiphene citrate is the usual first choice for ovulation induction in most patients because of its relative safety, efficacy, route of administration (oral), and relatively low cost (142). Clomiphene citrate is indicated primarily in patients with adequate levels of estrogen and normal levels of FSH and prolactin. It is generally ineffective in hypogonadotropic patients who already have a poor estrogen supply (143). Patients with inappropriate gonadotropin release (an increased LH-to-FSH ratio), such as that which occurs in PCOS, are candidates for therapy with clomiphene citrate. As many as 80% of certain patients can be expected to ovulate after clomiphene citrate therapy. Contraindications to the use of clomiphene citrate include pregnancy, liver disease, and preexisting ovarian cysts. Side effects include hot flashes and poorly understood visual symptoms, which generally were viewed as an indication to discontinue subsequent clomiphene citrate use. The risk of multiple pregnancy is increased with clomiphene citrate compared with an overall of risk of approximately 8% (142). The majority of multiple gestations are twins; triplets and higher order multiple gestations are rare.

The most commonly recommended treatment regimen for clomiphene citrate is 50 mg daily for 5 days, beginning on the third to fifth day of menstrual or withdrawal bleeding. Cycles may be monitored by measuring midluteal progesterone levels to assess ovulation.
Ovulation may be confirmed by an appropriate rise of basal body temperature and menses occurring at the expected time after the temperature rise. Ultrasonographic monitoring to assess folliculogenesis may be helpful, especially when hCG is used to induce ovulation. Endometrial thinning caused by the antiestrogenic effects of clomiphene citrate may be detected with midcycle ultrasound. With these data, it is possible to immediately adjust the dose in the subsequent cycle if a given regimen is ineffective. Dosage increases of 50 mg per day are usually used, and more than 70% of conceptions occur at doses no higher than 100 mg per day for 5 days (144). Dosages higher than 150 mg per day for 5 days are usually ineffective, and patients who remain anovulatory with this dosage should undergo further evaluation accompanied by changes in the therapeutic plan. Longer courses of clomiphene citrate therapy, and adjunctive therapy with glucocorticoids, are suggested if a patient does not ovulate with standard therapy (145).

Although a large randomized trial demonstrated that clomiphene alone is superior to metformin alone in achieving live birth in women with PCOS, a meta-analysis suggests that for some patients with PCOS, metformin and clomiphene combined may increase the likelihood of ovulation compared with clomiphene alone (146,147). Thinning of the endometrium at midcycle in the face of adequate midcycle estradiol and lack of success with repeated cycles of clomiphene are generally indications to consider injectable gonadotropins. Aromatase inhibitors, such as letrozole, were suggested as an option for ovulation induction (148).

Women with PCOS who do not ovulate or become pregnant with clomiphene citrate, and women with hypogonadotropic hypoestrogenic anovulation, may be candidates for therapy with injectable gonadotropins. Available preparations include recombinant FSH and LH and products purified from the urine of menopausal women (FSH or FSH-LH combinations). Administration protocols and dosages vary widely and should be adjusted to individual needs. Safe administration requires careful monitoring of ovarian response with ultrasonography and, in some cases, serial estradiol measurements. In general, gonadotropins are administered at a dose of 50 to 150 IU per day by subcutaneous injection for 3 to 5 days, after which time estradiol and follicular monitoring commence. In most cycles, gonadotropin is administered for 7 to 12 days. Ovulation is triggered by subcutaneous or intramuscular injection of 5,000 to 10,000 IU hCG or subcutaneous injection of 250 μg of recombinant hCG once the lead follicle reaches 16 to 20 mm in diameter based on ultrasonographic assessments. Ovulation generally occurs approximately 38 to 40 hours after hCG administration. Luteal phase support is sometimes provided with the administration of progesterone supplementation or with additional injections of hCG.

The two major complications associated with induction of ovulation with gonadotropins are multiple pregnancy (10% to 30%) and ovarian hyperstimulation syndrome. The incidence of both of these complications can be reduced but not eliminated by careful monitoring. Cycles complicated by the recruitment of numerous follicles or by high estradiol levels may be canceled by withholding the ovulatory dose of hCG. Selected patients may be converted safely to in vitro fertilization.
Because severe ovarian hyperstimulation syndrome is life-threatening and may lead to prolonged hospitalization, ovulation induction with gonadotropins generally is performed by experienced practitioners who devote a significant portion of their practice to the treatment of infertility.

Ovulation induction with pulsatile GnRH may be effective in patients who have chronic anovulation associated with low levels of estrogen and gonadotropins. For therapy to be successful, a functional ovary and pituitary gland must be present. Patients with ovarian or pituitary failure do not respond to GnRH therapy. To be effective, GnRH must be administered in a pulsatile fashion, either intravenously or subcutaneously by a programmable pump. Ovulation induction with GnRH, as compared with gonadotropins, is associated with a relatively low incidence of ovarian hyperstimulation and multiple births. In addition, the need for appropriate timing of the ovulatory dose of hCG is avoided because patients treated with pulsatile GnRH have an appropriately timed endogenous LH surge. Disadvantages are mainly related to maintaining the programmable pump and injection site and lack of availability of an appropriate pump in the United States. After ovulation, luteal phase support is necessary and may be provided with hCG, progesterone, or continuation of the GnRH therapy.

For women with overt POI (also known as premature ovarian failure, as noted above), there is no good evidence to suggest that any treatment can increase the chance of conception with autologous oocytes (85). Treatments that were tried include ovulation induction with clomiphene or gonadotropin, pretreatment with high-dose estrogen or gonadotropin-releasing hormone agonist followed by expectant management or gonadotropin stimulation, standard-dose hormone therapy followed by gonadotropin, and corticosteroid pretreatment followed by gonadotropin. Administration of dehydroepiandrosterone (DHEA) is suggested for women with POI (149). It is uncertain whether the benefit seen in preliminary reports will stand the test of time.

If POI is diagnosed while a patient still has a significant supply of oocytes, fertility preservation could be considered if the patient is not able to consider conception at the time of diagnosis. In most cases, patients with prolonged amenorrhea are not diagnosed at a time when significant numbers of reproductively competent oocytes are present. Fertility preservation is an option for patients about to undergo gonadotoxic chemotherapy or if a patient is known (e.g., based on family history) to be at risk for POI. Either embryos or oocytes can be cryopreserved. There is more worldwide experience with cryopreservation of embryos. Improvements are occurring in techniques of oocyte and ovarian tissue cryopreservation (150,151).

Patients with POI who desire pregnancy will in most cases have a high chance of having a child with the help of oocyte donation. Oocytes from donors may be harvested after ovulation induction, fertilized with sperm from the intended father, and transferred into the recipient’s uterus after the endometrium is appropriately prepared with estrogen and progesterone. Special concern is warranted for women with Turner
syndrome who appear to have a maternal mortality of at least 2% (58). Rupture of the aorta may occur even if an echocardiogram shows no dilatation (152). It is suggested that all women with Turner syndrome undergo a full cardiac evaluation, including a cardiac MRI at a center with expertise in cardiovascular imaging, and that pregnancy be contraindicated if the patient has known congenital cardiovascular disease (e.g., bicuspid aortic valve or aortic coarctation) or with aortic size greater than 2 cm/m² (153).

Hyperandrogenism most often presents as hirsutism, which usually arises as a result of androgen excess related to abnormalities of function in the ovary or adrenal glands. By contrast, virilization is rare and indicates marked elevation in androgen levels.

The most common cause of hyperandrogenism and hirsutism is polycystic ovarian syndrome (PCOS). There are only two major criteria for the diagnosis of PCOS: anovulation and the presence of hyperandrogenism as established by clinical or laboratory means. Patients with PCOS frequently exhibit insulin resistance and hyperinsulinemia.

Combination oral contraceptives (OCs) decrease adrenal and ovarian androgen production and reduce hair growth in nearly two-thirds of hirsute patients. Because hyperinsulinemia appears to play a role in PCOS-associated anovulation, treatment with insulin sensitizers may shift the endocrine balance toward ovulation and pregnancy, either alone or in combination with other treatment modalities.

Excluding cases that are of iatrogenic or factitious etiology, adrenocorticotropic hormone–independent forms of Cushing syndrome are adrenal in origin. Adrenal tumors are usually very large by the time Cushing syndrome is manifest.

Congenital adrenal hyperplasia is transmitted as an autosomal recessive disorder. Deficiency of 21-hydroxylase is responsible for more than 90% of cases of adrenal hyperplasia resulting from an adrenal enzyme deficiency. Patients with severe hirsutism, virilization, or recent and rapidly progressing signs of androgen excess require careful investigation for the presence of an androgen-secreting neoplasm. Ovarian neoplasms are the most frequent
androgen-producing tumors.
Elevations in prolactin may cause amenorrhea or galactorrhea. Amenorrhea without galactorrhea is associated with hyperprolactinemia in approximately 15% of women. In patients with both galactorrhea and amenorrhea, approximately two-thirds will have hyperprolactinemia; of those, approximately one-third will have a pituitary adenoma. In more than one-third of women with hyperprolactinemia, a radiologic abnormality consistent with a microadenoma (>1 cm) is found.

Because levels of thyroid-stimulating hormone (TSH) are sensitive to excessive or deficient levels of circulating thyroid hormone, and because most disorders of hyperthyroidism and hypothyroidism are related to dysfunction of the thyroid gland, TSH levels are used to screen for these disorders. The most common thyroid abnormalities in women, autoimmune thyroid disorders, represent the combined effects of the multiple antibodies produced. Severe primary hypothyroidism is associated with amenorrhea or anovulation. The classic triad of exophthalmos, goiter, and hyperthyroidism in Graves disease is associated with symptoms of hyperthyroidism.

The endocrine disorders encountered most frequently in gynecologic patients are those related to disturbances in the regular occurrence of ovulation and accompanying menstruation. The most prevalent are those characterized by androgen excess, often with insulin resistance, including what is arguably the most common endocrinopathy in women—polycystic ovary syndrome (PCOS). Other conditions leading to ovulatory dysfunction, hirsutism, or virilization, and common disorders of the pituitary and thyroid glands associated with reproductive abnormalities, are reviewed in this chapter.
Hyperandrogenism

Hyperandrogenism most often presents as hirsutism, which arises as a result of androgen excess related to abnormalities of function in the ovary or adrenal glands, constitutive increase in expression of androgen effects at the level of the pilosebaceous unit, or a combination of the two. **By contrast, virilization is rare and indicates marked elevations in androgen levels.** An ovarian or adrenal neoplasm that may be benign or malignant commonly causes virilization.
Hirsutism

Hirsutism, the most frequent manifestation of androgen excess in women, is defined as excessive growth of terminal hair in a male distribution. This refers particularly to midline hair, side burns, moustache, beard, chest or intermammary hair, and inner thigh and midline lower back hair entering the intergluteal area. The response of the pilosebaceous unit to androgens in these androgen responsive areas transforms vellus hair (fine, nonpigmented, short) that is normally present into terminal hair (coarse, stiff, pigmented, and long).

Androgen effects on hair vary in relation to specific regions of the body surface. Hair that shows no androgen dependence includes lanugo, eyebrows, and eyelashes. The hair of the limbs and portions of the trunk exhibits minimal sensitivity to androgens. Pilosebaceous units of the axilla and pubic region are sensitive to low levels of androgens, such that the modest androgenic effects of adult levels of androgens of adrenal origin are sufficient for substantial expression of terminal hair in these areas. Follicles in the distribution associated with male patterns of facial and body hair (midline, facial, inframammary) require higher levels of androgens, as seen with normal testicular function or abnormal ovarian or adrenal androgen production. Scalp hair is inhibited by gonadal androgens, in varying degrees, as determined by age and genetic determination of follicular responsiveness, resulting in the common frontal-parietal balding seen in some males and in virilized females. Hirsutism results from both increased androgen production and skin sensitivity to androgens. Skin sensitivity depends on the genetically determined local activity of 5α-reductase, the enzyme that converts testosterone to dihydrotestosterone (DHT), the bioactive androgen in hair follicles.

Hair demonstrates cyclic activity between growth (anagen), involution (catagen), and resting (telogen) phases. The durations of both the growth and resting phases vary according to region of the body, genetic factors, age, and hormonal effects. The cycles of growth, rest, and shedding are normally asynchronous, but when synchronous entry into telogen phase is triggered by major metabolic or endocrine events, such as pregnancy and delivery, or severe illness, dramatic (although transient) hair loss may occur in the following months (telogen effluvium).

Hirsutism is a relative, rather than absolute, designation. What is normal in one setting may be considered abnormal in others; social and clinical reactions to hirsutism can vary significantly, reflecting ethnic variation in skin sensitivity to androgens and cultural ideals. Androgen-dependent hair (excluding pubic and axillary hair) occurs in only 5% of premenopausal white women and is considered abnormal by white women of North America, whereas considerable facial and male pattern hair in other areas may be more common and more often considered acceptable and normal among such groups as the Inuit and women of Mediterranean background.

Hypertrichosis and Virilization
Two conditions should be distinguished from hirsutism. Hypertrichosis is the term reserved for androgen-independent terminal hair in nonsexual areas, such as the trunk and extremities. This may be the result of an autosomal-dominant congenital disorder, a metabolic disorder (such as anorexia nervosa, hyperthyroidism, porphyria cutanea tarda), or medications (e.g., acetazolamide, anabolic steroids, androgenic progestins, androgens, cyclosporine, diazoxide, dehydroepiandrosterone (DHEA), heavy metals, interferon, methyldopa, minoxidil, penicillamine, phenothiazines, phenytoin, streptomycin, reserpine, valproic acid). Virilization is a marked and global masculine transformation that includes coarsening of the voice, increase in muscle mass, clitoromegaly (normal clitoral dimensions ± standard deviation [SD] are 3.4 + 1 mm width by 5.1 + 1.4 mm length) and features of defeminization (loss of breast volume and body fat contributing to feminine body contour) (1). Although hirsutism accompanies virilization, the presence of virilization indicates a high likelihood of more serious conditions than are common with hirsutism alone and should prompt evaluation to exclude ovarian or adrenal neoplasm. Although rare, these diagnoses become likely when onset of androgen effects is rapid or sufficiently pronounced to produce the picture of virilization.

The history should focus on the age of onset and rate of progression of hirsutism or virilization. A rapid rate of progression or virilization is associated with a more severe degree of hyperandrogenism and should raise suspicion of ovarian and adrenal neoplasms or Cushing syndrome. This is true whether rapid progression or virilization occurs before, during, or after puberty. Anovulation, manifesting as amenorrhea or oligomenorrhea, increases the probability that there is underlying hyperandrogenism. Hirsutism occurring with regular cycles is more commonly associated with normal androgen levels and thus is attributed to increased genetic sensitivity of the pilosebaceous unit and is termed idiopathic hirsutism. When virilization is present, anovulation virtually always occurs.

In determining the extent of hirsutism, a sensitive and tactful approach by the physician is mandatory and should include questions regarding the use and frequency of shaving and/or chemical or mechanical depilatories. Typically, clinical evaluation of the degree of hirsutism is subjective. Most physicians arbitrarily classify the degree of hirsutism as mild, moderate, or severe. Objective assessment is helpful, especially in establishing a baseline from which therapy can be evaluated. The Ferriman–Gallwey Scoring System for Hirsutism quantitates the extent of hair growth in the most androgen sensitive sites. It is a scoring scale of androgen-sensitive hair in nine body areas rated on a scale of 0 to 4 (2). A total score higher than 8 is defined as hirsutism (Fig. 31.1) (3). Although widely used, this scoring system has limitations, one of which is the fact that the scale does not include the sideburn, buttocks, and perineal areas. Substantial hirsutism may be confined to one or two areas without exceeding the cutoff value in total hirsutism score. The score does not reflect the extent to which hirsutism affects a woman’s well being (3,4).

**Figure 31.1** Ferriman-Gallwey hirsutism scoring system. Each of the nine body areas most sensitive to androgen...
is assigned a score from 0 (no hair) to 4 (frankly virile), and these separate scores are summed to provide a hormonal hirsutism score. (Reproduced from Hatch R, Rosefield RL, Kim MH, et al. Hirsutism: implications, etiology, and management. Am J Obstet Gynecol 1981;140:815–30. ©Elsevier.)

A family history should be obtained to disclose evidence of idiopathic hirsutism, PCOS, congenital or adult onset adrenal hyperplasia (CAH or AOAH), diabetes mellitus, and cardiovascular disease. A history of drug use should be obtained. In addition to drugs that commonly cause hypertrichosis, anabolic steroids and testosterone derivatives may cause hirsutism and even virilization. During the physical examination, attention should be directed to obesity, hypertension, galactorrhea, male-
pattern baldness, acne (face and back), and hyperpigmentation. With virilization, the presence of an androgen-producing ovarian neoplasm or Cushing syndrome must be considered. In many cases of Cushing syndrome, the patient’s presenting symptom is hirsutism. This devastating disorder may masquerade as other disorders such as AOAH and PCOS. Before making these diagnoses, the physician should search for the physical signs of the syndrome such as “moon face,” plethora, purple striae, dorsocervical and supraclavicular fat pads, and proximal muscle weakness. A moon-shaped face, upper body obesity, muscle weakness, and the development of a pad of fat between the shoulder blades are particularly notable to both patients and diagnosticians considering the diagnosis of Cushing syndrome.

Role of Androgens

Androgens and their precursors are produced by both the adrenal glands and the ovaries in response to their respective trophic hormones, adrenocorticotropic hormone (ACTH) and luteinizing hormone (LH), respectively (Fig. 31.2). Biosynthesis begins with the rate-limiting conversion of cholesterol to pregnenolone by side-chain cleavage enzyme. Thereafter, pregnenolone undergoes a two-step conversion to the 17-ketosteroid DHEA along the Δ-5 steroid pathway. This conversion is accomplished by CYP17, an enzyme with both 17α-hydroxylase and 17,20-lyase activities. In a parallel fashion, progesterone undergoes transformation to androstenedione in the Δ-4 steroid pathway. The metabolism of Δ-5 to Δ-4 intermediates is accomplished via a Δ-5-isomerase, 3β-hydroxysteroid dehydrogenase (3β-HSD).

Adrenal 17-Ketosteroids

Secretion of adrenal 17-ketosteroids increases prepubertally and independently of pubertal maturation of the hypothalamic–pituitary–ovarian axis. This alteration in adrenal steroid secretion is termed adrenarche and is characterized by a dramatic change in the response of the adrenal cortex to ACTH and with preferential secretion of Δ-5 steroids, including 17-hydroxyprogrenolone, DHEA, and dehydroepiandrosterone sulfate (DHEAS). The basis for this action is related to the increase in the zona reticularis and in the increased activity of the 17-hydroxylase and the 17,20-lyase enzymes. Independent of the increase in ovarian androgen secretion accompanying puberty, the increase in adrenal androgens owing to adrenarche can account for significant increases in pubic and axillary hair and sweat production by the axillary pilosebaceous units.

Testosterone

Approximately half of a woman’s serum testosterone is derived from peripheral conversion of secreted androstenedione and the other half is derived from direct glandular (ovarian and adrenal) secretion. The ovaries and adrenal glands contribute almost equally to testosterone production in women.
The contribution of the adrenals is achieved primarily through secretion of androstenedione. Approximately 66% to 78% of circulatory testosterone is bound to sex hormone–binding globulin (SHBG) and is considered biologically inactive. Most of the proportion of serum testosterone that is not bound to SHBG is weakly associated with albumin (20% to 32%). A small percentage (1% to 2%) of testosterone is entirely unbound or free. **The fraction of circulating testosterone that is unbound by SHBG has an inverse relationship with the SHBG concentration.** Increased SHBG levels are noted in conditions associated with high estrogen levels. Pregnancy, the luteal phase, use of estrogen (including oral contraceptives), and conditions causing elevated thyroid hormone levels and cirrhosis of the liver are associated with reduced fractions of free testosterone caused by elevated SHBG levels. Conversely, levels of SHBG decrease and result in elevated free testosterone fractions in response to androgens, androgenic disorders (PCOS, adrenal hyperplasia or neoplasm, Cushing syndrome), androgenic medications (i.e., progestational agents with androgenic biologic activities, such as danazol, glucocorticoids, and growth hormones), hyperinsulinemia, obesity, and prolactin.

**Laboratory Assessment of Hyperandrogenemia**

In hyperandrogenic states, increases in testosterone production are not proportionately reflected in increased total testosterone levels because of the depression of SHBG levels that occurs concomitant with increasing androgen effects on the liver. Therefore, when moderate hyperandrogenism, characteristic of many functional hyperandrogenic states, occurs, elevations in total testosterone levels may remain within the normal range, and only free testosterone levels will reveal the hyperandrogenism. **Severe hyperandrogenism, as occurs in virilization and that results from neoplastic production of testosterone, is reliably detected by measures of total testosterone.** Therefore, in practical clinical evaluation of the hyperandrogenic patient, determination of the total testosterone level in concert with clinical assessment is frequently sufficient for diagnosis and management. When more precise delineation of the degree of hyperandrogenism is desired, measurement or estimation of free testosterone levels can be undertaken and will more reliably reflect increases in testosterone production. These measurements are not necessary in evaluating the majority of patients, but they are common in clinical research studies and may be useful in some clinical settings. Because many practitioners measure some form of testosterone level, they should understand the methods used and their accuracy. Although equilibrium dialysis is the gold standard for measuring free testosterone, it is expensive, complex, and usually limited to research settings. In a clinical setting, free testosterone levels can be estimated by assessment of testosterone binding to albumin and SHBG.

**Testosterone, that is nonspecifically bound to albumin (AT), is linearly related to free testosterone (FT) by the equation:**

\[ AT = K_a [A] \times FT, \]
where AT is the albumin-bound testosterone, $K_a$ is the association constant of albumin for testosterone, and [A] is the albumin concentration.

In many cases of hirsutism, albumin levels are within a narrow physiologic range and thus do not significantly affect the free testosterone concentration. When physiologic albumin levels are present, the free testosterone level can be estimated by measuring the total testosterone and SHBG. In individuals with normal albumin levels, this method has reliable results compared with those of equilibrium dialysis. It provides a rapid, simple, and accurate determination of the total and calculated free testosterone level and the concentration of SHBG.

**The bioavailable testosterone level is based on the relationship of albumin and free testosterone and incorporates the actual albumin level with the total testosterone and SHBG.** This combination of total testosterone, SHBG, and albumin level measurements can be applied to derive a more accurate estimate of available bioactive testosterone and thus the androgen effect derived from testosterone. Bioactive testosterone determined in this manner provides a superior estimate of the effective androgen effect derived from testosterone (5).

**Pregnancy can alter the accuracy of measurements of bioavailable testosterone.** During pregnancy, estradiol, which shares with testosterone a high affinity for SHBG, occupies a large proportion of SHBG binding sites, so that measurement of SHBG levels can overestimate the binding capacity of SHBG for testosterone. Derived estimates of free testosterone, as opposed to direct measure by equilibrium dialysis, are therefore inaccurate during pregnancy. Testosterone measurements in pregnancy are primarily of interest when autonomous secretion by tumor or luteoma is in question, and for these, total testosterone determinations provide sufficient information for diagnosis.

**For testosterone to exert its biologic effects on target tissues, it must be converted into its active metabolite, DHT, by 5α-reductase** (a cytosolic enzyme that reduces testosterone and androstenedione). Two isozymes of 5α-reductase exist: type 1, which predominates in the skin, and type 2, or acidic 5α-reductase, which is found in the liver, prostate, seminal vesicles, and genital skin. The type 2 isozyme has a 20-fold higher affinity for testosterone than type 1. Both type 1 and 2 deficiencies in males result in ambiguous genitalia, and both isozymes may play a role in androgen effects on hair growth. Dihydrotestosterone is more potent than testosterone, primarily because of its higher affinity and slower dissociation from the androgen receptor. Although DHT is the key intracellular mediator of most androgen effects, measurements of circulating levels are not clinically useful.

**The relative androgenicity of androgens is as follows:**

DHT = 300  
Testosterone = 100  
Androstenedione = 10  
DHEAS = 5.
Until adrenarche, androgen levels remain low. Around 8 years of age, adrenarche is heralded by a marked increase in DHEA and DHEAS. The half-life of free DHEA is extremely short (about 30 minutes) but extends to several hours if DHEA is sulfated. Although no clear role is identified for DHEAS, it is associated with stress and levels decline steadily throughout adult life. After menopause, ovarian estrogen secretion ceases, and DHEAS levels continue to decline, whereas testosterone levels are maintained or may even increase. Although postmenopausal ovarian steroidogenesis contributes to testosterone production, testosterone levels retain diurnal variation, reflecting an ongoing and important adrenal contribution. Peripheral aromatization of androgens to estrogens increases with age, but because small fractions (2% to 10%) of androgens are metabolized in this fashion, such conversion is rarely of clinical significance.

**Laboratory Evaluation**

The 2008 Endocrine Society Clinical Practice Guidelines suggest testing for elevated androgen levels in women with moderate (Ferriman–Gallwey hirsutism score 9 or greater) or severe hirsutism or hirsutism of any degree when it is sudden in onset, rapidly progressive, or associated with other abnormalities such as menstrual dysfunction, infertility, significant acne, obesity, or clitoromegaly. These guidelines suggest against testing for elevated androgen levels in women with isolated mild hirsutism because the likelihood of identifying a medical disorder that would change management or outcome is extremely low (Fig. 31.3) (4). Medications that cause hirsutism are listed and should be considered (Table 31.1).

When laboratory testing for the assessment of hirsutism is indicated, either a bioavailable testosterone level (includes a total testosterone, SHBG, and albumin level) or a calculated free testosterone level (if albumin levels are assumed to be normal) provides the most accurate assessment of the androgen effect derived from testosterone. In clinical situations requiring a testosterone evaluation, the addition of 17-hydroxyprogesterone will screen for adult onset adrenal hyperplasia, when indicated (Table 31.2). When hirsutism is accompanied by absent or abnormal menstrual periods, assessment of prolactin and thyroid-stimulating hormone (TSH) values are required to diagnose an ovulatory disorder. Hypothyroidism and hyperprolactinemia may result in reduced levels of SHBG and may increase the fraction of unbound testosterone levels, occasionally resulting in hirsutism. In cases of suspected Cushing syndrome, patients should undergo screening with a 24-hour urinary cortisol (most sensitive and specific) assessment or an overnight dexamethasone suppression test. For this test, the patient takes 1 mg of dexamethasone at 11 p.m., and a blood cortisol assessment is performed at 8 a.m. the next day. Cortisol levels of 2 μg/dL or higher after overnight dexamethasone suppression require a further workup for evaluation of Cushing syndrome. Elevated 17-hydroxyprogesterone (17-OHP) levels identify patients who may have AOAH, found in 1% to 5% of hirsute women. The 17-OHP
levels can vary significantly within the menstrual cycle, increasing in the periovulatory period and luteal phase, and may be modestly elevated in PCOS. Standardized testing requires early morning testing during the follicular phase.

According to the Endocrine Society clinical guidelines, patients with morning follicular phase 17-OHP levels of less than 300 ng/dL (10 nmol/L) are likely unaffected. When levels are greater than 300 ng/dL but less than 10,000 ng/dL (300 nmol/L), ACTH testing should be performed to distinguish between PCOS and AOAH. Levels greater than 10,000 ng/dL (300 nmol/L) are virtually diagnostic of congenital adrenal hyperplasia.

**Precocious pubarche precedes the diagnosis of adult onset congenital adrenal hyperplasia in 5% to 20% of cases.** Measurement of 17-OHP should be performed in patients presenting with precocious pubarche, and a subsequent ACTH stimulation test is recommended if basal 17-OHP is greater than 200 ng/dL. A study using a 200 ng/dL threshold for basal 17-OHP plasma levels to prompt ACTH stimulation testing offered 100% (95% confidence interval [CI], 69–100) sensitivity and 99% (95% CI, 96–100) specificity for the diagnosis of adult onset congenital adrenal hyperplasia within the cohort with precocious puberty (6).

Because increased testosterone production is not reliably reflected by total testosterone levels, the clinician may choose to rely on typical male pattern hirsutism as confirmation of its presence, or may elect measures that reflect levels of free or unbound testosterone (bioavailable or calculated free testosterone levels). Total testosterone does serve as a reliable marker for testosterone-producing neoplasms. **Total testosterone levels greater than 200 ng/dL should prompt a workup for ovarian or adrenal tumors.**

Although the ovary is the principal source of androgen excess in most of PCOS patients, 20% to 30% of patients with PCOS will demonstrate supranormal levels of DHEAS. Measuring circulating levels of DHEAS has limited diagnostic value, and overinterpretation of DHEAS levels should be avoided (7).

In the past, testing for androgen conjugates (e.g., 3α-androstenediol G [3α-diol G] and androsterone G [AOG] as markers for 5α-reductase activity in the skin) was advocated. Routine determination of androgen conjugates to assess hirsute patients is not recommended, because hirsutism itself is an excellent bioassay of free testosterone action on the hair follicle and because these androgen conjugates arise from adrenal precursors and are likely markers of adrenal and not ovarian steroid production (8).
confirmed with an 11-desoxycortisol level >25 ng/mL 60 minutes after ACTH(1-24) stimulation. ACTH, adrenocorticotropic hormone; AOAH, adult-onset adrenal hyperplasia; DHEAS, dehydroepiandrosterone sulfate; HAIR-AN, hyperandrogenemia, insulin resistance- acanthosis nigricans. 17-hydroxyprogesterone (follicular phase) 30–200 ng/dL

SHBG, sex hormone–binding globulin.

Normal values may vary among different laboratories. Free testosterone is calculated using measurements for total testosterone and sex hormone–binding globulin, whereas bioavailable testosterone is calculated using measured total testosterone, sex hormone–binding globulin, and albumin. Calculated values for free and bioavailable testosterone compare well with equilibrium dialysis methods of measuring unbound testosterone when albumin levels are normal. Bioavailable testosterone includes free plus very weakly bound (non-SHBG, nonalbumin) testosterone. Bioavailable testosterone is the most accurate assessment of bioactive testosterone in the serum without performing equilibrium dialysis.

In the zona reticularis layer of the adrenal cortex, DHEAS is generated by SULT2A1 (9). This layer of the adrenal cortex is thought to be the primary source of serum DHEAS. DHEAS levels decline as a person ages and the reticularis layer diminishes in size. In most laboratories, the upper limit of a DHEAS level is 350 μg/dL (9.5 nmol/L). A random sample is sufficient because the level of variation is minimized as a result of the long half-life characteristic of sulfated steroids. DHEAS is used as a screen for androgen-secreting adrenocortical tumors; however, moderate elevations are a common finding in the presence of PCOS, obesity, and stress, which reduces specificity (10).

A study of women with androgen-secreting adrenocortical tumors (ACT-AS) (N = 44), compared to women with nontumor androgen excess (NTAE) (N = 102), sheds additional light on the choice of hormones used to screen for an adrenocortical tumor. In the study, the demographics and the prevalence of hirsutism, acne, oligomenorrhea and amenorrhea were not different in each group. Free testosterone (free T) was the most commonly elevated androgen in ACT-AS (94%), followed by androstenedione (A) (90%), DHEAS (82%), and total testosterone (total T) (76%), and all three androgens were simultaneously elevated in 56% of the cases. Serum androgen levels became subnormal in all ACT-AS patients after the tumor was removed. In nontumor androgen excess alone, the most commonly elevated androgen was androstenedione (93%), while all three androgens (T, A, and DHEAS) were elevated in only 22% of the cases. Free testosterone values above 6.85 pg/mL (23.6 pmol/L) had the best diagnostic value for ACT-AS (sensitivity 82%; CI, 57%–96%; specificity 97%, CI, 91%–100%) (Table 31.3). The large
The overlap of androstenedione, testosterone, and DHEAS levels between ACT-AS and androgen excess groups suggests that thoughtful consideration should be employed when choosing hormone studies for this evaluation (11).

Thresholds were selected using Youden’s index, as described in the methods. (Reprinted with permission from d’Alva CB, Abiven-Lepage G, Viallon V, et al. Sex steroids in androgen-secreting adrenocortical tumors: clinical and hormonal features in comparison with non-tumor causes of androgen excess. *Eur J Endocrinol* 2008;159:641-647.)

When clinical signs of androgen excess reach the point of virilization or the free testosterone level is above 6.85 pg/mL (23.6 pmol/L), follow-up testing with a 11-desoxycortisol (>7 ng/mL), DHEAS (>3.6 μg/mL), and 24-hour urinary cortisol (>45 μg per day) are the most sensitive and specific for the detection of an androgen-secreting adrenocortical tumor. Careful consideration of the sensitivity and specificity, diurnal variation, and age-related variation of potentially measureable androgens will aid in choosing the most useful measurements (Table 31.3).
**Polycystic Ovary Syndrome**

PCOS is arguably one of the most common endocrine disorders in women of reproductive age, affecting 5% to 10% of women worldwide. This familial disorder appears to be inherited as a complex genetic trait (13). It is characterized by a combination of hyperandrogenism (either clinical or biochemical), chronic anovulation, and polycystic ovaries. It is frequently associated with insulin resistance and obesity (14). PCOS receives considerable attention because of its high prevalence and possible reproductive, metabolic, and cardiovascular consequences. **It is the most common cause of hyperandrogenism, hirsutism, and anovulatory infertility in developed countries** (15,16). The association of amenorrhea with bilateral polycystic ovaries and obesity was first described in 1935 by Stein and Leventhal (17). Its genetic origins are likely polygenic and/or multifactorial (18).

**Diagnostic Criteria**

In an international conference on PCOS organized by the National Institutes of Health (NIH) in 1990, diagnostic criteria for PCOS were based on consensus rather than clinical trial evidence. Their diagnostic criteria recommended clinical and/or biochemical evidence of hyperandrogenism, chronic anovulation, and exclusion of other known disorders. These criteria were an important initial step in standardizing diagnosis and led to a number of landmark randomized clinical trials in PCOS (19).

**Table 31.4 Revised Diagnostic Criteria of Polycystic Ovary Syndrome**

1990 Criteria (both 1 and 2)

1. Chronic anovulation and
2. Clinical and/or biochemical signs of hyperandrogenism and exclusion of other etiologies.

Revised 2003 criteria (2 out of 3)

1. Oligoovulation or anovulation
2. Clinical and/or biochemical signs of hyperandrogenism
3. Polycystic ovaries and exclusion of other etiologies (congenital adrenal hyperplasia, androgen-secreting tumors, Cushing’s syndrome)

Since the 1990 NIH-sponsored PCOS conference, evolving perception is that the syndrome may constitute a broader spectrum of signs and symptoms of ovarian dysfunction than those set forth in the original NIH diagnostic criteria. The 2003 Rotterdam Consensus Workshop concluded that PCOS is a syndrome of ovarian dysfunction along with the cardinal features hyperandrogenism and polycystic ovary (PCO) morphology (**Table 31.4**).
It is recognized that women with regular cycles, hyperandrogenism, and PCO morphology may be part of the syndrome. Some women with the syndrome will have PCO morphology without clinical evidence of androgen excess, but will display evidence of ovarian dysfunction with irregular cycles. In this new schema, PCOS remains a diagnosis of exclusion with the need to rule out other disorders that mimic the PCOS phenotype (19).

Using the Rotterdam PCOS Diagnostic Criteria, the presence of two of the three criteria is sufficient to diagnosis PCOS: menstrual cycle anomalies (amenorrhea, oligomenorrhea), clinical and/or biochemical hyperandrogenism, and/or the ultrasound appearance of polycystic ovaries after all other diagnoses are ruled out. Other pathologies that can result in a POCS phenotype include AOAH, adrenal or ovarian neoplasm, Cushing syndrome, hypo- or hypergonadotropin disorders, hyperprolactinemia, and thyroid disease (Fig. 31.4).

All other frequently encountered manifestations offer less consistent findings and therefore qualify only as minor diagnostic criteria for PCOS. They include elevated LH-to-FSH (follicle-stimulating hormone) ratio, insulin resistance, perimenarchal onset of hirsutism, and obesity.

Clinical hyperandrogenism includes hirsutism, male pattern alopecia, and acne (19). Hirsutism occurs in approximately 70% of patients with PCOS in the United States and in only 10% to 20% of patients with PCOS in Japan (20,21). A likely explanation for this discrepancy is the genetically determined differences in skin 5α-reductase activity (22,23).

Nonclassic adrenal hyperplasia and PCOS may present with similar clinical features. It is important to measure the basal follicular phase 17-hydroxyprogesterone level in all women presenting with hirsutism to exclude the presence of nonclassic congenital adrenal hyperplasia, regardless of the presence of polycystic ovaries or metabolic dysfunction (24).

The menstrual dysfunction in PCOS arises from anovulation or oligo-ovulation and ranges from amenorrhea to oligomenorrhea. Regular menses in the presence of anovulation in PCOS is uncommon, although one report found that among hyperandrogenic women with regular menstrual cycles, the rate of anovulation is 21% (25). Classically, the disorder is lifelong, characterized by abnormal menses from puberty with acne and hirsutism arising in the teens. It may arise in adulthood, concomitant with the emergence of obesity, presumably because this is accompanied by increasing hyperinsulinemia (26).

Figure 31.4 Diagnostic algorithm for polycystic ovary syndrome. (From Rosenfield RL. Clinical practice. Hirsutism. N Engl J Med 2005;353:2578–2588, with permission.)
The sonographic criteria for PCO requires the presence of 12 or more follicles in either ovary measuring 2 to 9 mm in diameter and/or increased ovarian volume (>10 mL). A single ovary meeting these criteria is sufficient to affix the PCO diagnosis (19). The appearance of PCO on ultrasound scanning is common. Only a fraction of those with PCO appearance have the clinical and/or endocrine features of PCOS. A PCO appearance is found in about 23% of women of reproductive age, while estimates of the incidence of PCOS vary between 5% and 10% (27). Polycystic appearing ovaries in women with PCOS was not associated with increased cardiovascular disease risk, independent of body mass index (BMI), age, and insulin levels (28). An English study demonstrated that without symptoms of polycystic ovary syndrome, a PCO appearance alone is not associated with impaired fecundity or fertility (29).

**Obesity occurs in more than 50% of patients with PCOS.** The body fat is usually deposited centrally (android obesity), and a higher waist-to-hip ratio is associated with insulin resistance indicating an increased risk of diabetes mellitus and cardiovascular disease (30). Among women with PCOS, there is widespread variability in the degree of adiposity by geographic location and ethnicity. In studies in Spain, China, Italy, and the United States, the percentage of obese women with PCOS were 20%, 43%, 38%, and 69%, respectively (31).

**Insulin resistance resulting in hyperinsulinemia is commonly exhibited in PCOS.** Insulin resistance may eventually lead to the development of hyperglycemia and type 2 diabetes mellitus (32). About one-third of obese PCOS patients have impaired glucose tolerance (IGT), and 7.5% to 10% have type 2 diabetes mellitus (33). These rates are mildly increased in nonobese women who have PCOS (10% IGT; 1.5% diabetes, respectively), compared with the general population of the United States (7.8% IGT; 1% diabetes, respectively) (34,35).

**Abnormal lipoproteins are common in PCOS** and include elevated total cholesterol,
triglycerides, and low-density lipoproteins (LDL); and low levels of high-density lipoproteins (HDL), and apoprotein A-I (30,36). According to one report, the most characteristic lipid alteration is decreased levels of HDL\(_2\alpha\) (37).

Other observations in women with PCOS include impaired fibrinolysis, as shown by elevated circulating levels of plasminogen activator inhibitor, an increased incidence of hypertension over the years (which reaches 40% by perimenopause), a greater prevalence of atherosclerosis and cardiovascular disease, and an estimated sevenfold increased risk for myocardial infarction (36,38–41).

**Pathology**

*Macroscopically, ovaries in women with PCOS are two to five times the normal size.* A cross-section of the surface of the ovary discloses a white, thickened cortex with multiple cysts that are typically less than a centimeter in diameter. Microscopically, the superficial cortex is fibrotic and hypocellular and may contain prominent blood vessels. In addition to smaller atretic follicles, there is an increase in the number of follicles with luteinized theca interna. The stroma may contain luteinized stromal cells (42).

**Pathophysiology and Laboratory Findings**

The hyperandrogenism and anovulation that accompany PCOS may be caused by abnormalities in four endocrinologically active compartments: (i) the ovaries, (ii) the adrenal glands, (iii) the periphery (fat), and (iv) the hypothalamus–pituitary compartment (Fig. 31.5).

*Figure 31.5 Pathophysiological characteristics of the polycystic ovary syndrome (PCOS).* Insulin resistance results in a compensatory hyperinsulinemia, which stimulates ovarian androgen production in an ovary genetically predisposed to PCOS. Arrest of follicular development (red “X”) and anovulation could be caused by the abnormal secretion of gonadotropins such as follicle-stimulating hormone (FSH) or luteinizing hormone (LH) (perhaps induced by hyperinsulinemia), intraovarian androgen excess, direct effects of insulin, or a combination of these factors. Insulin resistance, in concert with genetic factors, may also lead to hyperglycemia and an adverse profile of cardiovascular risk factors. (From Rosenfield RL. Clinical practice. Hirsutism. N Engl J Med 2005;353:2578–2588, with permission.)
In patients with PCOS, the ovarian compartment is the most consistent contributor of androgens. Dysregulation of CYP17, the androgen-forming enzyme in both the adrenals and the ovaries, may be one of the central pathogenetic mechanisms underlying hyperandrogenism in PCOS (43). The ovarian stroma, theca, and granulosa contribute to ovarian hyperandrogenism and are stimulated by LH (44). This hormone relates to ovarian androgenic activity in PCOS in a number of ways.

Total and free testosterone levels correlate directly with LH levels (45). The ovaries are more sensitive to gonadotropic stimulation, possibly as a result of CYP17 dysregulation (43).

Treatment with a gonadotropin-releasing hormone (GnRH) agonist effectively suppresses serum testosterone and androstenedione levels (46).

Larger doses of a GnRH agonist are required for androgen suppression than for endogenous gonadotropin-induced estrogen suppression (47).

The increased testosterone levels in patients with PCOS are considered ovarian in origin. The serum total testosterone levels are usually no more than twice
the upper normal range (20 to 80 ng/dL). However, in ovarian hyperthecosis, values may reach 200 ng/dL or more (48). The adrenal compartment plays a role in the development of PCOS. Although the hyperfunctioning CYP17 androgen-forming enzyme coexists in both the ovaries and the adrenal glands, DHEAS is increased in only about 50% of patients with PCOS (49,50). The hyperresponsiveness of DHEAS to stimulation with ACTH, the onset of symptoms around puberty, and the observation of 17,20-lyase activation (one of the two CYP17 enzymes) are key events in adrenarche that led to the hypothesis that PCOS arises as an exaggeration of adrenarche (48).

The peripheral compartment, defined as the skin and the adipose tissue, manifests its contribution to the development of PCOS in several ways.

The presence and activity of 5α-reductase in the skin largely determines the presence or absence of hirsutism (22,23).

Aromatase and 17β-hydroxysteroid dehydrogenase activities are increased in fat cells and peripheral aromatization is increased with increased body weight (51,52). With obesity the metabolism of estrogens, by way of reduced 2-hydroxylation and 17α-oxidation, is decreased and metabolism via estrogen active 16-hydroxyestrogens (estriol) is increased (53).

Whereas estradiol (E2) is at a follicular phase level in patients with PCOS, estrone (E1) levels are increased as a result of peripheral aromatization of androstenedione (54).

A chronic hyperestrogenic state, with reversal of the E1-to-E2 ratio, results and is unopposed by progesterone.

The hypothalamic–pituitary compartment participates in aspects critical to the development of PCOS.

An increase in LH pulse frequency relative to those in the normal follicular phase is the result of increased GnRH pulse frequency (55). This increase in LH pulse frequency explains the frequent observation of an elevated LH and LH-to-FSH ratio.

FSH is not increased with LH, likely because of the combination of increased gonadotropin pulse frequency and the synergistic negative feedback of chronically elevated estrogen levels and normal follicular inhibin.

About 25% of patients with PCOS exhibit mildly elevated prolactin levels, which may result from abnormal estrogen feedback to the pituitary gland. In some patients with PCOS, bromocriptine has reduced LH levels and restored ovulatory function (56).

Polycystic ovary syndrome is a complex multigenetic disorder that results from the interaction between multiple genetic and environmental factors. Genetic studies of PCOS reported allele sharing in large PCOS patient populations and linkage studies focused on candidate genes most likely to be involved in the pathogenesis of PCOS. These genes can be grouped in four categories: (i) insulin resistance–related genes, (ii) genes that interfere with the biosynthesis
and the action of androgens, (iii) genes that encode inflammatory cytokines, and (iv) other candidate genes (57).

Linkage studies identified the follistatin, CYP11A, Calpain 10, IRS-1 and IRS-2 regions and loci near the insulin receptor (19p13.3), SHBG, TCF7L2, and the insulin genes, as likely PCOS candidate genes (58–64). A polymorphic variant, D19S884, in FBN3 was found to be associated with risk of PCOS (65). Using theca cells derived from women with PCOS elevated mRNA levels was noted for CYP11A, 3BHSD2, and CYP17 genes with corresponding overproduction of testosterone, 17-α-hydroxyprogesterone, and progesterone. Despite the characteristically heightened steroidogenesis in POCs, the STARB gene was not overexpressed (58). Microarray data using theca cells from PCOS women did not identify any genes near the 19p13.3 locus that were differentially expressed; however, the mRNAs of several genes that map to 19p13.3, including the insulin receptor; p114-Rho-GEF, and several expressed sequence tags, were detected in both PCOS and normal theca cells. Those studies identified new factors that might impact theca cell steroidogenesis and function, including cAMP-GEFII, genes involved in all-transretinoic acid (atRA) synthesis signaling, genes that participate in the Wnt signal transduction pathway, and transcription factor GATA6. These findings suggest that a 19p13.3 locus or some other candidate gene may be a signal transduction gene that results in overexpression of a suite of genes downstream that may affect steroidogenic activity (66). Polymorphisms in major folliculogenesis genes, GDF9, BMP15, AMH, and AMHR2, are not associated with PCOS susceptibility (67).

**Insulin Resistance**

Patients with PCOS frequently exhibit insulin resistance and hyperinsulinemia. Insulin resistance and hyperinsulinemia participate in the ovarian steroidogenic dysfunction of PCOS. Insulin alters ovarian steroidogenesis independent of gonadotropin secretion in PCOS. Insulin and insulin-like growth factor I (IGF-I) receptors are present in the ovarian stromal cells. A specific defect in the early steps of insulin receptor–mediated signaling (diminished autophosphorylation) was identified in 50% of women with PCOS (68).

Insulin has direct and indirect roles in the pathogenesis of hyperandrogenism in PCOS. Insulin in collaboration with LH enhances the androgen production of theca cells. Insulin inhibits the hepatic synthesis of sex hormone–binding globulin, the main circulating protein that binds to testosterone, thus increasing the proportion of unbound or bioavailable testosterone (13).

The most common cause of insulin resistance and compensatory hyperinsulinemia is obesity, but despite its frequent occurrence in PCOS, obesity alone does not explain this important association (56). The insulin resistance associated with PCOS is not solely the result of hyperandrogenism based on the following:

Hyperinsulinemia is not a characteristic of hyperandrogenism in general but is uniquely
associated with PCOS (69).
In obese women with PCOS, 30% to 45% have glucose intolerance or frank diabetes mellitus, whereas ovulatory hyperandrogenic women have normal insulin levels and glucose tolerance (69). It seems that the associations between PCOS and obesity on the action of insulin are synergistic.
Suppression of ovarian steroidogenesis in women with PCOS with long-acting GnRH analogues does not change insulin levels or insulin resistance (70).
Oophorectomy in patients with hyperthecosis accompanied by hyperinsulinemia and hyperandrogenemia does not change insulin resistance, despite a decrease in androgen levels (70,71).

Acanthosis nigricans is a reliable marker of insulin resistance in hirsute women. This thickened, pigmented, velvety skin lesion is most often found in the vulva and may be present on the axilla, over the nape of the neck, below the breast, and on the inner thigh (72). The HAIR-AN syndrome consists of hyperandrogenism (HA), insulin resistance (IR), and acanthosis nigricans (AN) (68,73). These patients often have high testosterone levels (>150 ng/dL), fasting insulin levels of greater than 25 μIU/mL (normal <20 to 24 μIU/mL), and maximal serum insulin responses to glucose load (75 gm) exceeding 300 μIU/mL (normal is <160 μIU/m: at 2 hours postglucose load).

Screening Strategies for Diabetes and Insulin Resistance
The 2003 Rotterdam Consensus Group recommends that obese women with PCOS and nonobese PCOS patients with risk factors for insulin resistance, such as a family history of diabetes, should be screened for metabolic syndrome, including glucose intolerance with an oral glucose tolerance test (19). The standard 2-hour oral glucose tolerance test (OGTT) provides an assessment of both the degrees of hyperinsulinemia and glucose tolerance and yields the highest amount of information for a reasonable cost and risk (7).
Multiple other testing or screening schema were proposed to assess the presence of hyperinsulinemia and insulin resistance. In one, the fasting glucose-to-insulin ratio is determined, and values less than 4.5 indicate insulin resistance. Using the 2-hour GTT with insulin levels, 10% of nonobese and 40% to 50% of obese PCOS women have impaired glucose tolerance (IGT = 2-hour glucose level ≥140 but ≤199 mg/dL) or overt type 2 diabetes mellitus (any glucose level >200 mg/dL). Some research studies utilized a peak insulin level of over 150 μIU/mL or a mean level of over 84 μIU/mL over the three blood draws of a 2-hour GTT as a criteria to diagnoses hyperinsulinemia.

The documentation of hyperinsulinemia using either the glucose to insulin ratio or the 2-hour GTT with insulin is problematic. When compared to the gold standard measure for insulin resistance, the hyperinsulemic-euglycemic clamp, it shows that the glucose-to-insulin ratio does not always accurately portray insulin resistance. When hyperglycemia is
present, a relative insulin secretion deficit is present. This deficient insulin secretion exacerbates the effects of insulin resistance and renders inaccurate the use of hyperinsulinemia as an index of insulin resistance. Thus, routine measurements of insulin levels may not be particularly useful.

Although detection of insulin resistance, per se, is not of practical importance to the diagnosis or management of PCOS, testing women with PCOS for glucose intolerance is of value because their risk of cardiovascular disease correlates with this finding. An appropriate frequency for such screening depends on age, BMI and waist circumference, all of which increase risk.

Interventions

Abnormal glucose metabolism may be significantly improved with weight reduction, which may reduce hyperandrogenism and restore ovulatory function (74). In obese, insulin-resistant women, caloric restriction that results in weight reduction will reduce the severity of insulin resistance (a 40% decrease in insulin level with a 10-kg weight loss) (75). This decrease in insulin levels should result in a marked decrease in androgen production (a 35% decrease in testosterone levels with a 10-kg weight loss) (76). Exercise reduces insulin resistance, independent from any associated weight loss, but data on the impact of exercise on the principal manifestations of PCOS are lacking.

In addition to addressing the increased risk for diabetes, the clinician should recognize insulin resistance or hyperinsulinemia as a cluster syndrome called metabolic syndrome or dysmetabolic syndrome X. Recognition of the importance of insulin resistance or hyperinsulinemia as a risk factor for cardiovascular disease led to diagnostic criteria for the dysmetabolic syndrome. The more dysmetabolic syndrome X criteria are present, the higher the level of insulin resistance and its downstream consequences. The presence of three of the following five criteria confirm the diagnosis, and an insulin-lowering agent and/or other interventions may be warranted (19).

**Metabolic Syndrome Diagnostic Criteria**
Female waist >35 inches
Triglycerides >150 mg/dL
HDL <50 mg/dL
Blood pressure >130/85 mmHg
Fasting glucose: 110–126 mg/dL
Two-hour glucose (75 gm OGTT): 140–199 mg/dL

Risk factors for the dysmetabolic syndrome include nonwhite race, sedentary lifestyle, BMI greater than 25, age over 40 years, cardiovascular disease, hypertension, PCOS, hyperandrogenemia, insulin resistance, HAIR-AN syndrome, nonalcoholic steatohepatitis (NASH), and a family history of type 2 diabetes mellitus, gestational diabetes, or impaired glucose tolerance.

Long-Term Risks and Interventions
Comprehensive treatment of PCOS addresses reproductive, metabolic and psychological features.

Metabolic Syndrome
A report by the Androgen Excess and PCOS Society concluded that lifestyle management, either alone or combined with antiobesity pharmacologic and/or surgical treatments, should be used as the primary therapy in overweight and obese women with PCOS (31). Lifestyle management of obesity in PCOS is multifactorial. Dietary management of obesity should focus on reducing body weight, maintaining a lower long-term body weight, and preventing weight gain. An initial weight loss of greater than or equal to 5% to 10% is recommended. In obese and overweight women with PCOS, dietary interventions with a resultant weight reduction of more than 5% to less than 15% over the starting body weight is associated with a reduction in either total or free testosterone, adrenal androgens, and improvement in SHBG levels. Metabolic improvements in fasting insulin, glucose, glucose tolerance, total cholesterol, triglycerides, plasminogen activator inhibitor-1, and free fatty acids are reported. Clinically, hirsutism, menstrual function, and ovulation are all improved (31).

Structured exercise improves insulin resistance and offers significant benefits in PCOS. The incorporation of structured exercise, behavior modification, and stress management strategies as fundamental components of lifestyle management increases the success of the weight loss strategy (Table 31.5).

Even though lifestyle management strategies should be used as the primary therapy in obese and overweight women with PCOS, they are difficult to maintain long term. Alternative approaches to the treatment of obesity include the use of pharmacologic agents, such as orlistat, sibutramine, and rimonabant, or bariatric surgery (31). The NIH clinical recommendations advise bariatric surgery when BMI is greater than 40 kg/m² or greater than 35 kg/m² in patients with a high-risk, obesity-related condition after failure of other treatments for weight control (31,77).
Dyslipidemia is one of the most common metabolic disorders seen in PCOS patients (up to 70% prevalence in a US PCOS population) \(^{(78)}\). It is associated with insulin resistance and hyperandrogenism in combination with environmental (diet, physical exercise) and genetic factors. Various abnormal patterns include decreased levels of HDL, elevated levels of triglycerides, decreased total and LDL levels, and altered LDL quality \(^{(79,80)}\).

**Table 31.5 Lifestyle Modification Principles Suggested for Obesity Management in Polycystic Ovary Syndrome (PCOS)**

Guidelines for dietary and lifestyle intervention in PCOS

- Lifestyle modification is the first form of therapy, combining behavioral (reduction of psychosocial stressors), dietary, and exercise management.
- Reduced-energy diets (500–1,000 kcal/day reduction) are effective options for weight loss and can reduce body weight by 7% to 10% over a period of 6 to 12 months.
- Dietary plans should be nutritionally complete and appropriate for life stage and should aim for <30% of calories from fat, <10% of calories from saturated fat, with increased consumption of fiber, whole-grain breads and cereals, and fruit and vegetables.
- Alternative dietary options (increasing dietary protein, reducing glycemic index, reducing carbohydrate) may be successful for achieving and sustaining a reduced weight but more research is needed in PCOS specifically.
- The structure and support within a weight-management program is crucial and may be more important than the dietary composition. Individualization of the program, intensive follow-up and monitoring by a physician, and support from the physician, family, spouse, and peers will improve retention.
- Structured exercise is an important component of a weight-loss regime; aim for >30 min/day.

To assess cardiovascular risks and prevent disease in patients with PCOS, the Androgen Excess and Polycystic Ovary Syndrome (AE-PCOS) Society recommend the following monitoring activities \(^{(80)}\):

- Waist circumference and BMI measurement at every visit, using the National Health and Nutrition Examination Survey method.
- A complete lipid profile based using the American Heart Association guidelines (Fig. 31.6). If the fasting serum lipid profile is normal, it should be reassessed every 2 years or sooner if weight gain occurs.
A 2-hour post-75-g oral glucose challenge measurement in PCOS women with a BMI greater than 30 kg/m², or alternatively in lean PCOS women with advanced age (40 years), personal history of gestational diabetes, or family history of type 2 diabetes.

Blood pressure measurement at each visit. The ideal blood pressure is 120/80 or lower. Prehypertension should be treated because blood pressure control has the largest benefit in reducing cardiovascular diseases.

Regular assessment for depression, anxiety, and quality of life.

**Figure 31.6 Lipid guidelines in PCOS to prevent cardiovascular disease risk (values in mg/dL).** (Non-HDL = Total Cholesterol - HDL, if TG <400 mg/dL). (Data for figure derived from Wild RA, Carmina E, Diamanti-Kandarakis E, et al. Assessment of cardiovascular risk and prevention of cardiovascular disease in women with the polycystic ovary syndrome: a consensus statement by the Androgen Excess and Polycystic Ovary Syndrome (AE-PCOS) Society. J Clin Endocrinol Metab 2010;95(5):2038–2049.)

A significant proportion of the population and particularly the obese population have inadequate vitamin D levels. Because vitamin D plays a role in many metabolic activities, assessment and supplementation when indicated are recommended.

**25-hydroxy Vitamin D Levels**
- Deficient: 8 ng/mL or less (≤20 nmol/L)
- Insufficient: 8–20 ng/mL (20–50 nmol/L)
- Optimal: 20–60 ng/mL (50–150 nmol/L; 40–50 ng/mL is treatment goal)
- High: 60–90 ng/mL (150–225 nmol/L)
- Toxic: >90 ng/mL or greater (≥225 nmol/L)

**Supplementation Facts**
The body uses 3,000 to 5,000 IU D₃ per day.

In the absence of the sun, 600 IU of D₃ are required to maintain vitamin D levels. D₂ is more rapidly metabolized and is less potent than D₃.
Patients receiving 50,000 IU of vitamin D₂ once a week for 8 weeks will usually correct a vitamin D deficiency, and this can be followed by giving 50,000 U of vitamin D₂ once every other week to maintain vitamin D sufficiency. D₃ is more potent and appropriate dosing to correct levels is still under investigation.

Cancer

In chronic anovulatory patients with PCOS, persistently elevated estrogen levels, which are uninterrupted by progesterone, increase the risk of endometrial carcinoma (81,82). These endometrial cancers are usually well differentiated, stage I lesions with a cure rate of more than 90% (see Chapter 35). Endometrial biopsy should be considered in PCOS patients, because they may occasionally harbor these cancers as early as the third decade of life. Abnormal bleeding, increasing weight, and age are factors that should lower the threshold for endometrial sampling. **Prevention of endometrial cancer is a core management goal for patients with PCOS.** If other dimensions of management do not induce regular ovulation (e.g., clomiphene) or impose continuous progestation influence (e.g., oral contraceptives), regular secretory transformation and menstruation should be induced with periodic administration of a progestational agent. Even though the hyperestrogenic state is associated with an increased risk of breast cancer, studies examining the relationship between PCOS and breast cancer have not always identified a significantly increased risk (82–86). The risk of ovarian cancer is increased two- to threefold in women with PCOS (82,87).

Depression and Mood Disorders

The clinical features of PCOS, such as infertility, acne, hirsutism, and obesity, promote psychological morbidity. Women with PCOS face challenges to their feminine identity that can lead to loss of self-esteem, anxiety, poor body image, and depression (88).

A study examining the prevalence of depression and other mood disorders in women with PCOS reported a significantly increased prevalence of depression (35% to 40%) when compared with controls (10.7%), after adjusting for BMI, and a family history of depression and/or infertility. Other mood disorders such as anxiety and eating disorders were common in women with PCOS (89). The high prevalence of depression and other mental health disorders in women with PCOS suggests that assessment and treatment of mental health disorders should be included in the evaluation and management plan (89). Lifestyle management improves quality of life and depression in obese and overweight and women with PCOS (88).
Treatment of Hyperandrogenism and PCOS

Treatment depends on a patient’s goals. Some patients require hormonal contraception, whereas others desire ovulation induction. In all cases where there is significant ovulatory dysfunction, progestational interruption of the unopposed estrogen effects on the endometrium is necessary. This may be accomplished by periodic luteal function resulting from ovulation induction, progestational suppression via contraceptive formulations, or intermittent administration of progestational agents for endometrial or menstrual regulation. Interruption of the steady state of hyperandrogenism and control of hirsutism usually can be accomplished simultaneously. Patients desiring pregnancy are an exception, and for them effective control of hirsutism may not be possible. Treatment regimens for hirsutism are listed in Table 31.6. The induction of ovulation and treatment of infertility are discussed in Chapter 32.

Weight Reduction

Weight reduction is the initial recommendation for patients with accompanying obesity because it promotes health, reduces insulin, SHBG, and androgen levels, and may restore ovulation either alone or combined with ovulation-induction agents (75). Weight loss of as little as 5% to 7% over a 6-month period can reduce the bioavailable or calculated free testosterone level significantly and restore ovulation and fertility in more than 75% of women (90). Exercise involving large muscle groups reduces insulin resistance and can be an important component of nonpharmacologic, lifestyle-modifying management.

Oral Contraceptives

Combination oral contraceptives (OCs) decrease adrenal and ovarian androgen production and reduce hair growth in nearly two-thirds of hirsute patients (91–94). Treatment with OCs offers the following benefits:

The progestin component suppresses LH, resulting in diminished ovarian androgen production.

The estrogen component increases hepatic production of SHBG, resulting in decreased free testosterone concentration (95,96).

Circulating androgen levels are reduced, including those of DHEAS, which to some extent is independent of the effects of both LH and SHBG (30,97).

Estrogens decrease conversion of testosterone to DHT in the skin by inhibition of 5α-reductase.

When an OC is used to treat hirsutism, a balance must be maintained between the decrease in free testosterone levels and the intrinsic androgenicity of the progestin. Three progestin compounds that are present in OCs (norgestrel, norethindrone, and norethindrone acetate) are believed to be androgen dominant. The
androgenic bioactivity of these steroids may be a factor of their shared structural similarity with 19-nortestosterone steroids (98). Oral contraceptives containing the so-called new progestins (desogestrel, gestodene, norgestimate, and drospirenone) have minimized androgenic activity. However, there is limited evidence of clinically measurable differences in outcome resulting from the disparity of in vitro estimates of androgenic potency.

The use of OCs alone may be relatively ineffective (<10% success rate) in the treatment of hirsutism in women with PCOS, and the OCs may exacerbate insulin resistance in these patients (99,100). Effective protocols for pharmacologic management of significant hirsutism with OCs usually include coadministration of agents that impede androgen action.

**Medroxyprogesterone Acetate**

Oral or intramuscular administration of medroxyprogesterone acetate (MPA) successfully treats hirsutism (101). It directly affects the hypothalamic–pituitary axis by decreasing GnRH production and the release of gonadotropins, thereby reducing testosterone and estrogen production by the ovary. Despite a decrease in SHBG, total and free androgen levels are decreased significantly (102). The recommended oral dose for GnRH suppression is 20 to 40 mg daily in divided dosages or 150 mg given intramuscularly every 6 weeks to 3 months in the depot form. Hair growth is reduced in up to 95% of patients (103). Side effects of the treatment include amenorrhea, bone mineral density loss, depression, fluid retention, headaches, hepatic dysfunction, and weight gain. MPA is not commonly used for hirsutism.

**Gonadotropin-Releasing Hormone Agonists**

Administration of GnRH agonists may allow the differentiation of androgen produced by adrenal sources from that of ovarian sources (47). It was shown to suppress ovarian steroids to castrate levels in patients with PCOS (104). Treatment with leuprolide acetate given intramuscularly every 28 days decreases hirsutism and hair diameter in both idiopathic hirsutism and hirsutism secondary to PCOS (105). Ovarian androgen levels are significantly and selectively suppressed. The addition of OC or estrogen replacement therapy to GnRH agonist treatment (add-back therapy) prevents bone loss and other side effects of menopause, such as hot flushes and genital atrophy. The hirsutism-reducing effect is retained (102,106). Suppression of hirsutism is not potentiated by the addition of estrogen replacement therapy to GnRH agonist treatment (107).

**Glucocorticoids**

Dexamethasone may be used to treat patients with PCOS who have either adrenal or mixed adrenal and ovarian hyperandrogenism. Doses of dexamethasone as low as 0.25 mg nightly or every other night are used initially to suppress DHEAS concentrations to
Because dexamethasone has 40 times the glucocorticoid effect of cortisol, daily doses greater than 0.5 mg every evening should be avoided to prevent the risk of adrenal suppression and severe side effects that resemble Cushing syndrome. To avoid oversuppression of the pituitary–adrenal axis, morning serum cortisol levels should be monitored intermittently (maintain at >2 μg/dL). Reduction in hair growth rate was reported, and significant improvement in acne associated with adrenal hyperandrogenism (108).

**Ketoconazole**

Ketoconazole inhibits the key steroidogenic cytochromes. Administered at a low dose (200 mg per day), it can significantly reduce the levels of androstenedione, testosterone, and calculated free testosterone (109). It is rarely used for the chronic inhibition of androgen production in women with hyperandrogenism because of the serious risk of adrenocortical suppression and development of adrenal crisis (15).

**Spironolactone**

Spironolactone is a specific antagonist of aldosterone, which competitively binds to the aldosterone receptors in the distal tubular region of the kidney. It is an effective potassium-sparing diuretic that originally was used to treat hypertension. The effectiveness of spironolactone in the treatment of hirsutism is based on the following mechanisms:

- Competitive inhibition of DHT at the intracellular receptor level (22).
- Suppression of testosterone biosynthesis by a decrease in the CYP enzymes (110).
- Increase in androgen catabolism (with increased peripheral conversion of testosterone to estrone).
- Inhibition of skin 5α-reductase activity (22).

Although total and free testosterone levels are reduced significantly in patients with both PCOS and idiopathic hirsutism (hyperandrogenism with regular menses) after treatment with spironolactone, total and free testosterone levels in patients with PCOS remain higher than those with idiopathic hirsutism (hyperandrogenism with regular menses) (111). In both groups, SHBG levels are unaltered. The reduction in circulating androgen levels observed within a few days of spironolactone treatment partially accounts for the progressive regression of hirsutism.

At least a modest improvement in hirsutism can be anticipated in 70% to 80% of women using at least 100 mg of spironolactone per day for 6 months (112). Spironolactone reduces the daily linear growth rate of sexual hair, hair shaft diameters, and daily hair volume production (113). Combination therapy with spironolactone and oral contraceptives seems effective via their differing but synergistic activities (15,114).

The most common dose is 50 to 100 mg twice daily. Women treated with 200 mg per day show a greater reduction in hair shaft diameter than women
receiving 100 mg per day (115). Maximal inhibition of hirsutism is noted between 3 and 6 months but continues for 12 months. Electrolysis can be recommended 9 to 12 months after the initiation of spironolactone for permanent hair removal.

The most common side effect of spironolactone is menstrual irregularity (usually metrorrhagia), which may occur in over 50% of patients with a dosage of 200 mg per day (115). Normal menses may resume with reduction of the dosage. Infrequently, other side effects such as mastodynia, urticaria, or scalp hair loss may occur. Nausea and fatigue can occur with high doses (112). Because spironolactone can increase serum potassium levels, its use is not recommended in patients with renal insufficiency or hyperkalemia. Periodic monitoring of potassium and creatinine levels is suggested.

Return of normal menses in amenorrheic patients is reported in up to 60% of cases (111). Patients must be counseled to use contraception while taking spironolactone because it theoretically can feminize a male fetus.

**Cyproterone Acetate**

Cyproterone acetate is a synthetic progestin derived from 17-OHP, which has potent antiandrogenic properties. The primary mechanism of cyproterone acetate is competitive inhibition of testosterone and DHT at the level of the androgen receptor (116). This agent induces hepatic enzymes and may increase the metabolic clearance rate of plasma androgens (117).

A European formulation of ethinyl estradiol with cyproterone acetate significantly reduces plasma testosterone and androstenedione levels, suppresses gonadotropins, and increases SHBG levels (118). Cyproterone acetate shows mild glucocorticoid activity (and may reduce DHEAS levels) (116,119). Administered in a reverse sequential regimen (cyproterone acetate 100 mg per day on days 5 to 15, and ethinyl estradiol 30 to 50 mg per day on cycle days 5 to 26), this cyclic schedule allows regular menstrual bleeding, provides excellent contraception, and is effective in the treatment of even severe hirsutism and acne (120).

Side effects of cyproterone acetate include fatigue, weight gain, decreased libido, irregular bleeding, nausea, and headaches. These symptoms occur less often when ethinyl estradiol is added. Cyproterone acetate administration is associated with liver tumors in beagles and is not approved by the U.S. Food and Drug Administration (FDA) for use in the United States.

**Flutamide**

Flutamide, a pure nonsteroidal antiandrogen, is approved for treatment of advanced prostate cancer. Its mechanism of action is inhibition of nuclear binding of androgens in target tissues. Although it has a weaker affinity to the androgen receptor than spironolactone or cyproterone acetate, larger doses (250 mg given two or three times
Flutamide is a weak inhibitor of testosterone biosynthesis. In a single, 3-month study of flutamide alone, most patients demonstrated significant improvement in hirsutism with no change in androgen levels (121). Significant improvement in hirsutism with a significant drop in androstenedione, DHT, LH, and FSH levels was observed in an 8-month follow-up of flutamide and low-dose OCs in women who did not respond to OCs alone (122). The side effects of flutamide treatment combined with a low-dose OC included dry skin, hot flashes, increased appetite, headaches, fatigue, nausea, dizziness, decreased libido, liver toxicity, and breast tenderness (123).

In hyperinsulinemic hyperandrogenemic nonobese PCOS adolescents on a combination of metformin (850 mg per day) and flutamide (62.5 mg per day), the low-dose OC containing drospirenone resulted in a more effective and more efficient reduction in total and abdominal fat excess than was demonstrated by those utilizing an OC with gestodene as the progestin (124). The combination of ethinyl-drospirenone, metformin, and flutamide is effective in reducing excess total and abdominal fat and attenuating dysadipocytokinemia in young women with hyperinsulinemic PCOS. The use of the antiandrogen flutamide appeared to emphasize effects (125). Many patients taking flutamide (50% to 75%) report dry skin, blue-green discoloration of urine, and liver enzyme elevation. Liver toxicity or failure and death are rare but severe side effects of flutamide appear to be dose related (126). The 2008 Endocrine Society clinical practice guidelines do not recommend using flutamide as first-line therapy for treating hirsutism. If it is used, the lowest effective dose should be given, and the patient’s liver function should be monitored closely (4). Flutamide should not be used in women desiring pregnancy.

**Finasteride**

Finasteride is a specific inhibitor of type 2 5α-reductase enzyme activity, approved in the United States at a 5-mg dose for the treatment of benign prostatic hyperplasia, and at a 1-mg dose to treat male-pattern baldness. In a study in which finasteride (5 mg daily) was compared with spironolactone (100 mg daily), both drugs resulted in similar significant improvement in hirsutism, despite differing effects on androgen levels (127). Most of the improvement in hirsutism with finasteride occurred after 6 months of therapy with 7.5 mg of finasteride daily (128). The improvement in hirsutism in the presence of rising testosterone levels is convincing evidence that it is the binding of DHT, and not testosterone, to the androgen receptor that is responsible for hair growth. Finasteride does not prevent ovulation or cause menstrual irregularity. The increase in SHBG caused by OCs further decreases free testosterone levels; OCs in combination with finasteride are more effective in reducing hirsutism than finasteride alone. As with spironolactone and flutamide, finasteride could theoretically feminize a male fetus; therefore, both of these agents are used only with additional contraception.
Ovarian Wedge Resection

Bilateral ovarian wedge resection is associated with only a transient reduction in androstenedione levels and a prolonged minimal decrease in plasma testosterone (129,130). In patients with hirsutism and PCOS who had wedge resection, hair growth was reduced by approximately 16% (17,131). Although Stein and Leventhal’s original report cited a pregnancy rate of 85% following wedge resection and maintenance of ovulatory cycles, subsequent reports show lower pregnancy rates and a concerning incidence of periovarian adhesions (17,132). Instances of premature ovarian failure and infertility were reported (133).

Laparoscopic Electrocautery

Laparoscopic ovarian electrocautery is used as an alternative to wedge resection in patients with severe PCOS whose condition is resistant to clomiphene citrate. In a recent series, ovarian drilling was achieved laparoscopically with an insulated electrocautery needle, using 100-W cutting current to assist entry and 40-W coagulating current to treat each microcyst over 2 seconds (8-mm needle in ovary) (134). In each ovary, 10 to 15 punctures were created. This led to spontaneous ovulation in 73% of patients, with 72% conceiving within 2 years. Of those who underwent a follow-up laparoscopy, 11 of 15 were adhesion free. To reduce adhesion formation, a technique that cauterized the ovary in only four points led to a similar pregnancy rate, with a miscarriage rate of 14% (135). Other laparoscopic techniques using laser instead of electrocautery for laparoscopic ovarian drilling were described (136). Most series report a decrease in both androgen and LH concentrations and an increase in FSH concentrations (137,138). The beneficial endocrinological effects of laparoscopic ovarian drilling and the improvement in hirsutism were sustained for up to 9 years in patients with PCOS (139). Unilateral diathermy results in bilateral ovarian activity (140). Further studies are anticipated to define candidates who may benefit most from such a procedure. The risk of adhesion formation should be discussed with the patient.

Physical Methods of Hair Removal

Depilatory creams remove hair only temporarily. They break down and dissolve hair by hydrolyzing disulfide bonds. Although depilatories can have a dramatic effect, many women cannot tolerate these irritative chemicals. The topical use of corticosteroid cream may prevent contact dermatitis. Efornithine hydrochloride cream, also known as difluoromethylornithine (DMFO), irreversibly blocks ornithine decarboxylase (ODC), the enzyme in hair follicles that is important in regulating hair growth. It is effective in the treatment of unwanted facial hair (141). Noticeable results take about 6 to 8 weeks of therapy. Treatment must be continued while inhibition of hair growth is desired, and when the cream is discontinued, hair returns to pretreatment levels after about 8 weeks (4).

Shaving is effective and, contrary to common belief, it does not change the
quality, quantity, or texture of hair. Plucking, if done unevenly and repeatedly, may cause inflammation and damage to hair follicles and render them less amenable to electrolysis. Waxing is a grouped method of plucking in which hairs are plucked out from under the skin surface. The results of waxing last longer (up to 6 weeks) than shaving or depilatory creams (142).

Bleaching removes the hair pigment through the use of hydrogen peroxide (usually 6% strength), which is sometimes combined with ammonia. Although hair lightens and softens during oxidation, this method is frequently associated with hair discoloration or skin irritation and is not always effective (141).

Electrolysis and laser hair removal are the only permanent means recommended for hair removal. Under magnification, a trained technician destroys each hair follicle individually. When a needle is inserted into a hair follicle, galvanic current, electrocautery, or both used in combination (blend) destroy the hair follicle. After the needle is removed, a forceps is used to remove the hair. Hair regrowth ranges from 15% to 50%. Problems with electrolysis include pain, scarring, and pigmentation. Cost can be an obstacle (143). Laser hair removal destroys the hair follicle through photoablation. These methods are most effective after medical therapy arrests further growth.

Insulin Sensitizers

Because hyperinsulinemia appears to play a role in PCOS-associated anovulation, treatment with insulin sensitizers may shift the endocrine balance toward ovulation and pregnancy, either alone or in combination with other treatment modalities.

Metformin (Glucophage) is an oral biguanide antihyperglycemic drug used extensively for non–insulin-dependent diabetes. Metformin is pregnancy category B drug with no known human teratogenic effect. It lowers blood glucose mainly by inhibiting hepatic glucose production and by enhancing peripheral glucose uptake. Metformin enhances insulin sensitivity at the postreceptor level and stimulates insulin-mediated glucose disposal (144).

Metformin has been used extensively to treat oligo-ovulatory infertility, insulin resistance, and hyperandrogenism in PCOS patients. Metformin is used to treat PCOS oligo-ovulatory infertility either alone or in combination with dietary restriction, clomiphene, or gonadotropins. In randomized control studies, metformin improves the odds of ovulation in women with PCOS when compared with placebo (145,146). A large multicenter, randomized control trial in women with PCOS concluded that clomiphene is superior to metformin in achieving live births in infertile women with PCOS. When ovulation was used as the outcome, the combination of metformin and clomiphene was superior to either clomiphene alone or metformin alone (147). Multiple births are a complication of clomiphene therapy.
The most common side effects are gastrointestinal, including nausea, vomiting, diarrhea, bloating, and flatulence. Because the drug caused fatal lactic acidosis in men with diabetes who have renal insufficiency, baseline renal function testing is suggested (148). The drug should not be given to women with elevated serum creatinine levels (144).

Concepts regarding the role of obesity and insulin resistance or hyperinsulinemia in PCOS suggest that the primary intervention should be recommending and assisting with weight loss (5% to 10% of body weight). In those with an elevated BMI, orlistat proved helpful in initiating and maintaining weight loss. A percentage of PCOS patients will respond to weight loss alone with spontaneous ovulation. In those who do not respond to weight loss alone or who are unable to lose weight, the sequential addition of clomiphene citrate followed by an insulin sensitizer, followed by the combination of these agents may promote ovulation without resorting to injectable gonadotropins.

A prevailing concern over the increased incidence of spontaneous abortions in women with PCOS and the potential reduction afforded by insulin sensitizers suggests that insulin sensitizers may be beneficial in combination with gonadotropin therapy for ovulation induction or in vitro fertilization (149). Women with early pregnancy loss have a low level of insulin-like growth factor (IGF) binding protein-1 (IGFBP-1), and of circulating glycodecin, which has immunomodulatory effects protecting the developing fetus. Use of metformin increased levels of both factors, which might explain early findings suggesting that metformin use may reduce the high spontaneous abortion rates seen among women with PCOS (150).

A number of observational studies suggested that metformin reduces the risk of pregnancy loss (151,152). However, there are no adequately designed and sufficiently powered randomized control trials to address this issue. In the prospective randomized pregnancy and PCOS (PPCOS) trial, there was a concerning nonsignificant trend toward a greater rate of miscarriages in the metformin only group (151). This trend was not noted in other trials.

There are no conclusive data to support a beneficial effect of metformin on pregnancy loss, and the trend toward a higher miscarriage rate in the PPCOS trial, which used extended release metformin, is of some concern (145,147).

The incidence of ovarian hyperstimulation syndrome is reduced with adjuvant metformin in PCOS patients at risk for severe ovarian hyperstimulation syndrome (153).
Cushing Syndrome

The adrenal cortex produces three classes of steroid hormones: glucocorticoids, mineralocorticoids, and sex steroids (androgen and estrogen precursors). Hyperfunction of the adrenal gland can produce clinical signs of increased activity of any or all of these hormones. Increased glucocorticoid action results in nitrogen wasting and a catabolic state. This causes muscle weakness, osteoporosis, atrophy of the skin with striae, nonhealing ulcerations and ecchymoses, reduced immune resistance that increases the risk of bacterial and fungal infections, and glucose intolerance resulting from enhanced gluconeogenesis and antagonism to insulin action.

Although most patients with Cushing syndrome gain weight, some lose it. **Obesity is typically central, with characteristic redistribution of fat over the clavicles around the neck and on the trunk, abdomen, and cheeks.** Cortisol excess may lead to insomnia, mood disturbances, depression, and even overt psychosis. With overproduction of sex steroid precursors, women may exhibit hyperandrogenism (hirsutism, acne, oligomenorrhea or amenorrhea, thinning of scalp hair). Masculinization is rare, and its presence suggests an autonomous adrenal origin, most often an adrenal malignancy. With overproduction of mineralocorticoids, patients may manifest arterial hypertension and hypokalemic alkalosis. The associated fluid retention may cause pedal edema (Table 31.7) (154).

ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone.

ACTH-dependent Cushing syndrome may be caused by pituitary adenoma, basophil hyperplasia, nodular adrenal hyperplasia, or cyclic Cushing syndrome.

Characteristic clinical laboratory findings associated with hypercortisolism are confined mainly to a complete blood count showing evidence of granulocytosis and reduced levels of lymphocytes and eosinophils. Increased urinary calcium secretion may be present.

**Causes**

The six recognized noniatrogenic causes of Cushing syndrome can be divided between those that are ACTH dependent and those that are ACTH independent.
The ACTH-dependent causes can result from ACTH secreted by pituitary adenomas or from an ectopic source. The hallmark of ACTH-dependent forms of Cushing syndrome is the presence of normal or high plasma ACTH concentrations with increased cortisol levels. The adrenal glands are hyperplastic bilaterally. Pituitary ACTH-secreting adenoma, or Cushing disease, is the most common cause of endogenous Cushing syndrome (154). These pituitary adenomas are usually microadenomas (<10 mm in diameter) that may be as small as 1 mm. They behave as though they are resistant, to a variable degree, to the feedback effect of cortisol. Like the normal gland, these tumors secrete ACTH in a pulsatile fashion; unlike the normal gland, the diurnal pattern of cortisol secretion is lost. **Ectopic ACTH syndrome most often is caused by malignant tumors** (155). About one-half of these tumors are small-cell carcinomas of the lung (156). Other tumors include bronchial and thymic carcinomas, carcinoid tumors of the pancreas, and medullary carcinoma of the thyroid.

Ectopic corticotropin-releasing hormone (CRH) tumors are rare and include such tumors as bronchial carcinoids, medullary thyroid carcinoma, and metastatic prostatic carcinoma (156). The presence of an ectopic CRH-secreting tumor should be suspected in patients whose dynamic testing suggests pituitary ACTH-dependent disease but who have rapid disease progression and very high plasma ACTH levels.

**Figure 31.7 Algorithm for testing patients suspected of having Cushing syndrome (CS).** Diagnostic criteria that suggest Cushing syndrome are a urinary-free cortisol (UFC) greater than the normal range for the assay, serum cortisol greater than 1.8 μg/dL (50 nmol/L) after 1 mg dexamethasone (1 mg DST), and a late night salivary cortisol greater than 145 ng/dL (4 nmol/L). (Based on recommendations from Nieman LK, Biller BM, Findling JW, et al. The diagnosis of Cushing's syndrome: an Endocrine Society Clinical Practice Guideline. J Clin Endocrinol Metab 2008;93:1526–1540.)

The most common cause of ACTH-independent Cushing syndrome is exogenous or iatrogenic (i.e., superphysiologic therapy with corticosteroids) or factitious (self-induced). Corticosteroids are used in pharmacologic quantities to treat a variety of diseases with an inflammatory component. Over time, such therapy will result in Cushing syndrome. When corticosteroids are taken by the patient but not prescribed by a
physician, the diagnosis may be especially challenging. The diagnostic workup for Cushing syndrome focuses on the ability to suppress autonomous cortisol secretion and whether ACTH is elevated or suppressed. According to the 2008 Endocrine Society’s clinical practice guidelines for the diagnosis of Cushing syndrome, the initial use of one test with high diagnostic accuracy (24-hour urine free cortisol, late night salivary cortisol, 1 mg overnight or 2 mg 48-hour dexamethasone suppression test) is recommended. The 24-hour urine-free cortisol (UFC) should be used to diagnose Cushing syndrome in pregnant women and in patients with epilepsy, whereas the 1-mg overnight dexamethasone suppression test, rather than UFC, should be used for initial testing for Cushing syndrome in patients with severe renal failure and adrenal incidentaloma. The 2-mg 48-hour dexamethasone suppression test is the optimal test in conditions that are associated with overactivation of the hypothalamic–pituitary–adrenal (HPA) axis: depression, morbid obesity, alcoholism, and diabetes mellitus.

Patients with an abnormal result should see an endocrinologist and undergo a second test, either one of the above or, in some cases, a serum midnight cortisol or dexamethasone CRH test. These guidelines are summarized in (Fig. 31.7) (154).

Treatment of ACTH-independent Forms of Cushing Syndrome

Excluding cases that are of iatrogenic or factitious etiology, ACTH-independent forms of Cushing syndrome are adrenal in origin. Adrenal cancers are usually very large by the time Cushing syndrome is manifest. This is because the tumors are relatively inefficient synthesizers of steroid hormones. Tumors are larger than 6 cm in diameter and are easily detectable by computed tomography (CT) scanning or magnetic resonance imaging (MRI). Adrenal cancers often produce steroids other than cortisol. Thus, when Cushing syndrome is accompanied by hirsutism or virilization in women or feminization in men, adrenal cancer should be suspected.

An adrenal tumor that appears large and irregular on radiologic imaging is suggestive of carcinoma. In these cases, a unilateral adrenalectomy through an abdominal exploratory approach is preferable. In most malignant tumors, complete resection is virtually impossible. However, a partial response to postoperative chemotherapy or radiation may be achieved. Most patients with malignancy die within 1 year. When administered immediately after surgery, mitotane (O,P-DDD, an adrenocorticolytic drug) may be of benefit in preventing or delaying recurrent disease (157). Manifestations of Cushing syndrome in these patients are controlled by adrenal enzyme inhibitors.

Adrenal adenomas are smaller than carcinomas and average 3 cm in diameter. These tumors are usually unilateral and infrequently associated with other steroid-mediated syndromes. Micronodular adrenal disease is a disorder of children, adolescents, and young adults. The adrenal glands contain numerous small (>3 mm) nodules, which often are pigmented and secrete sufficient cortisol to suppress pituitary ACTH. This condition can be sporadic or familial.

Surgical removal of a neoplasm is the treatment of choice (158,159). If a unilateral, well-
circumscribed adenoma is identified by MRI or CT scanning, the flank approach may be the most convenient. The cure rate following surgical removal of adrenal adenomas approaches 100%. Because normal function of the HPA axis is suppressed by autonomous cortisol production, cortisol replacement follows surgery and is titrated downward over several months, during which recovery of normal adrenal function is monitored.

Treatment of Cushing Disease
The main goals of treatment in ACTH-dependent Cushing syndrome are reversal of clinical features, normalization of biochemical changes with minimal morbidity, and long-term control without recurrence (155).

The treatment of choice for Cushing disease is transsphenoidal resection. The remission rate is approximately 70% to 90% and the recurrence rate is 5% to 10% at 5 years and 10% to 20% at 10 years in patients with microadenomas who undergo surgery by an experienced surgeon (160–164). Patients with macroadenoma have lower remission rates (<60%) and higher recurrence rates (12% to 45%) (165–167). Following surgery, transient diabetes insipidus and enduring compromise of anterior pituitary secretion of growth hormone, gonadotropins, and TSH are common (167,168).

Radiation Therapy
Fractionated external beam radiotherapy or stereotactic radiosurgery is used to treat patients with Cushing disease in whom transsphenoidal microsurgery was not successful or in patients who are poor surgical candidates. This therapy can achieve control of hypercortisolemia in approximately 50% to 60% of patients within 3 to 5 years (155,169,170). Hypopituitarism is the most common side effect of pituitary irradiation, and long-term follow-up is essential to detect relapse, which can occur after an initial response to radiotherapy.

High-voltage external pituitary radiation (4,200 to 4,500 cGy) is given at a rate not exceeding 200 cGy per day. Only 15% to 25% of adults show total improvement, but approximately 80% of children respond (168,171).

Medical Therapy
Mitotane can be used to induce medical adrenalectomy during or after pituitary radiation (157). The role of medical therapy is to prepare the severely ill patient for surgery and to maintain normal cortisol levels while a patient awaits the full effect of radiation. Occasionally, medical therapy is used for patients who respond to therapy with only partial remission. Adrenal enzyme inhibitors include aminoglutethimide, metyrapone, trilostane, and etomidate.

A combination of aminoglutethimide and metyrapone may cause a total adrenal enzyme block, requiring corticosteroid-replacement therapy. Ketoconazole, an FDA-approved antifungal agent, inhibits adrenal steroid biosynthesis at the side arm cleavage and 11β-hydroxylation steps. The dose of ketoconazole for adrenal suppression is 600 to 800 mg
per day for 3 months to 1 year (172). Ketoconazole is effective for long-term control of hypercortisolism of either pituitary or adrenal origin.

Nelson syndrome results from adenomatous progression of ACTH-secreting cells in patients with Cushing syndrome treated by bilateral adrenalectomy. The macroadenoma that causes this syndrome produces sellar pressure symptoms of headaches, visual field disturbances, and ophthalmoplegia. Extremely high ACTH levels in Nelson syndrome are associated with severe hyperpigmentation (melanocyte-stimulating hormone activity). The treatment is surgical removal or radiation. The offending adenomatous tissue is often resistant to complete surgical removal (173). This syndrome reportedly complicates 10% to 50% of bilateral adrenalectomy cases. Measuring pituitary MRI and ACTH plasma levels at regular intervals after bilateral adrenalectomy will allow detection of the early progression of corticotroph tumors and the possibility of cure by surgery, particularly with microadenomas (155). Nelson syndrome is less common today because bilateral adrenalectomy is less frequently used as initial treatment.
Congenital Adrenal Hyperplasia

**CAH is transmitted as an autosomal recessive disorder.** Several adrenocortical enzymes necessary for cortisol biosynthesis may be affected. Failure to synthesize the fully functional enzyme has the following effects:

- A relative decrease in cortisol production.
- A compensatory increase in ACTH levels.
- Hyperplasia of the zona reticularis of the adrenal cortex.
- An accumulation of the precursors of the affected enzyme in the bloodstream.

**21-Hydroxylase Deficiency**

Deficiency of 21-hydroxylase is responsible for over 90% of all cases of adrenal hyperplasia due to adrenal synthetic enzyme deficiency. The disorder produces a spectrum of conditions; CAH, with or without salt wasting, and milder forms that are expressed as hyperandrogenism of pubertal onset (adult onset adrenal hyperplasia, AOAH). Salt-wasting CAH, the most severe form, affects 75% of patients with congenital manifestations during the first 2 weeks of life and results in a life-threatening hypovolemic salt-wasting crisis, accompanied by hyponatremia, hyperkalemia, and acidosis. The salt-wasting form results from a severity of enzyme deficiency sufficient to result in ineffective aldosterone synthesis. With or without salt-wasting and newborn adrenal crisis, the condition is usually diagnosed earlier in affected female newborns than in males as genital virilization (e.g., clitoromegaly, labioscrotal fusion, and abnormal urethral course) is apparent at birth.

In simple virilizing CAH, affected patients are diagnosed as virilized newborn females or as rapidly growing masculinized boys at 3 to 7 years of age. Diagnosis is based on basal levels of the substrate for 21-hydroxylase, 17-OHP; in cases of congenital adrenal hyperplasia caused by 21-hydroxylase deficiency and in milder forms of the disorder with manifestations later in life (acquired, late onset, or adult-onset adrenal hyperplasia), diagnosis depends on basal and ACTH-stimulated levels of 17-OHP.

Patients with morning follicular phase 17-OHP levels of less than 300 ng/dL (10 nmol/L) are likely unaffected. When levels are greater than 300 ng/dL, but less than 10,000 ng/dL (300 nmol/L), ACTH testing should be performed to distinguish between 21-hydroxylase deficiency and other enzyme defects or to make the diagnosis in borderline cases. Levels greater than 10,000 ng/dL (300 nmol/L) are virtually diagnostic of congenital adrenal hyperplasia.

**Nonclassic Adult Onset Congenital Adrenal Hyperplasia**

The nonclassic type of 21-hydroxylase deficiency represents partial deficiency in 21-hydroxylation, which produces a late-onset, milder hyperandrogenemia. Its occurrence depends on some degree of functional deficit resulting from mutations affecting both alleles for the 21-hydroxylase enzyme. Heterozygote carriers for mutations
in the 21-hydroxylase enzyme will demonstrate normal basal and modestly elevated stimulated levels of 17-OHP, but no abnormalities in circulating androgens. Some women with mild gene defects in both alleles demonstrate modest elevations in circulating 17-OHP concentrations, but no clinical symptoms or signs.

The hyperandrogenic symptoms of AOAH are mild and typically present at or after puberty. The three phenotypic varieties are (174):

Those with ovulatory abnormalities and features consistent with PCOS (39%)
Those with hirsutism alone without oligomenorrhea (39%)
Those with elevated circulating androgens but without symptoms (cryptic) (22%).

Precocious puberty reveals late-onset congenital adrenal hyperplasia in 5% to 20% of cases that mainly are caused by nonclassic 21-hydroxylase deficiency.

Measurement of 17-OHP should be performed in patients presenting with precocious puberty, and a subsequent ACTH stimulation test is recommended if basal 17-OHP is greater than 200 ng/dL.

The need for screening patients with hirsutism for adult-onset adrenal hyperplasia depends on the patient population. The frequency of some form of the disorder varies by ethnicity and is estimated at 0.1% of the general population, 1% to 2% of Hispanics and Yugoslavs, and 3% to 4% of Ashkenazi Jews (175).

Genetics of 21-Hydroxylase Deficiency

The 21-hydroxylase gene is located on the short arm of chromosome 6, in the midst of the HLA region.
The 21-hydroxylase gene is now termed CYP21. Its homologue is the pseudogene CYP21P (176).
Because CYP21P is a pseudogene, the lack of transcription renders it nonfunctional. The CYP21 is the active gene.
The CYP21 gene and the CYP21P pseudogene alternate with two genes called C4B and C4A, both of which encode for the fourth component (C4) of serum complement (176).
The close linkage between the 21-hydroxylase genes and HLA alleles allowed the study of 21-hydroxylase inheritance patterns in families through blood HLA typing (e.g., linkage of HLA-B14 was found in Ashkenazi Jews, Hispanics, and Italians) (177).

Prenatal Diagnosis and Treatment

Women with congenital and adult-onset forms of the disorder are at a significant risk for having affected infants, owing to the high frequency of 21-hydroxylase mutations in the general population. This presents an important rationale for screening hyperandrogenic women for this disorder when they anticipate childbearing. In families at risk for CAH and in instances where one partner expresses the congenital or adult onset form of the disease, first-trimester
Prenatal screening using chorionic villus sampling is advocated (176). The fetal DNA is used for specific amplification of the CYP21 gene using polymerase chain reaction (PCR) amplification (178). When the fetus is at risk for CAH, maternal dexamethasone treatment can suppress the fetal HPA axis and prevent genital virilization in affected females (179). The dose is 20 μg/kg in three divided doses administered as soon as pregnancy is recognized and no later than 9 weeks of gestation. This is done prior to performing chorionic villus sampling or amniocentesis in the second trimester. Dexamethasone crosses the placenta and suppresses ACTH in the fetus. If the fetus is determined to be an unaffected female or a male, treatment is discontinued. If the fetus is an affected female, dexamethasone therapy is continued.

The practice of prenatal dexamethasone treatment for women whose fetuses are at risk for CAH is controversial; seven of eight pregnancies will be treated with dexamethasone unnecessarily, albeit briefly, to prevent one case of ambiguous genitalia. The efficacy and safety of prenatal dexamethasone treatment is not established, and long-term follow-up data on the offspring of treated pregnancies are lacking (180).

Numerous studies in experimental animal models showed that prenatal dexamethasone exposure could impair somatic growth, brain development, and blood pressure regulation. A human study of 40 fetuses at risk for CAH who were treated prenatally with dexamethasone to prevent virilization of affected females reported long-term effects on neuropsychological functions and scholastic performance (179,181).

The 2010 Endocrine Society guidelines conclude that prenatal dexamethasone therapy should be pursued only through institutional review boards' approved protocols at centers capable of collecting sufficient outcome data (182).

11β-Hydroxylase Deficiency

In a small percentage of patients with CAH, hypertension, rather than mineralocorticoid deficiency, develops. The hypertension responds to corticosteroid replacement (183–186). Many of these patients have a deficiency in 11β-hydroxylase (184,185). In most populations, 11β-hydroxylase deficiency accounts for 5% to 8% of the cases of CAH, or 1 in 100,000 births (187). A much higher incidence, 1 in 5,000 to 7,000, was described in Moroccan Jewish immigrants (186).

Two 11β-hydroxylase isoenzymes are responsible for cortisol and aldosterone synthesis, respectively, CYP11-B1 and CYP11-B2. They are encoded by two genes on the middle of the long arm of chromosome 8 (187–189).

Inability to synthesize a fully functional 11β-hydroxylase enzyme causes a decrease in cortisol production, a compensatory increase in ACTH secretion, and increased production of androstenedione, 11-deoxycortisol, 11-deoxycorticosterone, and DHEA. The diagnosis of 11β-hydroxylase-deficient late-onset adrenal hyperplasia is determined when 11-deoxycortisol levels are higher than 25 ng/mL 60 minutes after ACTH(1–24) stimulation (190).
Patients with 11β-hydroxylase deficiency may present with either a classic pattern of the disorder or symptoms of a mild deficiency. The severe classic form is found in about two-thirds of the patients with mild-to-moderate hypertension during the first years of life. In about one-third of the patients it is associated with left ventricular hypertrophy, with or without retinopathy, and occasionally death is reported from cerebrovascular accident (183). Signs of androgen excess are common in the severe form and are similar to those seen in the 21-hydroxylase deficiency.

In the mild, nonclassic form, children have virilization or precocious puberty but not hypertension. Adult women will seek treatment for postpubertal onset of hirsutism, acne, and amenorrhea.

3β-Hydroxysteroid Dehydrogenase Deficiency

Deficiency of 3β-hydroxysteroid dehydrogenase occurs with varying frequency in hirsute patients (191,192). The enzyme is found in both the adrenal glands and ovaries (unlike 21- and 11-hydroxylase) and is responsible for transforming Δ-5 steroids into the corresponding Δ-4 compounds, a step integral to the synthesis of glucocorticoids, mineralocorticoids, and testosterone and estradiol. In severe forms, cortisol and mineralocorticoids are deficient. The clinical spectrum of 3β-hydroxysteroid dehydrogenase deficiency ranges from the classic salt wasting, hypogonadism, and ambiguous genitalia in males and females, to nonclassic hyperandrogenic symptoms in children and young women (193). In mild forms, elevated ACTH levels overcome these critical deficiencies, and the diagnosis of this disorder relies on the relationship of Δ-5 and Δ-4 steroids. A marked elevation of DHEA and DHEAS in the presence of normal, or mildly elevated, testosterone or androstenedione can suggest the initiation of a screening protocol for 3β-hydroxysteroid dehydrogenase deficiency using exogenous ACTH stimulation (191). Following intravenous administration of a 0.25-mg ACTH(1-24) bolus, within 60 minutes 17-hydroxypregnenolone levels rise significantly in women with 3β-hydroxysteroid dehydrogenase deficiency, compared with normal women (2,276 ng/dL compared with normal of 1,050 ng/dL). The mean poststimulation ratio between 17-hydroxypregnenolone and 17-OHP is markedly elevated (mean ratio of 11 compared with 3.4 in normal controls and 0.4 in 21-hydroxylase deficiency). The rarity of this disorder indicates that routine screening of hyperandrogenic patients is not justified (191,192).

Treatment of Adult-Onset Congenital Adrenal Hyperplasia

Many patients with congenital AOAH do not need treatment. Glucocorticoid treatment should be avoided in asymptomatic patients with AOAH because the potential adverse effects of glucocorticoids probably outweigh any benefits (180,182).

Glucocorticoid therapy is recommended only to reduce hyperandrogenism for those with significant symptoms. Dexamethasone and antiandrogen drugs (both cross the placenta) should be used with caution and in conjunction with oral contraceptives in adolescent
girls and young women with signs of virilization or irregular menses. When fertility is desired, ovulation induction might be necessary, and a glucocorticoid that does not cross the placenta (e.g., prednisolone or prednisone) should be used (179).

Many patients who are undiagnosed but who actually have AOAH are treated with therapies for ovarian hyperandrogenism and/or PCOS, with progestins for endometrial regulation, clomiphene or gonadotropins for ovulation induction, or progestins and antiandrogens for control of hirsutism. These therapies may be appropriate, as an alternative to glucocorticoid therapy, even when AOAH is recognized as the cause for the patient’s symptoms.
Patients with severe hirsutism, virilization, or recent and rapidly progressing signs of androgen excess require careful investigation for the presence of an androgen-secreting neoplasm. The two most common sources of androgen-secreting tumors are the adrenal glands and the ovaries. To assess the symptoms, serum and urine tests for androgens and their metabolites should be obtained along with modern abdominal imaging techniques such as CT, MRI, and ultrasound scans (194). In prepubertal girls, virilizing tumors may cause signs of heterosexual precocious puberty in addition to hirsutism, acne, and virilization. In patients suspected of harboring an adrenal or ovarian tumor because of rapidly progressing or severe hyperandrogenism, the bioavailable testosterone level (free testosterone level above 6.85 pg/mL; 23.6 pmol/L), followed by an 11-desoxycortisol (above 7 ng/mL; 20.2 nmol/L), DHEAS (>3.6 μg/mL) and a 24-hour urinary cortisol (>45 μg per day) are the most sensitive and specific for the detection of an androgen-secreting adrenocortical tumor (Table 31.3). A markedly elevated free testosterone level (2.5 times the upper normal range) is considered typical of an adrenal androgen-secreting tumor, while moderately elevated free testosterone levels are often ovarian in origin. A DHEAS level greater than 800 μg/dL is typical of an adrenal tumor. An adrenal tumor is unlikely when serum DHEAS and urinary 17-ketosteroid excretion measurements are in the normal basal range and the serum cortisol concentration is less than 3.3 μg/dL after dexamethasone administration (195). The results of other dynamic tests, especially testosterone suppression and stimulation, are unreliable (196).

A vaginal and abdominal ultrasonographic examination is the first step in the evaluation of findings suggesting ovarian neoplasm. Duplex Doppler scanning may increase the accuracy of tumor diagnosis and localization (197).

CT scanning can reveal tumors larger than 10 mm (1 cm) in the adrenal gland but may not help to distinguish among different types of solid tumors or benign incidental nodules (198). In the ovaries, CT scanning cannot help differentiate hormonally active from functional tumors (197,198).

MRI is comparable, if not superior, to CT scanning in detecting ovarian neoplasms, but is neither more sensitive than high-quality ultrasound nor more useful in clinical decision making when ultrasound identifies a likely neoplasm. Nuclear medicine imaging of the abdomen and pelvis after injection with NP-59 ((131-iodine) 6-beta-iodomethyl-19-norcholesterol), preceded by adrenal and thyroid suppression, may facilitate tumor localization. In the rare circumstances when imaging fails to provide clear evidence for a neoplastic source of excess androgens, selective venous catheterization with measurement of site-specific androgen levels to identify an occult source of for androgen excess may be utilized (199). If all four vessels are catheterized transfemorally, selective venous catheterization allows direct localization of the tumor. Samples are obtained for hormonal analysis, with positive localization defined as a 5:1 testosterone gradient compared with lower vena cava values (200). Under such circumstances specificity
approaches 80%, but this rate should be weighed against the 5% rate of significant complications, such as adrenal hemorrhage and infarction, venous thrombosis, hematoma, and radiation exposure (201).
Androgen-Producing Ovarian Neoplasms

Ovarian neoplasms are the most frequent androgen-producing tumors. Granulosa cell tumors constitute 1% to 2% of all ovarian tumors and occur mostly in adult women (in postmenopausal more frequently than in premenopausal women) (see Chapter 37). Usually associated with estrogen production, they are the most common functioning tumors in children and can lead to isosexual precocious puberty (202). Patients can present with vaginal bleeding caused by endometrial hyperplasia or endometrial cancer resulting from prolonged exposure to tumor-derived estrogen (203). Total abdominal hysterectomy and bilateral salpingo-oophorectomy are the treatments of choice. If fertility is desired, a more conservative approach involving unilateral salpingo-oophorectomy with careful staging can be performed in women with stage IA (the cancer does not extend outside the involved ovary and a concomitant uterine cancer is excluded) (203). The malignant potential of these lesions is variable. The 10-year survival rates vary from 60% to 90%, depending on the stage, tumor size, and histologic atypia (202).

Thecomas are rare and occur in older patients. In one study only 11% were androgenic, even in the presence of steroid-type cells (luteinized thecomas) (202). They are unilateral in more than 90% of the cases and rarely malignant. A unilateral oophorectomy is adequate treatment (204).

Sclerosing stromal tumors are benign neoplasms that usually occur in patients younger than 30 years (202). A few cases with estrogenic or androgenic manifestations were reported.

Sertoli-Leydig cell tumors, previously classified as androblastoma or arrhenoblastoma, account for 11% of solid ovarian tumors. They contain various proportions of Sertoli cells, Leydig cells, and fibroblasts (202). Sertoli-Leydig cell tumors are the most common virilizing tumors in women of reproductive age; however, masculinization occurs in only one-third of patients. The tumor is bilateral in 1.5%. In 80% of cases, it is diagnosed at stage IA (202). Sertoli-Leydig cell tumors are frequently low-grade malignancies, and their prognosis is related to their degree of differentiation and stage of disease (205). Treatment with unilateral salpingo-oophorectomy is justified in patients with stage IA disease who desire fertility. Total abdominal hysterectomy, bilateral salpingo-oophorectomy, and adjuvant therapy are recommended for postmenopausal women who have advanced-stage disease.

Pure Sertoli cell tumors are usually unilateral. For a premenopausal woman with stage I disease, a unilateral salpingo-oophorectomy is the treatment of choice. Malignant tumors are rapidly fatal (206).

Gynandroblastomas are benign tumors with well-differentiated ovarian and testicular elements. A unilateral oophorectomy or salpingo-oophorectomy is sufficient treatment.

Sex cord tumors with annular tubules (SCTAT) are frequently associated with Peutz-Jeghers syndrome (gastrointestinal polyposis and mucocutaneous melanin pigmentation)
Their morphologic features range between those of the granulosa cell and Sertoli cell tumors. Whereas SCTAT with Peutz-Jeghers syndrome tend to be bilateral and benign, SCTAT without Peutz-Jeghers syndrome is almost always unilateral and malignant in one-fifth of cases (202).

**Steroid Cell Tumors**

According to Young and Scully, **steroid cell tumors are composed entirely of steroid-secreting cells subclassified into stromal luteoma, Leydig cell tumors (hilar and nonhilar), and steroid cell tumors that are not otherwise specific** (202). Virilization or hirsutism is encountered with three-fourths of Leydig cell tumors, with one-half of steroid cell tumors not otherwise specific, and with 12% of stromal luteomas.

**Nonfunctioning Ovarian Tumors**

Ovarian neoplasms that do not directly secrete androgens are occasionally associated with androgen excess, resulting from excess secretion by adjacent ovarian stroma, and include serous and mucinous cystadenomas, Brenner tumors, Krukenberg tumors, benign cystic teratomas, and dysgerminomas (208). Gonadoblastomas arising in the dysgenetic gonads of patients with a Y chromosome are rarely associated with androgen and estrogen secretion (209,210).
Stromal Hyperplasia and Stromal Hyperthecosis

Stromal hyperplasia is a nonneoplastic proliferation of ovarian stromal cells. Stromal hyperthecosis is defined as the presence of luteinized stromal cells at a distance from the follicles (211). Stromal hyperplasia, which is typically seen in patients between 60 and 80 years of age, may be associated with hyperandrogenism, endometrial carcinoma, obesity, hypertension, and glucose intolerance (211,212). Hyperthecosis is seen in a mild form in older patients. In patients of reproductive age, hyperthecosis may demonstrate severe clinical manifestations of virilization, obesity, and hypertension (213). Hyperinsulinemia and glucose intolerance may occur in up to 90% of patients with hyperthecosis and may play a role in the etiology of stromal luteinization and hyperandrogenism (72). **Hypothecosis is found in many patients with HAIR-AN syndrome (hyperandrogenemia, insulin resistance, and acanthosis nigricans).**

In patients with hyperthecosis, levels of ovarian androgens, including testosterone, DHT, and androstenedione, are increased, usually in the male range. The predominant estrogen, as in PCOS, is estrone, which is derived from peripheral aromatization. The E1-to-E2 ratio is increased. Unlike in PCOS, gonadotropin levels are normal (214). Ovaries with stromal hyperthecosis have variable sonographic appearances (215).

**Wedge resection for the treatment of mild hyperthecosis was successful and resulted in resumption of ovulation and in a pregnancy (216).** In cases of more severe hyperthecosis and high total testosterone levels, the ovulatory response to wedge resection is transient (214). In a study in which bilateral oophorectomy was used to control severe virilization, hypertension and glucose intolerance sometimes disappeared (217). When a GnRH agonist was used to treat patients with severe hyperthecosis, ovarian androgen production was dramatically suppressed (218).
Virilization During Pregnancy

Luteomas of pregnancy are frequently associated with maternal and fetal masculinization. This is not a true neoplasm but rather a reversible hyperplasia, which usually regresses postpartum. A review of the literature reveals a 30% incidence of maternal virilization and a 65% incidence of virilized female newborns in the presence of a pregnancy luteoma and maternal masculinization (219–221).

Other tumors causing virilization in pregnancy include (in descending order of frequency) Krukenberg tumors, mucinous cystic tumors, Brenner tumors, serous cystadenomas, endodermal sinus tumors, and dermoid cysts (202).
Virilizing Adrenal Neoplasms

The most common virilizing adrenal neoplasms are adrenal carcinomas. Adrenocortical carcinomas are rare aggressive tumors that have a bimodal age incidence, with most cases presenting at ages 40 to 50 years (222). Virilization was reported in 20% to 30% of adults with functional adrenocortical carcinoma (223).

When these malignancies virilize, frequently they are associated with elevations in 11-deoxycortisol, cortisol, and DHEAS. These tumors are commonly large and often detectable on abdominal examination. Adrenal tumors that secrete androgens exclusively, whether benign or malignant, are extraordinarily rare (194,224). Modern imaging techniques, such as CT, ultrasonography, MRI, or venous sampling, are extremely useful for distinguishing between an ovarian and an adrenal tumor as a cause of virilization (222).
Prolactin Disorders

Prolactin was first identified as a product of the anterior pituitary in 1933 (225). It is found in nearly every vertebrate species. Its presence in humans was long inferred by the association of the syndrome of amenorrhea and galactorrhea in the presence of pituitary macroadenomas, though it was not definitively identified as a human hormone until 1971. The specific activities of human prolactin (hPRL) were defined by the separation of its activity from growth hormone and subsequently by the development of radioimmunoassays (226–228). Although the initiation and maintenance of lactation is the primary function of prolactin, many studies document roles for prolactin activity both within and beyond the reproductive system.
Prolactin Secretion

There are 199 amino acids within human prolactin, with a molecular weight (MW) of 23,000 D (Fig. 31.8). Although human growth hormone and placental lactogen have significant lactogenic activity, they have only a 16% and 13% amino acid sequence homology with prolactin, respectively. In the human genome, a single gene on chromosome 6 encodes prolactin. The prolactin gene (10 kb) has five exons and four introns, and its transcription is regulated in the pituitary by a proximal promotor region and in extrapituitary locations by a more upstream promotor (229).

**Figure 31.8 Amino acid sequence of prolactin.** Three cysteine disulfide bands are located within the molecule. (From Bondy PK. Rosenberg leukocyte esterase: metabolic control and disease, 8th ed. Philadelphia: WB Saunders, 1980, with permission.)

In the basal state three forms are released: a monomer, a dimer, and a multimeric species, called little, big, and big-big prolactin, respectively (230–232). The two larger species can be degraded to the monomeric form by reducing disulfide bonds (233). The proportions of each of these prolactin species vary with physiologic, pathologic, and hormonal stimulation (233–236). The heterogeneity of secreted forms remains an active area of research. Studies indicate that little prolactin (MW 23,000 D) constitutes more than 50% of all combined prolactin production and is most responsive to extrapituitary stimulation or suppression (233,235,236). **Clinical assays for prolactin measure the little prolactin, and in all but extremely rare circumstances, these measures are sufficient to assess diseases of abnormal pituitary production of the hormone.** Prolactin, and its relatives growth hormone and placental lactogen, do not require glycosylation for most of their primary activities, as is the case for the gonadotropins and TSH. Glycosylated forms are secreted, and glycosylation does affect the bioactivity and immunoreactivity of little prolactin (237–240). It appears that the glycosylated form is the predominant species secreted, but the most potent biologic form appears to be the 23,000-D nonglycosylated form of prolactin (239). Prolactin has over 300 known biological activities. Prolactin’s most recognized activities include those associated with
reproduction (lactation, luteal function, reproductive behavior) and homeostasis (immune responsivity, osmoregulation, and angiogenesis) (241). Despite these many activities, the only recognized disorder associated with deficiency of prolactin secretion is inability to lactate.

Table 31.9 Chemical Factors Modulating Prolactin Release and Conditions that Result in Hyperprolactinemia

**Inhibitory factors**
- Dopamine
- γ-Aminobutyric acid
- Histidyl-proline diketopiperazine
- Pyroglutamic acid
- Somatostatin

**Stimulatory factors**
- β-Endorphin
- 17β-Estradiol
- Enkephalins
- Gonadotropin-releasing hormone
- Histamine
- Serotonin
- Substance P
- Thyrotropin-releasing hormone
- Vasoactive intestinal peptide

**Physiologic conditions**
- Anesthesia
- Empty sella syndrome
- Idiopathic
- Intercourse
- Major surgery and disorders of chest wall (burns, herpes, chest percussion)
- Newborns
- Nipple stimulation
- Pregnancy
- Postpartum (nonnursing: days 1–7; nursing: with suckling)
- Sleep
- Stress
- Postpartum

**Hypothalamic conditions**
- Arachnoid cyst
Craniopharyngioma
Cystic glioma
Cysticercosis
Dermoid cyst
Epidermoid cyst
Histiocytosis
Neurotuberculosis
Pineal tumors
Pseudotumor cerebri
Sarcoidosis
Suprasellar cysts
Tuberculosis

**Pituitary conditions**
Acromegaly
Addison disease
Craniopharyngioma
Cushing syndrome
Hypothyroidism
Histiocytosis
Lymphoid hypophysitis
Metastatic tumors (especially of the lungs and breasts)
Multiple endocrine neoplasia
Nelson syndrome
Pituitary adenoma (microadenoma or macroadenoma)
Post—oral contraception
Sarcoidosis
Thyrotropin-releasing hormone administration
Trauma to stalk
Tuberculosis

**Metabolic dysfunction**
Ectopic production (hypernephroma, bronchogenic sarcoma)
Hepatic cirrhosis
Renal failure
Starvation refeeding

**Drug conditions**
α Methylldopa
Antidepressants (amoxapine, imipramine, amitriptyline)
Cimetidine
Dopamine antagonists (phenothiazines, thioxanthenes, butyrophenone, diphenylbutylpiperidine, dibenzoxazepine, dihydroindolone, procainamide, metoclopramide)
Estrogen therapy
Opiates
Reserpine
Sulpiride
Verapamil

To some degree, the physical heterogeneity of prolactin may explain the biologic heterogeneity of this hormone, and although this complicates the physiologic evaluation of prolactin’s myriad effects, it is of little import to the diagnosis and management of hyperprolactinemic states.

In contrast to other anterior pituitary hormones, which are controlled by hypothalamic-releasing factors, prolactin secretion is primarily under inhibitory control mediated by dopamine. **Multiple lines of evidence suggest that dopamine, which is secreted by the tuberoinfundibular dopaminergic neurons into the portal hypophyseal vessels, is the primary prolactin-inhibiting factor.** Dopamine receptors were found on pituitary lactotrophs, and treatment with dopamine or dopamine agonists suppresses prolactin secretion (242–248). The dopamine antagonist metoclopramide abolishes the pulsatility of prolactin release and increases serum prolactin levels (244, 245, 249).

**Interference with dopamine transit from the hypothalamus to the pituitary by mass lesions, or blockade of the dopamine receptor as occurs with antipsychotic and other medications, increases serum prolactin levels.** Thyrotropin-releasing hormone (TRH) causes prolactin release when present at supraphysiologic levels (as in primary hypothyroidism), but does not appear to play an important modulatory role in the normal physiologic regulation of prolactin secretion. γ-Aminobutyric acid (GABA) and other neurohormones and neurotransmitters may function as prolactin-inhibiting factors (250–253). Several hypothalamic polypeptides that modulate prolactin-releasing activity are listed in Table 31.9. It appears that dopamine and TRH act as primary neurohormones, while others (i.e., neuropeptide Y, galanin, and enkephalin) act as modulators. It is likely that under differing physiologic conditions (i.e., pregnancy, lactation, stress, aging) a modulator may become a principal regulator of hormone secretion.

The prolactin receptor is a member of the class 1 cytokine receptor superfamily and is encoded by a gene on chromosome 5 (254). Transcriptional regulation of the prolactin receptor is accomplished through three tissue-specific promoter regions; promoter I for the gonads, promoter II for the liver, and promoter III, a generic promoter that includes the mammary gland (255).
Hyperprolactinemia

Physiologic disturbances, pharmacologic agents, or markedly compromised renal function may cause elevations in prolactin levels, and transient elevations occur with acute stress or painful stimuli. The most common cause of elevated prolactin levels is likely pharmacologic; most patients using antipsychotic medications and many other patients using agents with antidopaminergic properties will exhibit moderately elevated prolactin levels. Drug-related and physiologic conditions resulting in hyperprolactinemia do not always require direct intervention to normalize prolactin levels.

Evaluation

Plasma levels of immunoreactive prolactin are 5 to 27 ng/mL throughout the normal menstrual cycle. Samples should not be drawn soon after the patient awakes or after procedures. Prolactin is secreted in a pulsatile fashion with a pulse frequency ranging from about 14 pulses per 24 hours in the late follicular phase to about 9 pulses per 24 hours in the late luteal phase. There also is a diurnal variation, with the lowest levels occurring in midmorning. Levels rise 1 hour after the onset of sleep and continue to rise until peak values are reached between 5 and 7 a.m. \(256,257\). The pulse amplitude of prolactin appears to increase from early to late follicular and luteal phases \(258–260\). Because of the variability of secretion and inherent limitations of radioimmunoassay, an elevated level should always be rechecked. This sample preferably is drawn midmorning and not after stress, previous venipuncture, breast stimulation, or physical examination, all of which transiently increase prolactin levels.

When prolactin levels are found to be elevated, hypothyroidism and medications should first be ruled out as a cause. Prolactin and TSH determinations are basic evaluations in infertile women. Infertile men with hypogonadism should be tested. Likewise, prolactin levels should be measured in the evaluation of amenorrhea, galactorrhea, hirsutism with amenorrhea, anovulatory bleeding, and delayed puberty (Fig. 31.9).

Physical Signs

Elevations in prolactin may cause amenorrhea, galactorrhea, both, or neither. Amenorrhea without galactorrhea is associated with hyperprolactinemia in approximately 15% of women \(261–263\). The cessation of normal ovulatory processes resulting from elevated prolactin levels is primarily caused by the suppressive effects of prolactin, via hypothalamic mediation, on GnRH pulsatile release \(243,261,262,264–272\). In addition to causing a hypogonadotrophic state, prolactin elevations may secondarily impair the mechanisms of ovulation by causing a reduction in granulosa cell number and FSH binding, inhibition of granulosa cell 17β-estradiol production by interfering with FSH action, and by causing inadequate luteinization and
reduced luteal secretion of progesterone (273–278). Other etiologies for amenorrhea are detailed in Chapter 30.

Although isolated galactorrhea is considered indicative of hyperprolactinemia, prolactin levels are within the normal range in nearly 50% of such patients (279–281) (Fig. 31.9). In these cases, whether caused by a prior transient episode of hyperprolactinemia or other unknown factors, the sensitivity of the breast to the lactotrophic stimulus engendered by normal prolactin levels is sufficient to result in galactorrhea. This situation is very similar to that observed in nursing mothers in whom milk secretion, once established, continues and even increases despite progressive normalization of prolactin levels. Repeat testing is occasionally helpful in detecting hyperprolactinemia. Approximately one-third of women with galactorrhea have normal menses. Conversely, hyperprolactinemia commonly occurs in the absence of galactorrhea (66%), which may result from inadequate estrogenic or progestational priming of the breast.

In patients with both galactorrhea and amenorrhea (including the syndromes described and named by Forbes, Henneman, Griswold, and Albright in 1951, Argonz and del Castilla in 1953, and Chiari and Frommel in 1985), approximately two-thirds will have hyperprolactinemia; in that group, approximately one-third will have a pituitary adenoma (282). In anovulatory women, 3% to 10% of women diagnosed with polycystic ovary disease have coexistent and usually modest hyperprolactinemia (283,284) (Fig. 31.10).

Figure 31.9 Workup for hyperprolactinemia. TSH, thyroid-stimulating hormone; MRI, magnetic resonance imaging; CT, computed tomography; HRT, hormone replacement therapy; OCPs, oral contraceptive pills; CNS, central nervous system.
Figure 31.10 Prolactin levels in 235 patients with galactorrhea. Among patients with a tumor, open triangles denote associated acromegaly, and solid circles and solid triangles denote previous radiotherapy or surgical resection, respectively. (From Kleinberg DL, Noel GL, Frantz AG. Galactorrhea: a study of 235 cases, including 48 with pituitary tumors. N Engl J Med 1977;296:589–600, with permission.)
Prolactin and TSH levels should be measured in all patients with delayed puberty. Pituitary abnormalities, including craniopharyngiomas and adenomas, should be considered in all cases of delayed puberty accompanied by low levels of gonadotropins, regardless of whether prolactin levels are elevated. When prolactin-secreting pituitary adenomas are present, the condition of multiple endocrine neoplasia type 1 (MEN-1) syndrome (gastrinomas, insulinoma, parathyroid hyperplasia, and pituitary neoplasia) should be considered, although symptoms of pituitary adenoma are rarely the presenting symptom. Patients who have a pituitary adenoma and a family history of multiple adenomas warrant special attention (285). Prolactinomas are noted in approximately 20% of patients with MEN-1. The MEN-1 gene is localized to chromosome 11q13 and appears to act as a constitutive tumor suppressor gene. An inactivating mutation results in development of the tumor. It is thought that prolactin-secreting pituitary adenomas that occur in patients with MEN-1 may be more aggressive than sporadic cases (286).

When an elevated prolactin level is documented and medications or hypothyroidism as the underlying cause is excluded, knowledge of neuroanatomy and imaging techniques and their interpretation is essential to further evaluation (see Chapter 7). Pituitary hyperprolactinemia is most often caused by a microadenoma or associated
with normal imaging findings. These patients can be reassured that the probable course of their condition is benign. Macroadenomas or juxtasellar lesions are less common and require more complex evaluation and treatment, including surgery, radiation, or both. Levels of TSH should be measured in all patients with hyperprolactinemia (Fig. 31.9).

### Imaging Techniques

In patients with larger microadenomas and macroadenomas, prolactin levels usually are higher than 100 ng/mL. However, levels lower than 100 ng/mL may be associated with smaller microadenomas, macroadenomas that produce a “stalk section” effect, and suprasellar tumors that may be missed on a “coned-down” view of the sella turcica. Modest elevations of prolactin can be associated with microadenomas or macroadenomas, nonlactotroph pituitary tumors, and other central nervous system abnormalities; thus, imaging of the pituitary gland must be considered when otherwise unexplained and persistent prolactin elevation is present. In patients with a clearly identifiable drug-induced or physiologic hyperprolactinemia, imaging is not necessary unless accompanied by symptoms suggesting a mass lesion (headache, visual field deficits). MRI with gadolinium enhancement of the sella and pituitary gland appears to provide the best anatomic detail. The cumulative radiation dose from multiple CT scans may cause cataracts, and the “coned-down” views or tomograms of the sella are very insensitive and expose the patient to radiation. For patients with hyperprolactinemia who desire future fertility, MRI is indicated to differentiate a pituitary microadenoma from a macroadenoma and to identify other potential sellar-suprasellar masses. Although rare, when pregnancy-related complications of a pituitary adenoma occur, they occur more frequently in the presence of macroadenomas.

In over 90% of untreated women, microadenomas do not enlarge over a 4- to 6-year period. The argument that medical therapy will prevent a microadenoma from growing is false. Although prolactin levels correlate with tumor size, both elevations and reductions in prolactin levels may occur without any change in tumor size. If during follow-up a prolactin level rises significantly or central nervous system symptoms (headache, visual changes) are noted, repeat imaging may be indicated. Treatment is discussed below.

### Hypothalamic Disorders

Dopamine was the first of many substances whose production was demonstrated in the arcuate nucleus. Dopamine-releasing neurons innervate the external zone of the median eminence. When released into the hypophyseal portal system, dopamine inhibits prolactin release in the anterior pituitary. Lesions that disrupt dopamine release can result in hyperprolactinemia. Such lesions may arise from the suprasellar area, pituitary gland, and infundibular stalk, and from adjacent bone, brain, cranial nerves, dura, leptomeninges, nasopharynx, and vessels. Numerous pathologic entities and physiologic conditions in the
hypothalamic–pituitary region can disrupt dopamine release and cause hyperprolactinemia.

Pituitary Disorders

Microadenoma

In over one-third of women with hyperprolactinemia, a radiologic abnormality consistent with a microadenoma (<1 cm) is found. Release of pituitary stem cell growth inhibition via activation or loss-of-function mutations results in cell cycle dysregulation and is critical to the development of pituitary microadenomas and macroadenomas. Microadenomas are monoclonal in origin. Genetic mutations are thought to release stem cell growth inhibitors and result in autonomous anterior pituitary hormone production, secretion, and cell proliferation. Additional anatomic factors that may contribute to adenoma formation include reduced dopamine concentrations in the hypophyseal portal system and vascular isolation of the tumor or both. Recently, the heparin-binding secretory-transforming (HST) gene was noted in a variety of cancers and in prolactinomas (288). Patients with microadenomas can be reassured of a probable benign course, and many of these lesions exhibit gradual spontaneous regression (289,290).

Both microadenomas and macroadenomas are monoclonal in origin. Pituitary prolactinomas and lactotrope adenomas are sparsely or densely granulated histologically. The sparsely granulated lactotrope adenomas have trabecular, papillary, or solid patterns. Calcification of these tumors may take the form of a psammoma body or a pituitary stone. Densely granulated lactotrope adenomas are strongly acidophilic tumors and appear to be more aggressive than sparsely granulated lactotrope adenomas. Unusual acidophil stem cell adenomas can be associated with hyperprolactinemia, with some clinical or biochemical evidence of growth hormone excess.

Microadenomas rarely progress to macroadenomas. Six large series of patients with microadenomas reveal that, with no treatment, the risk of progression for microadenoma to a macroadenoma is only 7% (291). Treatments include expectant, medical, or, rarely, surgical therapy. All affected women should be advised to notify their physicians of chronic headaches, visual disturbances (particularly tunnel vision consistent with bitemporal hemianopsia), and extraocular muscle palsies. Formal visual field testing is rarely helpful, unless imaging suggests compression of the optic nerves.

Autopsy and radiographic series reveal that 14.4% to 22.5% of the US population harbor microadenomas, and approximately 25% to 40% stain positively for prolactin (292). Clinically significant pituitary tumors requiring some type of intervention affect only 14 per 100,000 individuals (292)

Expectant Management
In women who do not desire fertility, expectant management can be used for both microadenomas and hyperprolactinemia without an adenoma while menstrual function remains intact. Hyperprolactinemia-induced estrogen deficiency, rather than prolactin itself, is the major factor in the development of osteopenia (293). Therefore, estrogen replacement with typical hormone replacement regimens or hormonal contraceptives is indicated for patients with amenorrhea or irregular menses. Patients with drug-induced hyperprolactinemia can be managed expectantly with attention to the risks of osteoporosis. In the absence of symptoms of pituitary enlargement, imaging may be repeated in 12 months, and if prolactin levels remain stable, less frequently thereafter, to assess further growth of the microadenoma.

Medical Treatment

Ergot alkaloids are the mainstay of therapy. In 1985, bromocriptine was approved for use in the United States to treat hyperprolactinemia caused by a pituitary adenoma. These agents act as strong dopamine agonists, thus decreasing prolactin levels. Effects on prolactin levels occur within hours, and lesion size may decrease within 1 or 2 weeks. Bromocriptine decreases prolactin synthesis, DNA synthesis, cell multiplication, and overall size of prolactinomas. Bromocriptine treatment results in normal prolactin blood levels or return of ovulatory menses in 80% to 90% of patients.

Because ergot alkaloids, like bromocriptine, are excreted via the biliary tree, caution is required when using it in the presence of liver disease. The major adverse effects include nausea, headaches, hypotension, dizziness, fatigue and drowsiness, vomiting, headaches, nasal congestion, and constipation. Many patients tolerate bromocriptine when the dose is increased gradually, by 1.25 mg (one-half tablet) daily each week until prolactin levels are normal or a dose of 2.5 mg twice daily is reached. A proposed regimen is as follows: one-half tablet every evening (1.25 mg) for 1 week, one-half tablet morning and evening (1.25 mg) during the second week, one-half tablet in the morning (1.25 mg) and a full tablet every evening (2.5 mg) during the third week, and one tablet every morning and every evening during the fourth week and thereafter (2.5 mg twice a day). The lowest dose that maintains the prolactin level in the normal range is continued (1.25 mg twice daily often is sufficient to normalize prolactin levels in individuals with levels less than 100 ng/mL). Pharmacokinetic studies show peak serum levels occur 3 hours after an oral dose, with a nadir at 7 hours. Because little detectable bromocriptine is in the serum by 11 to 14 hours, twice-a-day administration is required. Prolactin levels can be checked soon (6 to 24 hours) after the last dose.

One rare, but notable, adverse effect of bromocriptine is a psychotic reaction. Symptoms include auditory hallucinations, delusional ideas, and changes in mood that quickly resolve after discontinuation of the drug (294).

Many investigators report no difference in fibrosis, calcification, prolactin immunoreactivity, or the surgical success in patients pretreated with bromocriptine...
compared to those not receiving bromocriptine (291).

An alternative to oral administration is the vaginal administration of bromocriptine tablets, which is well tolerated, and actually results in increased pharmacokinetic measures (295). Cabergoline, another ergot alkaloid, has a very long half-life and can be given orally twice per week. Its long duration of action is attributable to slow elimination by pituitary tumor tissue, high affinity binding to pituitary dopamine receptors, and extensive enterohepatic recirculation.

Cabergoline, which appears to be as effective as bromocriptine in lowering prolactin levels and in reducing tumor size, has substantially fewer adverse effects than bromocriptine. Very rarely, patients experience nausea and vomiting or dizziness with cabergoline; they may be treated with intravaginal cabergoline as with bromocriptine. A gradually increasing dosage helps avoid the side effects of nausea, vomiting, and dizziness. Cabergoline at 0.25 mg twice per week is usually adequate for hyperprolactinemia with values less than 100 ng/mL. If required to normalize prolactin levels, the dosage can be increased by 0.25 mg per dose on a weekly basis to a maximum of 1 mg twice weekly.

Recent studies reveal an increased risk of cardiac valve regurgitation in patients with Parkinson disease who were treated with high doses of cabergoline or pergolide but not with bromocriptine (296,297). Higher doses and a longer duration of therapy were associated with a higher risk of valvulopathy. It is postulated that 5HT2b-receptor stimulation leads to fibromyoblast proliferation (298). A recent cross-sectional study showed a higher rate of asymptomatic tricuspid regurgitation among cabergoline-treated patients compared to untreated patients with newly diagnosed prolactinomas as well as normal controls (299,300).

The demonstrated relative safety of bromocriptine in reproductive-aged women and during more than 2,500 pregnancies suggest bromocriptine is the first choice for hyperprolactinemia and micro- and macroadenomas (301).

When bromocriptine or cabergoline cannot be used, other medications such as pergolide or metergoline may be used. In patients with a microadenoma who are receiving bromocriptine therapy, a repeat MRI scan may be performed 6 to 12 months after prolactin levels are normal, if indicated. Further MRI scans should be performed if new symptoms appear.

Discontinuation of bromocriptine therapy after 2 to 3 years may be attempted in a select group of patients who have maintained normoprolactinemia while on therapy (302,303). In a retrospective series of 131 patients treated with bromocriptine for a median of 47 months, normoprolactinemia was sustained in 21% at a median follow-up of 44 months after treatment discontinuation (303). Discontinuation of cabergoline therapy was successful in patients treated for 3 to 4 years who maintained normoprolactinemia (304). In cabergoline discontinuers who met stringent inclusion criteria, a recurrence rate of 64% was noted (305). A recent meta-analysis involving 743 patients noted sustained normoprolactinemia in only a minority of patients (21%) after discontinuation. Patients
with 2 years or more of therapy before discontinuation and no demonstrable tumor visible on MRI had the highest chance of persistent normoprolactinemia (306). Recurrence rates are higher for macroadenomas (as compared to microadenomas or hyperprolactinemia without adenoma) after cessation of bromocriptine or cabergoline, warranting close follow-up with serum prolactin and MRI after cessation of therapy. In patients with macroadenomas, withdrawal of therapy should proceed with caution, as rapid tumor reexpansion may occur.

**Macroadenomas**

Macroadenomas are pituitary tumors that are larger than 1 cm in size. Bromocriptine is the best initial and potentially long-term treatment option, but transsphenoidal surgery may be required. High-dose cabergoline therapy was used in bromocriptine resistant or intolerant macroadenoma patients with success; however, cautions remain regarding the development of cardiac valve abnormalities (307).

Evaluation for pituitary hormone deficiencies may be indicated. Symptoms of macroadenoma enlargement include severe headaches, visual field changes, and, rarely, diabetes insipidus and blindness. After prolactin has reached normal levels following ergot alkaloid treatment, a repeat MRI is indicated within 6 months to document shrinkage or stabilization of the size of the macroadenoma. This examination may be performed earlier if new symptoms develop or if there is no improvement in previously noted symptoms.

**Medical Treatment**

Treatment with bromocriptine decreases prolactin levels and the size of macroadenomas; nearly one-half show a 50% reduction in size, and another one-fourth show a 33% reduction after 6 months of therapy. Because tumor regrowth occurs in more than 60% of cases after discontinuation of bromocriptine therapy, long-term therapy is usually required.

After stabilization of tumor size is documented, the MRI scan is repeated 6 months later and, if stable, yearly for several years. This examination may be performed earlier if new symptoms develop or if there is no improvement in symptoms. Serum prolactin levels are measured every 6 months. Because tumors may enlarge despite normalized prolactin values, a reevaluation of symptoms at regular intervals (6 months) is prudent. Normalized prolactin levels or resumption of menses should not be taken as absolute proof of tumor response to treatment (306,308).

**Surgical Intervention**

Tumors that are unresponsive to bromocriptine or that cause persistent visual field loss require surgical intervention. Some neurosurgeons have noted that a short (2- to 6-week) preoperative course of bromocriptine increases the efficacy of surgery in patients with larger adenomas (291). Unfortunately, despite surgical resection,
recurrence of hyperprolactinemia and tumor growth is common. Complications of surgery include cerebral carotid artery injury, diabetes insipidus, meningitis, nasal septal perforation, partial or panhypopituitarism, spinal fluid rhinorrhea, and third nerve palsy. Periodic MRI scanning after surgery is indicated, particularly in patients with recurrent hyperprolactinemia.

**Metabolic Dysfunction and Hyperprolactinemia**

Occasionally, patients with hypothyroidism exhibit hyperprolactinemia with remarkable pituitary enlargement caused by thyrotroph hyperplasia. These patients respond to thyroid replacement therapy with reduction in pituitary enlargement and normalization of prolactin levels \(^{(309)}\).

Hyperprolactinemia occurs in 20% to 75% of women with chronic renal failure. Prolactin levels are not normalized through hemodialysis but are normalized after transplantation \((310–312)\). Occasionally, women with hyperandrogenemia also have hyperprolactinemia. Elevated prolactin levels may alter adrenal function by enhancing the release of adrenal androgens such as DHEAS \((313)\).

**Drug-Induced Hyperprolactinemia**

Numerous drugs interfere with dopamine secretion and can be responsible for hyperprolactinemia and its attendant symptoms \((314)\). If medication can be discontinued, resolution of hyperprolactinemia is uniformly prompt. If not, endocrine management should be directed at estrogen replacement and normalization of menses for those with disturbed or absent ovulation. Treatment with dopamine agonists may be utilized if ovulation is desired and the drug-inducing hyperprolactinemia cannot be discontinued.

**Use of Estrogen in Hyperprolactinemia**

In rodents, pituitary prolactin-secreting adenomas occur with high-dose estrogen administration \((314)\). Elevated levels of estrogen, as found in pregnancy, are responsible for hypertrophy and hyperplasia of lactotrophic cells and account for the progressive increase in prolactin levels in normal pregnancy. The increase in prolactin during pregnancy is physiologic and reversible; adenomas are not fostered by the hyperestrogemia of pregnancy. Pregnancy may have a favorable influence on preexisting prolactinomas \((315,316)\). Estrogen administration is not associated with clinical, biochemical, or radiologic evidence of growth of pituitary microadenomas or the progression of idiopathic hyperprolactinemia to an adenoma status \((317–320)\). For these reasons, estrogen replacement or OC use is appropriate for hypoestrogenic patients with hyperprolactinemia secondary to microadenoma or hyperplasia.

**Monitoring Pituitary Adenomas During Pregnancy**

Prolactin-secreting microadenomas rarely create complications during pregnancy.
Monitoring of patients with serial gross visual field examinations and funduscopic examination is recommended. If persistent headaches, visual field deficits, or visual or funduscopic changes occur, MRI scanning is advisable. Because serum prolactin levels progressively rise throughout pregnancy, prolactin measurements are rarely of value.

For those women who become pregnant while taking bromocriptine to treat a return of spontaneous ovulations, discontinuation of bromocriptine is recommended. This does not preclude subsequent use of bromocriptine during the pregnancy to treat symptoms (visual field defects, headaches) that arise from further enlargement of the microadenoma (301,321–323). Bromocriptine did not exhibit teratogenicity in animals, and observational data do not suggest harm to pregnancy or fetus in humans.

Pregnant women with previous transsphenoidal surgery for microadenomas or macroadenomas may be monitored with monthly Goldman perimetry visual field testing. Periodic MRI scanning may be necessary in women with symptoms or visual changes. Breastfeeding is not contraindicated in the presence of microadenomas or macroadenomas (301,321–323). The use of bromocriptine and presumably other dopaminergic agents that may cause blood pressure elevation during the postpartum period is contraindicated (324–328).
Thyroid Disorders

Thyroid disorders are 10 times more common in women than men. Approximately 1% of the female population of the United States will develop overt hypothyroidism (329). Even prior to the discovery of the long-acting thyroid stimulator (LATS) in women with Graves disease in 1956, numerous investigations demonstrated a link between these autoimmune thyroid disorders and reproductive physiology and pathology (330).
Thyroid Hormones

Iodide is a critical component of the class of hormones known as thyronines, among which the most important are triiodothyronine (T₃) and thyroxine (T₄). Iodide obtained from dietary sources is actively transported into the thyroid follicular cell for the synthesis of these hormones. The sodium–iodide symporter (NIS) is a key molecule in thyroid function. It allows the accumulation of iodide from the circulation into the thyrocyte against an electrochemical gradient. The NIS requires energy that is supplied by Na-K ATPase, and iodine uptake is stimulated by TSH or thyrotropin. The enzyme thyroid peroxidase (TPO) then oxidizes iodide near the cell-colloid surface and incorporates it into tyrosyl residues within the thyroglobulin molecule, which results in the formation of monoiodotyrosine (MIT) and diiodotyrosine (DIT). T₃ and T₄, formed by secondary coupling of MIT and DIT, are catalyzed by TPO. The membrane-bound, heme-containing oligomer, TPO, is localized in the rough endoplasmic reticulum, Golgi vesicles, lateral and apical vesicles, and on the follicular cell surface. Thyroglobulin, the major protein formed in the thyroid gland, has an iodine content of 0.1% to 1.1% by weight. About 33% of the iodine is present in thyroglobulin in the form of T₃ and T₄, and the remainder is present in MIT and DIT or found as unbound iodine. Thyroglobulin provides a storage capacity capable of maintaining a euthyroid state for nearly 2 months without the formation of new thyroid hormones. The thyroid antimicrosomal antibodies found in patients with autoimmune thyroid disease are directed against the TPO enzyme (331,332).

TSH regulates thyroidal iodine metabolism by activation of adenylate cyclase. This facilitates endocytosis as a component of iodide uptake, digestion of thyroglobulin-containing colloid, and the release of thyroid hormones T₄, T₃, and reverse T₃. T₄ is released from the thyroid at 40 to 100 times the concentration of T₃. The concentration of reverse T₃, which has no intrinsic thyroid activity, is 30% to 50% of T₃, and 1% of T₄ concentration. Of thyroid hormones released, 70% are bound by circulating thyroid-binding globulin (TBG). T₄ is present in higher concentrations in the circulating storage pool and has a slower turnover rate than T₃. Approximately 30% of T₄ is converted to T₃ in the periphery. Reverse T₃ participates in regulation of the conversion of T₄ to T₃. T₃ is the primary physiologically functional thyroid hormone at the cellular level. T₃ binds the nuclear receptor with 10 times the affinity of T₄. Thyroid hormone effects on cells include increased oxygen consumption, heat production, and metabolism of fats, proteins, and carbohydrates. Systemically, thyroid hormone activity is responsible for the basal metabolic rate. It balances fuel efficiency with performance. Hyperthyroid states result in excessive fuel consumption with marginal performance.

Iodide Metabolism

Normal function of the thyroid gland is dependent on iodine. The World Health Organization recommends 150 µg of iodine per day in women of reproductive age and 250 µg per day is recommended during pregnancy and nursing.
Adequate iodination of household salt is defined as salt containing 15 to 40 mg of iodine per kilogram of salt (333).

Optimal iodine intake to prevent disease lies within a relatively narrow range around the recommended daily consumption. Extreme iodine deficiency states are associated with cretinism, goiter, and hypothyroidism, while iodine sufficiency is associated with autoimmune thyroid disease and reduced remission rates in Graves disease (334).

Risk Factors for Autoimmune Thyroid Disorders

Environmental factors associated with the occurrence of autoimmune thyroid diseases include pollutants (plasticizers, polychlorinated biphenyls) and exposure to infections such as yersinia enterocolitica, coxsackie B, Helicobacter pylori, and hepatitis C (335,336). For reasons not entirely known, women experience a 5- to 10-fold increased incidence of autoimmune thyroid disease (337). This difference is postulated to be the result of differences in sex steroid hormone levels, differences in environmental exposures, innate differences in female and male immune systems, and inherent chromosomal differences in the sexes (338,339). The immunoglobulins produced against the thyroid are polyclonal, and the multiple combinations of various antibodies consolidate to create the clinical spectrum of autoimmune thyroid diseases that may affect health and reproductive function.
Evaluation

Thyroid Function
Measurements of free serum T₄ and T₃ are complicated by the low levels of free hormone in systemic circulation, with only 0.02% to 0.03% of T₄ and 0.2% to 0.3% of T₃ circulating in the unbound state (340). Of the T₄ and T₃ in circulation, approximately 70% to 75% is bound to TBG, 10% to 15% attached to prealbumin, 10% to 15% bound to albumin, and a minor fraction (<5%) is bound to lipoprotein (340,341). Total thyroid measurements are dependent on levels of TBG, which are variable and affected by many conditions such as pregnancy, oral contraceptive pill use, estrogen therapy, hepatitis, and genetic abnormalities of TBG. Thus, assays for the measurement of free T₄ and T₃ are more clinically relevant than measuring total thyroid hormone levels.

There are many different laboratory techniques to measure estimated free serum T₄ and T₃. These methods invariably measure a portion of free hormone that is dissociated from the in vivo protein bound moiety. This is of little clinical significance assuming the same proportions are measured for all assays and considered in the calibration of the assay (342). The T₃ resin uptake test is an example of one laboratory method used to estimate free T₄ in the serum. The T₃ resin uptake (T₃ RU) determines the fractional binding of radiolabeled T₃, which is added to a serum sample in the presence of a resin that competes with TBG for T₃ binding. The binding capacity of TBG in the sample is inversely proportional to the amount of labeled T₃ bound to the artificial resin. Therefore, a low T₃ resin uptake indicates high TBG T₃ receptor site availability and implies high circulating TBG levels.

The free T₄ index (FTI) is obtained by multiplying the serum T₄ concentration by the T₃ resin uptake percentage, yielding an indirect estimate of the levels of free T₄:

\[ \text{T₃ RU\%} \times \text{T₄ total} = \text{free T₄ index}. \]

A high T₃ RU percentage indicates reduced TBG receptor site availability and high free T₄ index and thus hyperthyroidism, whereas a low T₃ resin uptake percentage is a result of increased TBG receptor site binding and thus hypothyroidism. Equilibrium dialysis and ultrafiltration techniques may be used to determine the free T₄ directly. Free T₄ and T₃ may also be determined by radioimmunoassay. Most available laboratory methods used for determining estimations of free T₄ are able to correct for moderate variations in serum TBG but are prone to error in the setting of large variations of serum TBG, when endogenous T₄ antibodies are present, and in the setting of inherent albumin abnormalities (340).

### Table 31.12 Nomenclature of Anti-TSH Receptor Antibodies
Because most disorders of hyperthyroidism and hypothyroidism are related to dysfunction of the thyroid gland and TSH levels are sensitive to excessive or deficient levels of circulating thyroid hormone, TSH levels are used to screen for these disorders. Current thyrotropin or TSH sandwich immunoassays are extremely sensitive and capable of differentiating low-normal from pathologic or iatrogenically subnormal values and elevations. TSH measurements provide the best way to screen for thyroid dysfunction and accurately predict thyroid hormone dysfunction in about 80% of cases (343). Reference values for TSH are traditionally based on the central 95% of values for healthy individuals, and some controversy exists regarding the upper limit of normal. Values in the upper limit of normal may predict future thyroid disease (342,344). In a longitudinal study, women with positive thyroid antibodies (TPOAbs or TgAbs), the prevalence of hypothyroidism at follow-up was 12.0% (3.0% to 21.0%; 95% CI) when baseline TSH was 2.5 mU/L or less, 55.2% (37.1%–73.3%) for TSH between 2.5 and 4.0 mU/L, and 85.7% (74.1%–97.3%) for TSH above 4.0 mU/L (345). Physicians ordering thyrotropin values should be aware of their limitations in the setting of acute illness, central hypothyroidism, the presence of heterophile antibodies, and TSH autoantibodies. In the setting of heterophile antibodies or TSH autoantibodies, TSH values will be falsely elevated (342). In cases of central hypothyroidism, decreased sialylation of TSH results in a longer half-life and a reduction in bioactivity (346,347). TSH levels may be elevated or normal when the patient remains clinically hypothyroid in states of central hypothyroidism, and successful treatment is often associated with low or undetectable TSH levels.

Immunologic Abnormalities
Many antigen–antibody reactions affecting the thyroid gland can be detected. Antibodies to TgAb, the TSH receptor (TSHRAb), TPOAb, the sodium iodine symporter (NISAb), and
to thyroid hormone were identified and implicated in autoimmune thyroid disease states (348). A number of recognized thyroid autoantigens are listed in Table 31.10. Antibody production to thyroglobulin depends on a breach in normal immune surveillance (349,350). The incidence of thyroid autoantibodies in various autoimmune thyroid disorders is shown in Table 31.11.

Antithyroglobulin antibodies are predominantly in the noncomplement fixing, polyclonal, immunoglobulin-G (IgG) class. Antithyroglobulin antibodies are found in 35% to 60% of patients with hypothyroid autoimmune thyroiditis, 12% to 30% of patients with Graves disease, and 3% of the general population (351–353). Antithyroglobulin antibodies are associated with acute thyroiditis, nontoxic goiter, and thyroid cancer (348).

Previously referred to as antimicrosomal antibodies, TPO antibodies are directed against thyroid peroxidase and are found in Hashimoto thyroiditis, Graves disease, and postpartum thyroiditis. The antibodies produced are characteristically cytotoxic, complement-fixing IgG antibodies. In patients with thyroid autoantibodies, 99% will have positive anti-TPO antibodies, whereas only 36% will have positive antithyroglobulin antibodies, making anti-TPO a more sensitive test for autoimmune thyroid disease (353). Anti-TPO antibodies are present in 80% to 99% of patients with hypothyroid autoimmune thyroiditis, 45% to 80% of patients with Graves disease, and 10% to 15% of the general population (352–354). These antibodies can cause artifact in the measurement of thyroid hormone levels. Antithyroid peroxidase antibodies are used clinically in the diagnosis of Graves disease, the diagnosis of chronic autoimmune thyroiditis, in conjunction with TSH testing as a means to predict future hypothyroidism in subclinical hypothyroidism, and to assist in the diagnosis of autoimmune thyroiditis in euthyroid patients with goiter or nodules (348).

Another group of antibodies important in autoimmune thyroid disease bind the TSH receptor (TSHR). The TSHR belongs to the family of G-protein coupled receptors. TSHRαb are pathogenic and capable of activating (TSI) or blocking (TBI) TSH receptor functions. TBIαs are detectable in two varieties: those that block TSH binding and those that block both pre- and postreceptor processes. Several investigators detected such blocking antibodies in patients with primary hypothyroidism and atrophic thyroid glands (355,356). The nomenclature and detection assay of TSH receptor antibodies are listed in Table 31.12. Anti-TSH receptor antibodies were reported in 6% to 60% of patients with hypothyroid autoimmune thyroiditis, 70% to 100% of patients with Graves disease, and 1% to 2% of the general population (357–361). Untreated Graves disease patients tested with third-generation immunometric assays are uniformly positive (362). TSHRαb are classified as binding inhibitory immunoglobulins by competitive binding assays (TBII); and in functional assays: stimulating (TSI)—according to their capacity to increase cyclic adenosine monophosphate (cAMP) production; blocking (TBI)—which possesses the capacity to reduce TSH effects; and, neutral (TNI)—with no effect on TSH binding or alteration of cAMP levels. A number of competitive and functional assays are available to determine the levels of each antibody type, which, in toto, correlate with severity of disease, extraglandular signs, risk of fetal effects, and chances for remission and
recurrence. TSHRAb are used clinically to distinguish postpartum thyroiditis from Graves disease, to predict the risk of fetal and neonatal thyrotoxicosis in women with prior ablative treatment or current thionamide therapy in the setting of Graves disease, and in the diagnosis of euthyroid Graves ophthalmopathy (348). These assays will increasingly optimize individual patient testing and treatment (363).

Antibodies to the NIS are prevalent in a number of thyroid conditions. Anti-NISAbs were detected in 24% of patients with Hashimoto disease and 22% of patients with Graves disease (364). Anti-NISAbs are used experimentally (348).
Autoimmune Thyroid Disease

The most common thyroid abnormalities in women, autoimmune thyroid disorders, represent the combined effects of the multiple thyroid autoantibodies (365). The various antigen–antibody reactions result in the wide clinical spectrum of these disorders. Transplacental transmission of some of these immunoglobulins may affect thyroid function in the fetus. The presence of autoimmune thyroid disorders, particularly Graves disease, is associated with other autoimmune conditions: Hashimoto thyroiditis, Addison disease, ovarian failure, rheumatoid arthritis, Sjögren syndrome, diabetes mellitus (type 1), vitiligo, pernicious anemia, myasthenia gravis, and idiopathic thrombocytopenic purpura. Other factors that are associated with the development of autoimmune thyroid disorders include low birth weight, iodine excess and deficiency, selenium deficiency, parity, oral contraceptive pill use, reproductive age span, fetal microchimerism, stress, seasonal variation, allergy, smoking, radiation damage to the thyroid, and viral and bacterial infections (366).

Recommendations for Testing and Treatment

Overt and subclinical hypothyroidism are defined as an elevated TSH with a low T\textsubscript{4} and an elevated TSH and normal T\textsubscript{4}, respectively, using appropriate patient ranges (nonpregnant and pregnant). A number of professional organizations published various recommendations for thyroid function assessment via a TSH in women. Because of the long interval from development of disease to diagnosis, the nonspecific nature of symptoms, and the potential adverse neonatal and maternal outcomes associated with untreated hypothyroidism in pregnancy, the American Association of Clinical Endocrinologists (AACE) recommended screening women prior to conceiving or at the first prenatal appointment (367,368). The AACE also recommended screening for the presence of hypothyroidism in patients with type 1 diabetes mellitus (threefold increased risk of postpartum thyroid dysfunction and 33% prevalence overall), patients taking lithium therapy (35% prevalence), and consideration of testing in patients presenting with infertility (>12% prevalence) or depression (10% to 12% prevalence), as these populations are at an increased risk of hypothyroidism (368). A screening TSH was recommended in women starting at the age of 50 because of the increased prevalence of hypothyroidism in this population (369). Thyroid function testing at 6-month intervals was recommended for patients taking amiodarone, as hyperthyroidism or hypothyroidism occurs in 14% to 18% of these patients (368). Any woman with a history of postpartum thyroiditis should be offered annual surveillance of thyroid function, as 50% of these patients will develop hypothyroidism within 7 years of diagnosis (370). Because there is a high prevalence of hypothyroidism in women with Turner and Down syndromes, an annual check of thyroid function is recommended for these patients (371,372).

Alternatively, the Endocrine Society’s clinical practice guidelines regarding the management of thyroid dysfunction during pregnancy and postpartum recommends
targeted screening for the following individuals: history of thyroid disorder, family history of thyroid disease, goiter, thyroid autoantibodies, clinical signs or symptoms of thyroid disease, autoimmune disorders, infertility, head and/or neck radiation, and preterm delivery (373). The American Congress of Obstetricians and Gynecologists accepted these recommendations for TSH testing (374). Because of the (i) potentially significant neurologic affects on the fetus and other adverse pregnancy events; (ii) physiologic rise in TBG and the TSH-like activity of hCG in pregnancy, and (iii) potential for the targeted screening groups to have overt or subclinical hypothyroidism defined by the reference ranges for pregnancy (TSH <2.5, 3.1, and 3.5 μIU/mL for the first, second, and third trimesters, respectively), targeted maternal testing for hypothyroidism is encouraged. The targeted screening protocol allows that 30% of subclinical hypothyroidism cases may be missed. According to these recommendations, preconceptionally diagnosed hypothyroid women (overt or subclinical) should have their T₄ dosage adjusted such that the TSH value is less than 2.5 μIU/mL before pregnancy. The T₄ dosage in women already on replacement will routinely require a dose escalation (30% to 50%) at 4 to 6 weeks gestation in order to maintain a TSH value less than 2.5 μIU/mL. Pregnant women with overt hypothyroidism should be normalized as rapidly as possible to maintain TSH at less than 2.5 and 3 μIU/mL in the first, second, and third trimesters, respectively. Euthyroid women with thyroid autoantibodies are at risk of hypothyroidism and should have TSH screening in each trimester. After delivery, hypothyroid women need a reduction in T₄ dosage used during pregnancy. Because subclinical hypothyroidism is associated with adverse outcomes for mother and the fetus, T₄ replacement is recommended.

Hashimoto Thyroiditis

Hashimoto thyroiditis, or chronic lymphocytic thyroiditis, was first described in 1912 by Dr. Hakaru Hashimoto. Hashimoto thyroiditis can manifest as hyperthyroidism, hypothyroidism, euthyroid goiter, or diffuse goiter. High levels of antimicrosomal and antithyroglobulin antibody are usually present, and TSHRAb may be present (353,375,376). Typically, glandular hypertrophy is found, but atrophic forms are also present. Three classic types of autoimmune injury are found in Hashimoto thyroiditis: (i) complement-mediated cytotoxicity, (ii) antibody-dependent cell-mediated cytotoxicity, and (iii) stimulation or blockade of hormone receptors, which results in hypo- or hyperfunction or growth (Fig. 31.11).

Figure 31.11 Types of autoimmune injury found in Hashimoto thyroiditis. A: Complement-mediated cytotoxicity, which can be abolished by inactivating the complement system. B: Antibody-dependent cell-mediated cytotoxicity (ADCC) function through killer T cells, monocytes, and natural killer cells that have immunoglobulin G fragment receptors. C: Stimulation of blockade of hormone receptors leading to hyperfunction or hypofunction or growth, depending on the types of immunoglobulins acting on the target cell. TBII, TSH-binding inhibitor immunoglobulin; TGI, thyroid growth–promoting immunoglobulin; TSAb, thyroid-stimulating antibodies; TSH, thyroid-stimulating hormone. (From Coulam CB, Faulk WP, McIntyre JA. Immunologic obstetrics. New York: Norton Medical Books, 1992:658, with permission.)
The histologic picture of Hashimoto thyroiditis includes cellular hyperplasia, disruption of follicular cells, and infiltration of the gland by lymphocytes, monocytes, and plasma cells. Occasionally, adjacent lymphadenopathy may be noted. Some epithelial cells are enlarged and demonstrate oxyphilic changes in the cytoplasm (Askanazy cells or Hürthle cells, which are not specific to this disorder). The interstitial cells show fibrosis and lymphocytic infiltration. Graves disease and Hashimoto thyroiditis may cause very similar histologic findings manifested by a similar mechanism of injury.

**Clinical Characteristics and Diagnosis of Hashimoto Thyroiditis**

Patients with Hashimoto thyroiditis may present with typical symptoms of hypothyroidism or may be relatively asymptomatic. Patients often present with a goiter, which can involve the parietal lobe. At later stages of the disease, hypothyroidism can be found without a goiter. Notable clinical manifestations associated with Hashimoto thyroiditis include fatigue, weight gain, hyperlipidemia, dry hair, dry skin, cold intolerance, depression, menstrual irregularities, bradycardia, and or memory impairment. Hashitoxicosis, the hyperthyroid manifestation of Hashimoto thyroiditis, may occur after a hypothyroid state and development into a euthyroid or hyperthyroid state and is thought to be the result of development of TSH-stimulating antibodies (TSI) associated with Graves disease (368). This variant is estimated to occur in 4% to 8% of patients with Hashimoto thyroiditis. In the setting of Hashitoxicosis, the patient requires frequent follow-up and the potential for adjustments in thyroid supplementation. These patients often become hypothyroid during the course of treatment.

**Table 31.13 Potential Causes of Hypothyroidism**

**Primary**
- Congenital absence of thyroid gland
- External thyroid gland radiation
Familial disorders and thyroxine synthesis
Hashimoto thyroiditis
Iodine-131 ablation for Graves disease
Ingestion of antithyroid drugs
Iodine deficiency
Idiopathic myxedema (autoimmune)
Surgical removal of thyroid gland

Secondary
Hypothalamic thyrotropin-releasing hormone deficiency
Pituitary or hypothalamic tumors or disease

In many cases, an elevated serum TSH is detected during routine screening. Elevated serum anti-TPO antibodies confirm the diagnosis, and free T4 and T3 document overt or subclinical hypothyroidism. The sedimentation rate may be elevated, depending on the course of the disease at the time of recognition. Other causes of hypothyroidism should be considered, as listed in Table 31.13. Progression from subclinical to clinically overt hypothyroidism is reported to vary from 3% to 20%, with a higher risk noted in patients with goiter or thyroid antibodies (329,377). Treatment of subclinical hypothyroidism is somewhat controversial, but clinical studies suggested treatment of subclinical hypothyroidism is associated with a reduction in neurobehavioral abnormalities, a reduction in cardiovascular risk factors, and an improvement in lipid profile (378,379).

Treatment
Thyroxine replacement is initiated in patients with clinically overt hypothyroidism or subclinical hypothyroidism with a goiter. Regression of gland size usually does not occur, but treatment often prevents further growth of the thyroid gland. Treatment is recommended for patients with subclinical hypothyroidism in the setting of a TSH greater than 10 mIU/L on repeat measurements, pregnant patients, a strong habit of tobacco use, signs or symptoms associated with thyroid failure, or patients with severe hyperlipidemia (380). All pregnant patients with an elevated TSH level should be treated with levothyroxine. Treatment does not slow progression of the disease. The initial dosage of levothyroxine may be as little as 12.5 μg per day up to a full replacement dose. The mean replacement dosage of levothyroxine is 1.6 μg/kg of body weight per day, although the dosage varies greatly between patients (368). Aluminum hydroxide (antacids), cholestyramine, iron, calcium, and sucralfate may interfere with absorption. Rifampin and sertraline hydrochloride may accelerate the metabolism of levothyroxine. The half-life of levothyroxine is nearly 7 days; therefore, nearly 6 weeks of treatment are necessary before the effects of a dosage change can be evaluated.

Hypothyroidism appears to be associated with decreased fertility resulting from disruption in ovulation, and thyroid autoimmune disease is associated
with an increased risk of pregnancy loss with or without overt thyroid dysfunction (381). A meta-analysis of case-control and longitudinal studies performed since 1990 reveals a possible association between miscarriage and thyroid antibodies with an odds ratio of 2.73 (95% CI, 2.20–3.40). This association may be explained by a heightened autoimmune state affecting the fetal allograft or a slightly higher age of women with antibodies compared with those without antibodies (0.7 ± 1 year, p < .001) (382). Studies suggest that early subclinical hypothyroidism may be associated with menorrhagia (383).

Severe primary hypothyroidism is associated with menstrual irregularities in 23% of women, with oligomenorrhea being the most common (382). Reproductive dysfunction in hypothyroidism may be caused by a decrease in the binding activity of sex hormone–binding globulin, resulting in increased estradiol and free testosterone and from hyperprolactinemia (382). The increase in prolactin levels is the result of enhanced sensitivity of the prolactin-secreting cells to TRH (with elevated TRH seen in primary hypothyroidism) and defective dopamine turnover resulting in hyperprolactinemia (384–387). Hyperprolactinemia-induced luteal phase defects are associated with less severe forms of hypothyroidism (388, 389). Replacement therapy appears to reverse the hyperprolactinemia and correct ovulatory defects (390, 391).

Combined thyroxine and triiodothyronine therapy is no more effective than thyroxine therapy alone, and patients with hypothyroidism should be treated with thyroxine alone (392). Treatment should target normalizing TSH values, and a daily dose of 0.012 mg up to a full replacement dose of levothyroxine (1.6 μg/kg of body weight per day) may be required with dosage dependent on the patient’s weight, age, cardiac status, and duration and severity of hypothyroidism (368).

Graves Disease
Graves disease, characterized by exophthalmos, goiter, and hyperthyroidism, was first identified as an association of findings in 1835. A heritable specific defect in immunosurveillance by suppressor T lymphocytes is believed to result in the development of a helper T-cell population that reacts to multiple epitopes of the thyrotropin receptor. This activity induces a B-cell–mediated response, resulting in the clinical features of Graves disease (389). The TSHRAb bind to conformational epitopes in the extracellular domain of the thyrotropin receptor and are uniformly detected in patients with untreated Graves disease (390).

Graves disease is a complex autoimmune disorder in which several genetic susceptibility loci and environmental factors are likely to play a role in the development of the disease. Human leukocyte antigen and polymorphisms in the cytotoxic T-lymphocyte antigen 4 (CTLA-4) gene were established as susceptibility loci; however, the magnitude of their contributions seems to vary among patient populations and study groups. Additional loci are likely to be identified by a combination of genome-wide linkage analyses and allelic association analyses of candidate genes. The rate of concordance for Graves disease is
only 20% in monozygotic twins and even lower in dizygotic twins, consistent with a multifactorial inheritance pattern highly influenced by environmental factors. Linkage analysis identified loci on chromosomes 14q31, 20q11.2, and Xq21 that are associated with susceptibility to Graves disease (393).

Clinical Characteristics and Diagnosis

The classic triad in Graves disease consists of exophthalmos, goiter, and hyperthyroidism. The symptoms associated with Graves disease include frequent bowel movements, heat intolerance, irritability, nervousness, heart palpitations, impaired fertility, vision changes, sleep disturbances, tremor, weight loss, and lower extremity swelling. Physical findings may include lid lag, nontender thyroid enlargement (two to four times normal), onycholysis, dependent lower extremity edema, palmar erythema, proptosis, staring gaze, and thick skin. A cervical venous bruit and tachycardia may be noted. The tachycardia does not respond to increased vagal tone produced with a Valsalva maneuver. Severe cases may demonstrate acropachy, chemosis, clubbing, dermopathy, exophthalmos with ophthalmoplegia, follicular conjunctivitis, pretibial myxedema, and vision loss.

Approximately 40% of patients with new onset of Graves disease and many of those previously treated have elevated T₃ and normal T₄ levels. Abnormal T₄ or T₃ results are often caused by protein binding changes rather than altered thyroid function; therefore, assessment of free T₄ and free T₃ is indicated in conjunction with TSH. In Graves disease, the TSH levels are suppressed, and levels may remain undetectable for some time even after the initiation of treatment. Thyroid autoantibodies, including TSI, may be useful during pregnancy to more accurately predict fetal risk of thyrotoxicosis (368). Autonomously functioning, benign thyroid neoplasms that exhibit a similar clinical picture include toxic adenomas and toxic multinodular goiter. A radioactive iodine uptake thyroid scan may help differentiate these two conditions from Graves disease. Rare conditions resulting in thyrotoxicosis include metastatic thyroid carcinoma causing thyrotoxicosis, amiodarone induced thyrotoxicosis, iodine induced thyrotoxicosis, postpartum thyroiditis, a TSH-secreting pituitary adenoma, an hCG-secreting choriocarcinoma, struma ovarii, and “de Quervan's” or subacute thyroiditis (394). Factitious ingestion of thyroxine or desiccated thyroid should be considered in patients with eating disorders. Patients with thyrotoxicosis factitia demonstrate elevated T₃ and T₄, suppressed TSH, and a low serum thyroglobulin level, whereas other causes of thyroiditis and thyrotoxicosis demonstrate high levels of thyroglobulin. Potential causes of hyperthyroidism are listed in Table 31.14.

Treatment

Iodine-131 Ablation

Treatment of women with hyperthyroidism of an autoimmune origin presents unique challenges to the physician who must consider the patient’s needs and her reproductive plans. Because the drugs used to treat this disorder have potentially harmful effects on the fetus, special attention must be given to the use of contraception and the potential for pregnancy.

A single dose of radioactive iodine-131 is an effective cure in about 80% of cases and is the definitive treatment in nonpregnant women. Any woman of childbearing age should be tested for pregnancy before undergoing diagnostic or therapeutic administration of iodine. Ablation of a second-trimester fetal thyroid gland and congenital hypothyroidism (cretinism) from treatment during the first trimester were reported [395]. Nuclear medicine professionals provide expertise in the administration of the radioactive isotope, and because the effect of the radioactive iodine is not immediate, the endocrinologist continues to provide suppressive medical treatment for 6 to 12 weeks after administration of iodine while the patient remains hyperthyroid. As early as 2 to 3 months after treatment, patients may become hypothyroid and should be supplemented with thyroxine as indicated by serum levels of free thyroid hormone levels [368]. TSH testing is not sensitive for predicting thyroid function during this time as changes in TSH lag 2 weeks to several months behind thyroid function changes [368]. Failure to respond to iodine 6 months after treatment may require a repeat treatment with radioactive iodine [394]. Postablative hypothyroidism develops in 50% of patients within the first year after iodine therapy and in more than 2% of patients per year thereafter.

A higher rate of miscarriage was noted in women treated with iodine therapy in the year preceding therapy, but there is no reported increase in the rate of stillbirths, preterm birth, low birth weight, congenital malformation, or death after therapy [396]. Many thyroidologists and nuclear medicine specialists are willing to allow pregnancy earlier than 1 year after therapy if patients receive replacement therapy with levothyroxine.

Thyroid-Stimulating Receptor Antibody in Graves Disease
The level of TSHRAb of the TBII class grossly parallels the degree of hyperthyroidism as assessed by the serum levels of thyroid hormones and total thyroid volume. Studies suggest that the combination of a small goiter volume (<40 mL) and a low TBII level (<30 U/L) results in a 45% chance of remission during the 5 years after completion of a 12- to 24-month course of antithyroid drug therapy (397). In contrast, the overall rate of relapse exceeded 70% in patients with a large goiter volume (>70 mL) and a higher TBII level (>30 U/L). The subgroup of patients with larger goiters and higher TBII levels had less than a 10% chance to remain in remission in the 5 years after treatment. Although it is not necessary for the diagnosis of Graves disease, except in some cases of multinodular goiter, a TSHRAb measurement may be a useful marker of disease severity. Used in combination with other clinical factors, it may contribute to initial decisions regarding treatment. See Table 31.12 for a review of the nomenclature and assay methods for TSHRAb.

Measurements of TSHRAb (TBII category) during treatment with antithyroid drugs are predictive of subsequent outcome. In one series, 73% of TBII-negative patients had remission compared with only 28% of TBII-positive patients who achieved remission after 12 months of antithyroid drug therapy (398). The duration of a course of antithyroid drug therapy may potentially be modified according to the TSHRAb status. In patients whose TSHRAb status became negative and antithyroid drug therapy was discontinued, the relapse rate was 41% compared with a rate of 92% for those patients who remained TSHRAb positive (399). Regardless of the rapidity of the disappearance of TSHRAb, it does seem that antithyroid drug therapy should be maintained for 9 to 12 months to minimize the risk of relapse. TSHRAb status appears to determine, in an inverse relationship, the reduction in thyroid volume after radioactive iodine therapy.

Third-generation TSHRAb assays have been developed, and their utility in evaluation and treatment monitoring is being evaluated. Many patients with Graves disease have or will develop antineutrophil cytoplasmic antibodies (ANCA) after treatment, but the significance of this finding is still under study. Smoking appears to be an independent risk factor for relapse after medical therapy and should be considered when planning treatment.

**Antithyroid Drugs**

Antithyroid drugs of the thioamide class include propylthiouracil (PTU) and methimazole. Low doses of either agent block the secondary coupling reactions that form T\(_3\) and T\(_4\) from MIT and DIT. At higher doses, they also block iodination of tyrosyl residues in thyroglobulin. Propylthiouracil additionally blocks the peripheral conversion of T\(_4\) to T\(_3\). Approximately one-third of patients treated by this approach alone go into remission and become euthyroid (397).

In 2009, the FDA published a warning on the use of propylthiouracil because of 32 reported cases of serious liver injury associated with its use (400,401). The average daily dose associated with liver failure was 300 mg, and liver failure was reported to occur
anywhere from 6 days to 450 days after initiation of therapy (402). Traditionally PTU was the drug of choice to treat hyperthyroidism for the duration of pregnancy because it less readily crosses the placenta, and methimazole was associated with an increased risk of choanal atresia and aplasia cutis (403–406). Because of the case reports of PTU-related liver failure and the increased risk of birth defects associated with methimazole use during embryogenesis, the FDA and the Endocrine Society recommend PTU never be used as first-line medical treatment of hyperthyroidism for nonpregnant patients. It is recommended that its use be limited to pregnant women during the first trimester; situations where surgery or radioactive iodine treatment are contraindicated, and individuals who have developed a toxic reaction to methimazole (400, 402). The FDA recommends monitoring patients closely for signs and symptoms of liver injury while taking PTU. If liver injury is suspected, PTU should be promptly discontinued (400). The American Thyroid Association recommends an initial dose of 100 to 600 mg per day in three divided doses with a goal to maintain $T_4$ in the upper limit of normal using the lowest possible dose. Minor reactions such as pruritus affect 3% to 5% of patients treated with thionamide therapy, and antihistamines may eliminate symptoms and allow continued use. Agranulocytosis is a rare and potentially fatal complication of PTU and methimazole therapy, and developing in 0.2% of women treated, and it mandates immediate discontinuation of the drug (403). Agranulocytosis most commonly presents with fever and a sore throat followed by sepsis; the occurrence of fever, sore throat, or a viral-like syndrome should prompt an urgent evaluation.

Methimazole is the first-line drug for the treatment of hyperthyroidism, except in the first trimester of pregnancy, as it has been shown to be more effective than PTU at controlling severe hyperthyroidism and is associated with higher adherence rates and less toxicity (407). The American Thyroid Associated recommends initial daily doses of 10 to 40 mg per day in a single dose. Like treatment with PTU, the goal is to maintain a free $T_4$ level in the upper limits of normal using the lowest possible dose. Free $T_4$ levels show improvement 4 weeks after therapy, and TSH levels take 6 to 8 weeks to normalize (403). Methimazole use in pregnancy is associated with an 18-fold risk of fetal choanal atresia compared with the general population (95% CI, 3–121) (408). Congenital aplasia cutis was associated with maternal use of methimazole during pregnancy; however, it is not known at this time whether the risk (0.03%) is greater than that seen in the general population (409).

Studies suggest a potential role for an intrathyroid dexamethasone injection to prevent relapse (410). Other medical therapies include iodide and lithium, both of which reduce thyroid hormone release and inhibit the organification of iodine. Iodide leads to the secondary coupling of $T_3$ and $T_4$. Iodide inhibition of thyroid metabolism is only transient, and complete escape from inhibition occurs within 1 to 2 weeks of iodide therapy, making this useful only for acute management of severe thyrotoxicosis (394). Lithium may be used when thionamide therapy is contraindicated or in combination with PTU or methimazole (394). To avoid toxicity during treatment, serum lithium levels should be monitored. Lithium has been associated with fetal Ebstein anomaly, and iodide has been
associated with congenital goiter; these medications should not be used in pregnant women and should be used with caution in women of reproductive age. Because of the complications related to medical therapy of hyperthyroidism, women desiring pregnancy should be counseled to strongly consider surgical treatment or radioactive iodine treatment prior to pregnancy (402).

**Surgery**

**Thyroidectomy was used for the treatment of Graves disease but is now rarely used unless there is a suspicion for coexisting thyroid malignancy (368).** Potential candidates for surgical intervention include pregnant women refusing or not tolerating antithyroid medical therapy, pediatric patients presenting with Graves disease, or patients who refuse radioactive iodine therapy. Surgery is the most rapid and consistent method of achieving a euthyroid state in Graves disease and avoids the possible long-term risks of radioactive iodine. Surgical intervention may be considered in severe Graves ophthalmopathy. Patients should be rendered euthyroid before a thyroidectomy. The risks of surgery include postoperative hypoparathyroidism, recurrent laryngeal nerve paralysis, routine anesthetic and surgical risks, hypothyroidism, and failure to relieve thyrotoxicosis.

**β-Blockers**

Propranolol occasionally is used with or without concurrent antithyroid medications before radioactive iodine or surgery to provide relief of symptoms. Larger and more frequent doses may be required because of a relative resistance to β-adrenergic antagonists in the setting of hyperthyroidism.

**Thyroid Storm**

Thyroid storm is an acute, life-threatening exacerbation of hyperthyroidism and should be treated as a medical emergency in an intensive care unit setting. Symptoms include tachycardia, tremor, diarrhea, vomiting, fever, dehydration, and altered mental status that may proceed to coma. Patients with poorly controlled hyperthyroidism are most susceptible. Beta-blocker agents, glucocorticoids, PTU (the action of which includes inhibition of T₄-T₃ conversion), and iodides are all key elements of therapy.

**Hyperthyroidism in Gestational Trophoblastic Disease and Hyperemesis Gravidarum**

Because of the weak TSH-like activity of hCG, conditions with high levels of hCG, such as molar pregnancy, may be associated with biochemical and clinical hyperthyroidism. Symptoms regress with removal of the abnormal trophoblastic tissue and resolution of elevated levels of hCG. In a similar fashion, when hyperemesis gravidarum is associated with high levels of hCG, mild biochemical and clinical features of hyperthyroidism may be seen (411,412). Gestational trophoblastic disease is reviewed in Chapter 39.
Thyroid Function in Pregnancy

Physicians should be aware of the changes in thyroid physiology during pregnancy. Pregnancy is associated with reversible changes in thyroid physiology that should be noted before diagnosing thyroid abnormalities (see Fig. 31.12 for pregnancy associated changes in TBG, total T₄, hCG, TSH, and free T₄) (403). **Women with a history of hypothyroidism often require increased thyroxine replacement during pregnancy, and patients should have thyroid function tests performed at the first prenatal visit and during each trimester thereafter.** Evidence suggests that optimal fetal and infant neurodevelopmental outcomes may require careful titration of replacement thyroxine that meets the frequently increased requirements of pregnancy (413,414). Postpartum, women should return to their prepregnancy dosage of levothyroxine and have a follow-up TSH checked 6 to 8 weeks postpartum.

**Figure 31.12** Pregnancy-associated changes in TSH relative to hCG and free T₄ in relation to TBG. Relative serum concentration changes throughout pregnancy highlighting a fall in TSH associated with an increase in hCG early in pregnancy and a fall in free T₄ as TBG levels rise during pregnancy. hCG, human chorionic gonadotropin; TSH, thyroid-stimulating hormone; TBG, thyroid-binding globulin, total T₄, total thyroxine; free T₄, free thyroxine. (Based on data from Brent GA. Maternal thyroid function: interpretation of thyroid function tests in pregnancy. Clin Obstet Gynecol 1997;40:3–15.)

Reproductive Effects of Hyperthyroidism

High levels of TSAb (TSI) in women with Graves disease are associated with fetal-neonatal hyperthyroidism (415,416). Despite both the inhibition and elevation of gonadotropins seen in thytoxicosis, most women remain ovulatory and fertile (387,417). Severe thyrotoxicosis can result in weight loss, menstrual cycle irregularities, and amenorrhea. An increased risk of spontaneous abortion is noted in women with thyrotoxicosis. An increased incidence of congenital anomalies, particularly choanal atresia and possibly aplasia cutis, can occur in the offspring of women treated with methimazole (404,405,408).

Autoimmune hyperthyroid Graves disease may improve spontaneously, in which case
antithyroid drug therapy may be reduced or stopped. TSHRAb production may persist for several years after radical radioactive iodine therapy or surgical treatment for hyperthyroid Graves disease. In this circumstance, there is a risk of exposing a fetus to TSHRAb. Fetal–neonatal hyperthyroidism is observed in 2% to 10% of pregnancies occurring in mothers with a current or previous diagnosis of Graves disease, secondary to the transplacental passage of maternal TSHRAb. This is a serious condition with a 16% neonatal mortality rate and a risk of intrauterine fetal death, stillbirth, and skeletal developmental abnormalities, such as craniosynostosis. Caution against overtreatment with antithyroid medication is warranted, as these medications may cross the placenta in sufficient quantities to induce fetal goiter. Guidelines for TSHRAb testing during pregnancy in women with previously treated Graves disease are found in Table 31.15. Fetal goiters and the associated fetal hypo- or hyperthyroid status were diagnosed accurately in mothers with Graves disease using a combination of fetal ultrasonography of the thyroid with Doppler, fetal heart rate monitoring, bone maturation, and maternal TSHRAb and antithyroid drug status (418).

Postpartum Thyroid Dysfunction

Postpartum thyroid dysfunction is much more common than recognized; it is often difficult to diagnose because its symptoms appear 1 to 8 months postpartum and are often confused with postpartum depression and difficulties adjusting to the demands of the neonate and infant. Postpartum thyroiditis appears to be caused by the combination of a rebounding immune system in the postpartum state and the presence of thyroid autoantibodies. Histologically, lymphocytic infiltration and inflammation are found and anti-TPO antibodies are often present (419,420). The following are criteria for the diagnosis of postpartum thyroiditis: (i) no history of thyroid hormonal abnormalities either before or during pregnancy, (ii) documented abnormal TSH level (either depressed or elevated) during the first year postpartum, and (iii) absence of a positive TSH-receptor antibody titer (Graves disease) or a toxic nodule. A number of studies describe clinical and biochemical evidence of postpartum thyroid dysfunction in 5% to 10% of new mothers (421,422).

Table 31.15 Guidelines for TSHRAb Testing During Pregnancy with Previously Treated Graves Disease

1. In the woman with antecedent Graves disease in remission after ATD treatment, the risk for fetal–neonatal hyperthyroidism is negligible, and systematic measurement of TSHRAb is not necessary. Thyroid function should be evaluated during pregnancy to detect an unlikely but possible recurrence. In that case, TSHRAb assay is mandatory.
2. In the woman with antecedent Graves disease previously treated with radiiodine or thyroidectomy and regardless of the current thyroid status (euthyroidism with or without thyroxine substitution), TSHRAb should be measured early in pregnancy to evaluate the risk for fetal hyperthyroidism.
If the TSHRAb level is high, careful monitoring of the fetus is mandatory for the early detection of signs of thyroid overstimulation (tachycardia, impaired growth rate, oligohydramnios, goiter). Cardiac echography and measurement of circulatory velocity may be confirmatory. Ultrasonographic measurements of the fetal thyroid have been defined from 20 weeks gestational age but require a well-trained operator, and thyroid visibility may be hindered because of fetal head position. Color Doppler ultrasonography is helpful in evaluating thyroid hypervascularization. Because of the potential risks of fetal-neonatal hyperthyroid cardiac insufficiency and the inability to measure the degree of hyperthyroidism in the mother because of previous thyroid ablation, it may be appropriate to consider direct diagnosis in the fetus. Fetal blood sampling through cordocentesis is feasible as early as 25 to 27 weeks gestation with less than 1% adverse effects (fetal bleeding, bradycardia, infection, spontaneous abortion, in utero death) when performed by experienced clinicians. ATD administration to the mother may be considered to treat the fetal hyperthyroidism.

In the woman with concurrent hyperthyroid Graves disease, regardless of whether it has preceded the onset of pregnancy, ATD treatment should be monitored and adjusted to keep free T4 in the high-normal range to prevent fetal hypothyroidism and minimize toxicity associated with higher doses of these medications. TSHR-Ab should be measured at the beginning of the last trimester, especially if the required ATD dosage is high. If the TSHRAb assay is negative or the level low, fetal–neonatal hyperthyroidism is rare. If antibody levels are high (TBII ≥40 U/L or TSAb ≥300%), evaluation of the fetus for hyperthyroidism is required. In this condition, there is usually a fair correlation between maternal and fetal thyroid function such that monitoring the ATD dosage according to the mother’s thyroid status is appropriate for the fetus. In some cases in which a high dose of ATD >20 mg/d of methimazole or >300 mg/d of propylthiouracil [PTU]) is necessary, there is a risk of goitrous hypothyroidism in the fetus, which might be indistinguishable from goitrous Graves disease. The correct diagnosis relies on the assay of fetal thyroid hormones and TSH, which allows for optimal treatment.

In any woman who has previously given birth to a newborn with hyperthyroidism, a TSHR-Ab assay should be performed early in the course of pregnancy.

TSHRAb, thyroid-stimulating hormone receptor antibodies; ATD, autoimmune thyroid disease; T4, thyroxine; TBII, TSH-binding inhibitory immunoglobulin; TSAb, thyroid-stimulating antibody.

Clinical Characteristics and Diagnosis

Postpartum thyroiditis usually begins with a transient hyperthyroid phase between 6 weeks and 6 months postpartum followed by a hypothyroid phase. Only one-fourth of the cases follow this classic clinical picture, and more than one-third have either hyperthyroidism or hypothyroidism alone. Individuals with type 1 diabetes have a threefold increased risk of developing postpartum thyroiditis. Women with a history of
postpartum thyroiditis in a previous pregnancy have nearly a 70% chance of recurrence in a subsequent pregnancy. Although psychotic episodes are rare, postpartum thyroid dysfunction should be considered in all women with postpartum psychosis. The thyrotoxic phase may be subclinical and overlooked, particularly in areas where iodine intake is low (423). Unlike patients with Graves disease, those with the hyperthyroidism caused by postpartum thyroiditis have a low level of radioactive isotope uptake. Women with a history of postpartum thyroiditis should be followed closely as they have a 20% risk of permanent hypothyroidism immediately following the onset of thyroiditis, up to a 60% risk of permanent hypothyroidism over the next 5 to 10 years, and up to a 70% risk of postpartum thyroiditis in future pregnancies (424,425).

The absence of thyroid tenderness, pain, fever, elevated sedimentation rate, and leukocytosis helps to rule out subacute thyroiditis (de Quervain thyroiditis). Evaluation of TSH, T₄, T₃, T₃ resin uptake, and antimicrosomal antibody titer confirms the diagnosis.

**Treatment**

Most patients are diagnosed during the hypothyroid phase and require 6 to 12 months of thyroxine replacement if they are symptomatic (370). Because approximately 60% of women develop permanent hypothyroidism, TSH should be evaluated following discontinuation of replacement therapy.

Rarely, patients are diagnosed during the hyperthyroid phase (426). Antithyroid medications are not routinely used for these women. Propranolol may be used for relief of symptoms but should be used with appropriate counseling in nursing mothers.

**Antithyroid Antibodies and Disorders of Reproduction**

Women who have antithyroid autoantibodies before and after conception appear to be at an increased risk for spontaneous abortion (427,428). Nonorgan-specific antibody production and pregnancy loss are documented in cases of antiphospholipid abnormalities (429). The concurrent presence of organ-specific thyroid antibodies and nonorgan-specific autoantibody production is not uncommon (429–431). In cases of recurrent pregnancy loss, thyroid autoantibodies may serve as peripheral markers of abnormal T-cell function and further implicate an immune component as the cause of reproductive failure. The clinical implications of these findings in the management of patients with recurrent pregnancy loss are not known. Recurrent pregnancy loss is covered in Chapter 33.

**Thyroid Nodules**

Thyroid nodules are a common finding on physical examination and are demonstrated by high frequency ultrasonography in over two-thirds of patients (432). Occasionally such nodules are functional, and clinical and laboratory evaluation should be applied to distinguish these nodules from nonfunctional nodules, which are occasionally malignant. For nonfunctional
“cold” nodules, fine-needle biopsy and aspiration are required to rule out malignancy. In the case of indeterminate aspirates, 2% to 20% are malignant; therefore, surgical biopsy often is indicated (433). Molecular diagnosis screening of the BRAF mutation improves the diagnosis of cancer on fine-needle aspiration (434).

Turner Syndrome and Down Syndrome

Patients with Turner syndrome (and other forms of hypergonadotropic hypogonadism associated with abnormalities of the second sex chromosome) exhibit a high prevalence of autoimmune thyroid disorders. Approximately 50% of adult patients with Turner syndrome have antithyroid peroxidase (anti-TPO) and antithyroglobulin (anti-TG) autoantibodies. Of these patients, approximately 30% will develop subclinical or clinical hypothyroidism. The disorder is indistinguishable from Hashimoto thyroiditis. A susceptibility locus for Graves disease is noted on chromosome X (435). Because of the increased risk of autoimmune thyroid disease, it is recommended that women with Turner syndrome be screened with yearly TSH testing starting at the age of 4 (436).

Down syndrome, caused by an extra chromosome 21, is characterized by an atypical body habitus, mental retardation, cardiac malformations, an increased risk of leukemia, and a reduced life expectancy. The extra chromosome is almost always of maternal origin. Autoimmune thyroid disorders are more common in patients with Down syndrome than in the general population. The gene for autoimmune polyglandular syndrome I (APECED) was mapped to chromosome 21 and is thought to be a transcription factor involved in immune regulation (AIRE). This gene may play a role in the development of autoimmune thyroid disease in these patients (437). Hashimoto thyroiditis is the most common type of thyroid disease in individuals with Down syndrome. Hypothyroidism develops in as many as 50% of patients older than age 40 with Down syndrome. These clinical syndromes and other evidence suggest part of the genetic susceptibility to Hashimoto thyroiditis may reside on chromosomes X and 21. Because of the increased frequency of hypothyroidism associated with Down syndrome, it is recommended to screen individuals at 6 months, 12 months, and then annually thereafter (372).

The physician’s initial encounter with the infertile couple is extremely important because it sets the tone for subsequent evaluation and treatment. Factors from either or both partners may contribute to difficulties in conceiving; therefore, it is important to consider all possible diagnoses before pursuing invasive treatment. The main causes of infertility include male factor, decreased ovarian reserve, ovulatory disorders (ovulatory factor), tubal injury, blockage, or paratubal adhesions (including endometriosis with evidence of tubal or peritoneal adhesions), uterine factors, systemic conditions (including infections or chronic diseases such as autoimmune conditions or chronic renal failure), cervical and immunologic factors, and unexplained factors (including endometriosis with no evidence of tubal or peritoneal adhesions).

Basic investigations that should be performed before starting any infertility treatment are semen analysis, confirmation of ovulation, and the documentation of tubal patency. Male factor is the sole cause of infertility in 20% of infertile couples and may be a contributing factor in as many as 40% of cases. Treatment of reversible endocrine or infectious causes of subfertility, such as sexually transmitted diseases and thyroid disorders, tends to be efficacious. Intrauterine insemination (IUI) is the best studied and most widely practiced of all the insemination techniques. Intracytoplasmic sperm injection (ICSI) has allowed couples with male factor infertility to achieve assisted reproductive technology (ART) pregnancy outcomes that are comparable with those of couples with non–male factor infertility using conventional in vitro fertilization (IVF) treatment.
An association between the age of the woman and reduced fertility is well documented. The decline in fecundability begins in the early 30s and accelerates during the late 30s and early 40s.

Disorders of ovulation account for about 20% to 40% of all cases of female infertility. These disorders are generally among the most easily diagnosed and treatable causes of infertility.

The most common cause of oligo-ovulation and anovulation—both in the general population and among women presenting with infertility—is polycystic ovarian syndrome (PCOS).

Tubal and peritoneal factors account for 30% to 40% of cases of female infertility. Cervical factor is estimated to be a cause of infertility in no more than 5% of infertile couples. Uterine pathologies constitute the etiologic factor in infertility in as many as 15% of couples seeking treatment and are diagnosed in as many as 50% of infertile patients. Leiomyomas have not been shown to be a direct cause of infertility.

All methods of ART, by definition, involve interventions to retrieve oocytes. These techniques include IVF, ICSI, gamete intrafallopian transfer (GIFT), zygote intrafallopian transfer (ZIFT), cryopreserved embryo transfers, and the use of donor oocytes. Because of improved success rates associated with IVF-embryo transfer, the performance of GIFT and ZIFT has declined.

Multiple gestation, especially higher-order multiple gestation, is a serious complication of infertility treatment and has tremendous medical, psychological, social, and financial implications and complications. Fortunately, recent studies have not shown an increased risk for breast, uterine, or ovarian cancer secondary to medications used for superovulation in the treatment of infertility.

Information on the Society for Assisted Reproductive Technology (SART) and registered ART clinics are accessible on the Internet.

Infertility is defined as 1 year of unprotected intercourse without pregnancy (1). This condition may be further classified as primary infertility, in which no previous pregnancies have occurred, and secondary infertility, in which a prior pregnancy, although not necessarily a live birth, has occurred. About 90% of couples should conceive within 12 months of unprotected intercourse (2). Subfertility refers to couples who conceive after 12 months of attempted impregnation (2). Fecundability refers to the probability of pregnancy per cycle, which is considered to be at 20% in fertile couples (1). Fecundity refers to the probability of achieving a live birth in a single cycle and, by definition, has a value lower than fecundability. The diagnosis of impaired fecundity has been proposed to include couples with 36 months or more without conception or physical inability or difficulty in having a child; however, there is currently no clear consensus on any of these terms (3–5).
Epidemiology

Twenty-one percent of couples in the United States are expected to experience infertility in their lifetimes, with a current prevalence of 7.4% (6). In 2002, over 7 million US women age 22 to 44 reported using infertility services in their lifetimes (7). Once diagnosed, 13% of couples will not pursue treatment (8). The diagnosis of impaired fecundity has been rising, reaching 15% in 2002 and largely resulting from the trend toward delayed childbearing in developed countries (3). Worldwide, male factor accounts for 51.2% and tubal blockage for 25% to 35% of infertility and subfertility (conception after attempting for 1 year) (9,10). In Europe, ovulatory dysfunction accounts for 21% to 32%, male factor 19% to 57%, tubal factor 14% to 26%, unexplained 8% to 30%, endometriosis 4% to 6%, and combined male and female factors 34.4% of infertility (11–13). The odds of infertility increase with female age and in general among patients who have not graduated from college (14). The high cost of infertility treatment is a barrier for many in the United States where insurance typically does not cover these services (15). Language and other cultural barriers affect access for many minority groups (15,16). The women most likely to obtain specialized treatment are 30 years of age or older, white, married, and of relatively high socioeconomic status (7).
Initial Assessment

The physician’s initial encounter with the infertile couple is of primary importance because it sets the tone for subsequent evaluation and treatment. Ideally, both partners should be present at this first visit. It cannot be overemphasized that infertility is a problem of the couple. The presence of both partners, beginning with the initial evaluation, jointly involves them in the therapeutic process. This essential shared involvement demonstrates that the physician is receptive to the partner’s needs as well as those of the patient and offers the partner an opportunity to ask questions and voice concerns.

The physician should obtain a complete medical, surgical, and gynecologic history from the woman. Specifically, information regarding menstrual cycle regularity, pelvic pain, and previous pregnancy outcomes is important. Risk factors for infertility, such as a history of pelvic inflammatory disease (PID) or pelvic surgery, should be reviewed. A history of intrauterine exposure to diethylstilbestrol (DES) is significant. In addition, a review of systems relevant to pituitary, adrenal, and thyroid function is useful. Questions regarding galactorrhea, hirsutism, and changes in weight are particularly relevant. A directed history, including developmental defects such as undescended testes, past genital surgery, infections (including mumps orchitis), previous genital trauma, and medications should be obtained from the male partner. A history of occupational exposures that might affect the reproductive function of either partner is important, as is information about coital frequency, dyspareunia, and sexual dysfunction. Finally, information should be obtained on any family history of infertility, premature ovarian failure, congenital or developmental defects, mental retardation, and hereditary conditions relevant to preconceptional planning, such as cystic fibrosis, thalassemias, and Tay Sachs disease.

The initial interview provides the physician with the opportunity to assess the emotional impact of infertility on the couple. It presents a time for the physician to emphasize the emotional support available to the couple as they proceed with the diagnostic evaluation and suggested treatments. In some cases, referral to a trained social worker or psychologist may be beneficial.

The physical examination of the woman should be thorough, with particular attention given to height, weight, body habitus, hair distribution, thyroid gland, and pelvic examination. Referral of the male partner to a urologist for examination often is beneficial if historic information or subsequent evaluation suggests an abnormality. This initial encounter is an excellent time to outline the general causes of infertility and to discuss subsequent diagnostic and treatment plans (Figs. 32.1–32.3).

Figure 32.1 Diagnostic and treatment algorithm: infertility. HSG, hysterosalpingography. (From Yao M. Clinical management of infertility. Washington, DC: The Advisory Board: 2000, with permission.)
The basic investigations that ideally should be performed before starting any infertility treatment are semen analysis, confirmation of ovulation, and the documentation of tubal patency. Other noninfertility assessments should include rubella immunity testing (17). If a patient with severe systemic illness, such as renal failure, liver failure, or cancer, wishes to conceive, careful preconceptional assessment and counseling is advisable because the risks of fertility treatment and pregnancy can be substantial.
Causes of Infertility

The main causes of infertility include:

- Male factor
- Decreased ovarian reserve
- Ovulatory factor
- Tubal factor
- Uterine factor
- Pelvic factor
- Unexplained

Factors from either or both partners may contribute to difficulties in conceiving; therefore, it is important to consider all possible diagnoses before pursuing invasive treatments. The relative prevalence of the different causes of infertility varies widely among patient populations (Table 32.1). In many cases, no specific cause is detected despite a thorough evaluation, and the couple’s infertility is categorized as unexplained.

Very few couples have absolute infertility, which can result from congenital or acquired irreversible loss of functional gametes in either partner or the absence of reproductive structures in either partner. In these specific instances, couples should be counseled regarding their options for adoption, use of donor gametes, or surrogacy.
Impact of Lifestyle on Fertility

Overweight and obese women have higher rates of ovulatory dysfunction and infertility, along with 30% lower pregnancy rates with in vitro fertilization (IVF) compared to normal-weight women (18,19). Obese men have higher rates of hypogonadotropic hypogonadism and sperm DNA damage compared to normal-weight men (20,21). Substance abuse in men is discussed in the next section. Women who smoke need twice the number of IVF cycles to conceive as nonsmokers, but the effect of alcohol on fertility is less clear (18).

Washington, DC: The Advisory Board: 2000, with permission.)
Ovarian disorders

- Infrequent menses
  - Hot flashes
  - Signs of decreased estrogenization
  - High FSH, LH (postmenopausal range)

- High day 3 FSH
- Abnormal CCCT
- Advanced age

- Signs and symptoms
  - Hyperandrogenism
  - Oligomenorrhea or anovulation
  - Other medical causes excluded

Premature ovarian failure

- Assess for and treat secondary or associated medical problems

- Premature ovarian failure is usually irreversible, but spontaneous sporadic ovulation and pregnancy have been reported

- ART
  - Donor egg in vitro fertilization - embryo transfer
  - Discuss adoption

Decreased ovarian reserve

- Associated with increased age, decreased egg quality
- Predicts decreased chance of successful treatment
- Associated with increased risk of aneuploidy and miscarriage

- May have brief trials of superovulation-intratubine insemination or in vitro fertilization

Polycystic ovarian syndrome

- Primary care/disease prevention management

- Ovulation induction
Male Factor

Male factor is the only cause of infertility in about 20% of infertile couples, but it may be a contributing factor in as many as 50% of cases \(^{(9,11-13)}\). The concept of a global decline in sperm counts is controversial \(^{(22,23)}\). A decline in sperm density has been observed in the United States, Europe and Australia, while decreased motility and semen volume have been reported in India \(^{(22)}\). Given that decreases in sperm parameters have been noted in fertile men, the clinical relevance for fecundability is unknown \(^{(24)}\). However, one simulation model has suggested that if sperm concentrations decline by 21% to 47%, fecundability would decrease by 7% to 15% \(^{(25)}\).

### Physiology

#### Spermatogenesis

The male reproductive tract consists of the testis, epididymis, vas deferens, prostate, seminal vesicles, ejaculatory duct, bulbourethral glands, and urethra. Gonadotropin-responsive cells in the testes include Leydig cells (the site of androgen synthesis) and Sertoli cells, which line the seminiferous tubules (the site of spermatogenesis). The pituitary gland secretes luteinizing hormone (LH), which stimulates the synthesis and secretion of testosterone by the Leydig cells, and follicle-stimulating hormone (FSH), which acts with testosterone on the Sertoli cells to stimulate spermatogenesis \(^{(26)}\). In humans, a new cohort of spermatogonia enter the maturation process every 16 days, and the development from spermatogonia stem cells to the mature sperm cells takes about 75 days \(^{(27)}\). Spermatogonia undergo mitotic division to give rise to spermatocytes. These diploid spermatocytes subsequently undergo meiosis to produce haploid spermatids, which contain 23 (rather than 46) chromosomes \(^{(26)}\). Maturation of spermatids is called spermiogenesis and involves condensation of the nucleus, formation of the flagellum, and the formation of the acrosome (a structure derived from the Golgi complex covering the tip or head of the sperm nucleus) \(^{(28)}\). The resultant spermatozoa are released into the
Sperm Transport

During ejaculation, mature spermatozoa are released from the vas deferens along with fluid from the prostate, seminal vesicles, and bulbourethral glands. The released semen is a gelatinous mixture of spermatozoa and seminal plasma; however, this thins out 20 to 30 minutes after ejaculation. This process, called liquefaction, is the direct result of proteolytic enzymes within the prostatic fluid (30). Following ejaculation, the released spermatozoa must undergo capacitation to become competent to fertilize the oocyte. Capacitation occurs within the cervical mucus and involves removal of inhibitory mediators such as cholesterol from the sperm surface, tyrosine phosphorylation, and calcium ion influx, all of which allow the sperm to recognize additional fertilization cues during travel through the female reproductive tract. When the sperm reach the tubal isthmus they are slowly released into the ampulla, further reducing the number of sperm that reach the oocyte (31). Sperm transport from the posterior vaginal fornix to the fallopian tubes occurs within 2 minutes during the follicular phase of the menstrual cycle (32).

Fertilization

As the capacitated sperm near and pass through cumulus cells surrounding the oocyte, hydrolytic enzymes are released from the acrosome via exocytosis in a process called the acrosome reaction. Both capacitation and the acrosome reaction can be induced in vitro (28,31). Following the acrosome reaction, the sperm binds to and penetrates the zona pellucida (the extracellular coat surrounding the oocyte). This allows the sperm to fuse with the plasma membrane of the oocyte, an event that promotes changes in the oocyte and prevent entry by additional sperm (31). As the first sperm penetrates the zona pellucida, cortical granules are released (the cortical reaction) from the oocyte into the perivitelline space. This stops the oocyte’s zona pellucida from binding new sperm and inhibits penetration by previously bound sperm, further reducing the possibility of polyspermy (33).

Sperm Sensitivity to Toxins

Decreased sperm concentration and motility have been noted in areas of the United States with heavy agriculture and pesticide use, but occupational exposures have not been linked to infertility (24,34). Higher intake of food containing soy is associated with lower sperm concentrations (35). Alcoholism negatively affects all semen analysis parameters, and either smoked or chewed tobacco is associated with decreased density and motility (36–39). Marijuana inhibits motility and the acrosome reaction in vitro, and cocaine inhibits sperm motility and is associated with male infertility (40–42). Certain drugs may reduce sperm numbers or function or may cause ejaculatory
dysfunction (Table 32.2). Vaginal lubricants such as Astroglide, KY Jelly, saliva, and olive oil inhibit sperm motility in vitro, while no adverse effects are seen with hydroxyethylcellulose (Pre-Seed), mineral oil, or canola oil (32).

Semen Analysis

The basic semen analysis measures semen volume, sperm concentration, sperm motility, and sperm morphology (30). Recently revised, the normal values suggested by the World Health Organization (WHO) in 2010 are listed along with the previously published guidelines in Table 32.3 (30,43). Both criteria were developed using fertile men whose semen parameters were in the lowest fifth percentile of the group studied, but values above the reference ranges do not guarantee male fertility. Furthermore, since infertile men were not used to develop the criteria, values below the cutoffs may not necessarily indicate infertility (30). However, significant deviations from the reference limits are generally classified as male factor infertility (44). Given regional differences in semen quality and between laboratories, laboratories are encouraged to develop their own reference ranges. Typically, semen is assessed manually, but computer-aided sperm analysis (CASA) may be used. Limitations of CASA include a lack of standardization among instruments, an inability to differentiate intact from nonintact sperm, possible bias from artifacts during preparation, and a paucity of studies on fertility outcomes in large populations (30).

Terminology from **Hirsh A.** Male infertility. BMJ 2003;327:669–672, with permission.

### Abstinence

**Abstinence of a minimum of 2 to a maximum of 7 days usually is recommended prior to the semen analysis, but the optimal duration is unknown** (30). The epididymis stores the equivalent of three ejaculations (29). With prolonged abstinence, sperm overflow into the urethra and are flushed out into the urine (30). A study of men attending an infertility clinic found that the total motile sperm count and normal morphology decreased after 10 days' abstinence in normozoospermic men but after 5 days' abstinence in oligozoospermic men (45). There are conflicting reports regarding the impact of shorter abstinence of 1 or 2 days on semen parameters (45,46), but one study suggested intrauterine insemination success rates might be improved by shortening abstinence times prior to specimen collection (46).

### Specimen Collection

The specimen should be obtained by masturbation and collected in a clean container kept at ambient temperature (30). The patient should report any loss of the specimen, particularly the first portion of the ejaculate, which contains the highest sperm concentration. Collection may be performed either at home or in a private room near the laboratory. The sample should be taken to the laboratory within 30 minutes to 1 hour of collection to prevent dehydration and degradation. **If masturbation into a container is not possible, condoms specially designed for semen analysis should be used rather than latex condoms, which are toxic to sperm. Intercourse to collect the sample is discouraged because of the risk of contamination.** Even when the
specimen is obtained under optimal circumstances, interpretation of the results of the semen analysis is complicated by variability within the same individual and wide differences in normal semen parameters. Semen parameters may vary widely from one man to another and among men with proven fertility. **In many circumstances, several specimens are necessary to verify an abnormality** (30).

**Sperm Volume and pH**

The **lower limit of normal semen volume is 1.5 mL or more and the pH should be 7.2 or higher.** These parameters are affected mainly by the balance between the acidic secretions of the prostate gland and the alkaline fluid from the seminal vesicles. Low volume along with pH less than 7 suggests obstruction of the ejaculatory ducts or absence of the vas deferens. Difficulties with collection, retrograde ejaculation, or androgen deficiency can contribute to low volume. High volumes greater than 5 mL suggest inflammation of the accessory glands (30).

**Sperm Concentration**

Sperm concentration or density is defined as the number of sperm per milliliter in the total ejaculate. **The normal lower limit is 15 million/mL or more, recently revised from 20 million/mL or more** (30,43). Only intact sperm are counted in determining sperm concentration. Fifteen percent to 20% of infertile men are azoospermic (no sperm) and 10% have a density of less than 1 million/mL (30,47).

**Sperm Motility and Viability**

Sperm motility is the percentage of progressively motile sperm in the ejaculate. **The normal lower limit is 32% or more, recently revised from 50% or more** (30,43). **Viability should be at least 58%.** Progressive motility refers to movement either linearly or in a large circle regardless of speed. Nonprogressive motility describes sperm that display only small movements or twitching or no movement at all (immotile). Assessments of speed of progression, either rapid or slow, have been removed from the revised guidelines because of difficulty in unbiased measurement of this parameter. A reduction in sperm motility is referred to as asthenozoospermia. Leukocytes can impair sperm motility through oxidative stress. When a large number of immotile sperm are present or when progressive motility is less than 40%, viability studies should be performed. Viable immotile sperm may have flagellar defects, while the presence of nonviable immotile sperm (necrozoospermia) suggests epididymal pathology. Viable sperm have intact plasma membranes, which will not stain (dye exclusion) but will swell in hypoosmotic solutions (hypoosmotic swelling test) (30).

**Sperm Morphology**

Morphology refers to anatomic malformations of the sperm. **The lower limit for normal morphology is 4% or more using strict criteria, a change from previous guidelines using a more lenient assessment and a cutoff of 30% or more**
Assessment of sperm morphology involves fixing and staining of a portion of the specimen. The strict Tygerberg criteria were introduced by Kruger et al. in 1986 to assess sperm morphology (30,48,49). Using this system, the entire spermatozoon—including the head, midpiece, and tail—is assessed, and even mild abnormalities in head forms are classified as abnormal. Most sperm from normal men exhibit minor abnormalities when subjected to Tygerberg standards. An abnormality of sperm morphology is known as teratozoospermia, and these sperm have poor fertilizing potential and may have abnormal DNA. A disadvantage to any morphology assessment is that reproducibility may be hampered by the subjective nature of the assessment (30).

**Nonsperm Cells**

These include epithelial cells, round cells, and isolated sperm heads or tails. **Round cells include immature germ cells and leukocytes.** Immature germ cell elevation suggests testicular damage, while leukocytes (predominantly neutrophils) are associated with inflammation. Leukocytes can be distinguished by peroxidase positive staining, and normal leukocyte concentrations should be less than 1 million/mL. However, the prognostic significance of leukocytes in the semen is controversial (30,50). When bacterial colonization is found, the most common pathogens are Chlamydia trachomatis (41.4%), Ureaplasma urealyticum (15.5%), and Mycoplasma hominis (10.3%) (51).

**Antisperm Antibodies**

Antisperm antibodies, particularly those found on the surface of sperm, are associated with decreased pregnancy rates. Testing may be indicated with a history of ductal obstruction, prior genital infection, testicular trauma, and prior vasectomy reversal. It may be useful with oligozoospermia in the setting of normal hormonal levels, asthenospermia with normal sperm concentration, sperm agglutination, or unexplained infertility. **Antisperm antibody testing is not needed if the sperm are to be used for intracytoplasmic sperm injection (ICSI)** (44,47). Using the immunobead test, washed spermatozoa are exposed and assessed for binding to labeled beads. In the mixed agglutination reaction, human red blood cells sensitized with human immunoglobulin G (IgG) are mixed with the partner's semen. Spermatozoa that are coated with antibodies form mixed agglutinates with the red blood cells (30).

**Other Sperm Tests**

Although the standard semen analysis and associated tests provide a fairly reasonable picture of semen quality, they yield little information about sperm function. These specialized tests may be pursued to assess DNA integrity, fertilization potential (zona-free hamster oocyte test), and the effect of cervical mucus on sperm viability and function (postcoital test) (44,52). In general, these tests are not currently considered part of the standard assessment because their prognostic value and impact on management are limited by poor specificity, poor reproducibility, or controversies concerning the interpretation of the results (44,47,52).
Differential Diagnosis of Male Factor

If abnormalities in the semen are detected, further evaluation of the male partner by a urologist is indicated to diagnose the defect. Table 32.4 lists the differential diagnoses for male factor infertility (53). Several groups have attempted to assess the distribution of male infertility diagnoses; two such distributions are shown in Table 32.5 (54,55). The first is the result of a WHO study of 7,057 men with complete diagnoses based on the WHO standard investigation of the infertile couple (54). The figures include data from cases in which the male partner was normal and the presumed cause of the couple’s infertility was a female factor. The second distribution is the result of a study of 425 subfertile male patients (54). Although the two studies represent different populations (one is from a study of couples, the other from a urologic practice) and differ in their distribution of male infertility diagnoses, idiopathic male factor and varicocele predominate. Other anatomic and endocrine causes occur less frequently. Same sex female couples or single women without a male partner who desire pregnancy may be considered as part of this category.

*More than 100% because of multiple factors.

Male Age

Men reportedly have fathered children into their 90s, but pregnancy rates are decreased with paternal older than age 40 to 45 and particularly over age 50. Increasing paternal age is associated with a higher frequency of disomic sex chromosomes and structural chromosomal abnormalities in the sperm. With respect to the offspring, paternal age confers higher rates of autosomal dominant diseases such as achondroplasia and craniosynostotic conditions and somewhat higher rates of trisomy 21 (56). In mice, offspring of older fathers have decreased survival (57). Increased paternal age is associated with recurrent pregnancy loss (58).

Treatment of Male Factor Not From Azoosperma

Medical treatment of reversible infectious or endocrine causes of male subfertility, such as sexually transmitted diseases and thyroid disorders, tends to be efficacious. Although injections of exogenous FSH have been reported to improve pregnancy rates, the benefit is less clear for clomiphene citrate, an estrogen antagonist at the hypothalamus and pituitary that promotes gonadotropin release. **Exogenous testosterone is not recommended in the treatment of male subfertility because of negative feedback inhibition at the pituitary that results in decreased spermatogenesis, but the combination of testosterone and an antiestrogen may be of benefit.**
Antioxidant food supplements have been evaluated (59). Glutathione, carnitine, and vitamin E do not appear to affect semen parameters, but administration of zinc and folic acid were associated with improved sperm concentration and morphology (60). The diagnosis and treatment of azoospermia (no sperm on semen analysis) will be discussed separately from other forms of male factor infertility.

**Varicocele Repair**

A varicocele is an abnormal dilation of the veins within the spermatic cord. Varicoceles are present in 15% of normal men and 40% of men seeking infertility treatment, but semen parameters are lower among infertile men with varicoceles (61,62). The pathophysiologic effects of a varicocele appear to be mediated by an associated rise in testicular temperature, reflux of toxic metabolites from the left adrenal or renal veins, or higher reactive oxygen species (61,63). Although treatment is associated with improved semen parameters in some studies, it is not clear whether varicocele repair definitely improves fertility (61,64,65). Treatment is typically considered if the varicocele is palpable and the semen analysis is abnormal, but is not indicated if IVF would be required to treat the female partner and the existing semen analysis would be acceptable for ICSI. Treatment methods include surgical repair and percutaneous embolization. Complications of treatment include infection, varicocele persistence, recurrence, and hydrocele formation (61).

**Artificial Insemination**

Artificial insemination has been used mainly to treat unexplained infertility (usually combined with superovulation) and male factor infertility (including same sex female couples). All artificial insemination procedures involve the placement of whole semen or processed sperm into the female reproductive tract, which permits sperm–ovum interaction in the absence of intercourse. The placement of whole semen into the vagina as a mode of fertility treatment is now rarely performed except in cases of severe coital dysfunction. Currently, all of the common forms of artificial insemination involve processed sperm obtained from the male partner or a donor. Many techniques for artificial insemination have been described, but only intracervical and intrauterine inseminations (IUI) have been routinely employed. The success rates with intracervical insemination are lower than those with IUI, particularly when using frozen sperm (66–68).

**Insemination Processing**

During and after intercourse, seminal fluid usually is prevented from reaching the intrauterine cavity and intra-abdominal space by the cervical barrier. The introduction of seminal fluid past this barrier may be associated with pelvic infection and severe uterine cramping or anaphylactoid reactions, possibly mediated by seminal factors such as prostaglandins. Thus, protocols for processing whole semen include the washing of specimens to remove seminal factors and to isolate pure sperm.
Additional processing may include centrifugation through density gradients, sperm migration protocols, and differential adherence procedures (66). Finally, phosphodiesterase inhibitors, such as pentoxiphylline, have been used during semen processing in an attempt to enhance sperm motility, fertilization capacity, and acrosome reactivity for IVF procedures (60,69).

**Intrauterine Insemination**

IUI is the best studied and most widely practiced of all the insemination techniques. It involves placement of about 0.3 to 0.5 mL of washed, processed, and concentrated sperm into the intrauterine cavity by transcervical catheterization (66). Patients should remain immobile for approximately 15 minutes following the procedure (70). Studies of the efficacy of IUI in the treatment of male factor infertility have been difficult to assess because of variations in inclusion criteria and the limitations of sperm function tests. Although it makes intuitive sense that IUI would result in higher pregnancy rates rather than timed intercourse in the case of male factor subfertility, there are conflicting reports of the benefits of IUI (66,71–74). Ideally, the total motile sperm count in the IUI specimen should be 5 million or 10 million or more (75–78). Pregnancy rates with semen meeting those thresholds have been reported to be 10.5% per cycle and 38% after 4 to 6 cycles (77,78). No benefit has been found with respect to double IUI versus single IUI during a single cycle (79).

**Intracytoplasmic Sperm Injection**

In general, ICSI has allowed couples with male factor infertility to achieve assisted reproductive technology (ART) pregnancy outcomes that are comparable with those of couples with non–male factor infertility using conventional IVF treatment (80). ICSI has been used since 1992 to increase the fertilization rate of oocytes retrieved during ART by direct injection of a live sperm into the oocyte, thereby theoretically bypassing limitations imposed by sperm motility and defects in capacitation, the acrosome reaction, and/or sperm binding the zona pellucida (81). This microsurgical procedure involves stripping the aspirated cumulus complex of all surrounding granulosa cells, followed by insertion of a single viable sperm into the cytoplasm (ooplasm) of the mature metaphase II egg (9,82). ICSI should be offered if the semen analysis shows less than 2 million motile sperm, less than 5% motility, or if surgically recovered sperm are used. Its use for abnormal morphology is more controversial (47,83). Immature or round spermatid nucleus injection (ROSNI) for ICSI is considered experimental at this time (84). Higher pregnancy rates have been noted with fresh compared to frozen specimens and with ejaculated compared to surgically retrieved sperm. Success rates are affected by the age of the female partner and oocyte quality (47). Non–male factor indications for ICSI include a history of fertilization failure with conventional IVF and the fertilization of oocytes before preimplantation genetic diagnosis (85). Other uses are described under “Unexplained Infertility.”
Risks of Intracytoplasmic Sperm Injection

In skilled hands, oocyte damage with ICSI is reportedly 10% (81). However, oocyte degeneration can follow even an uncomplicated ICSI procedure, with rates as high as 30% to 50%. This is most likely a function of oocyte quality and/or patient factors rather than the ICSI process itself (82). Based on data from 5-year-old children, ICSI is associated with a higher congenital anomaly risk (4.2%) when compared with conventional IVF (typically 2% to 3%) (80). There may be an increased risk of imprinting disorders and hypospadias with ICSI (47). Reports indicate a slightly higher risk of sex chromosome abnormalities (0.8% to 1% ICSI vs. 0.2% IVF) and translocations (0.36% ICSI vs. 0.07% general population). It is unclear whether these relate to the ICSI procedure or inherent gamete defects; men with abnormal semen parameters have higher rates of sperm aneuploidy. Recent studies have not found an association with impaired intellectual or motor development among ICSI children. In the setting of specific genetic abnormalities such as Y chromosome microdeletions, abnormal karyotypes, cystic fibrosis mutations, or congenital absence of the vas deferens, genetic counseling should be offered to address the possible risk of infertility or other abnormality in the offspring (80).

Azoospermia: Classification and Treatment

Azoospermia describes the absence of spermatozoa in the ejaculate and is found in 1% of all men and up to 15% to 20% of infertile men. Causes are categorized into pretesticular (nonobstructive), testicular (nonobstructive), and posttesticular (includes obstructive and nonobstructive) etiologies, but in some cases the condition is idiopathic (47,86).

Pretesticular Azoospermia

Pretesticular azoospermia is relatively rare and results from gonadotropin deficiency, which leads to loss of spermatogenesis. The physician should perform a full endocrine history that includes information on puberty and growth and check for low serum levels of LH, FSH, and testosterone (44,47,86). Prolactin levels and pituitary imaging are indicated in cases of hypogonadotropic hypogonadism (47). Hormonal treatment includes pulsatile gonadotropin-releasing hormone (GnRH), human chorionic gonadotropin, and exogenous gonadotropins (44,47,86). The best predictors of good response are postpubertal onset of gonadotropin deficiency and testicular volume greater than 8 mL (47).

Testicular Azoospermia

Gonadal failure is the hallmark of testicular azoospermia. Causes of this condition may be genetic, acquired (e.g., radiation therapy, chemotherapy, testicular torsion, varicocele, or mumps orchitis), or developmental (e.g., testicular maldescent). Testicular atrophy is often present. Because of the low chance of obtaining sperm, testicular biopsy is generally not recommended with hypergonadotropin hypogonadism (elevated levels of
LH and FSH with low serum levels of testosterone) and consideration should be given to using donor sperm. Diagnostic testicular biopsies may be indicated in the setting of normal hormonal testing. If sperm are present on diagnostic testing, consideration can be given to using surgically retrieved spermatozoa for ICSI (44,47,86). If no sperm are present, consideration can be given to correcting acquired conditions such as varicocele, which may restore sperm to the ejaculate to permit ICSI or spontaneous pregnancy (87,88).

Chromosomal abnormalities by peripheral karyotype testing are present in about 7% of infertile, 5% of oligospermic, and 10% to 15% in azoospermic men. Sex chromosome aneuploidies such as Klinefelter syndrome (47,XXY) encompass two-thirds of these infertility-associated chromosome abnormalities. Microdeletions in the Y chromosome have been identified in 10% to 20% of men with idiopathic azoospermia or severe oligospermia with concentration less than 5 million/mL (44,47,86) (Table 32.6). These microdeletions can be transmitted to the male offspring, who may then suffer from infertility. Therefore, screening for genetic causes is indicated in nonacquired cases of testicular azoospermia so that genetic counseling can be provided before treatment (80). The two most commonly implicated candidate gene families are the RNA-binding motif (RBM) and the “deleted in azoospermia” (DAZ) families, but microdeletions at various loci on the Y chromosome have been described (44,47,86,89–91). For example, microdeletions in Yq11.23 can occur in one or more of three regions: AZFa (proximal), AZFb (central), and AZFc (distal) (44,47,86).

**Posttesticular Azoospermia**

Posttesticular or obstructive etiologies are associated with normal gonadotropin and testosterone levels and are present in up to 40% of azoospermic men (47,86). Ejaculatory dysfunction is associated with oligospermia or aspermia but rarely azoospermia (86). Obstructive causes include congenital absence or obstruction of the vas deferens or ejaculatory ducts, acquired obstruction of these ducts, or ductal dysfunction, including retrograde ejaculation (47,86). In the absence of congenital bilateral absence of the vas deferens (CBAVD) or hypogonadism, men with low
volume ejaculate should have a postejaculatory urinalysis to check for retrograde ejaculation, which is associated with diabetes and surgery to the bladder or prostate (44,47). Sperm may be isolated from the neutralized urine of men with retrograde ejaculation and processed for insemination or for ART (30). Transrectal ultrasound may be of use to diagnose ejaculatory duct obstruction or unilateral vasal agenesis (to demonstrate contralateral atresia) but is generally not needed for CBAVD (86). Renal imaging is necessary when either unilateral or bilateral vasal absence is diagnosed as a result of the 10% to 25% incidence of renal agenesis. Most men with CBAVD will have seminal vesicle agenesis, so almost all will have low semen volume, low pH, and low fructose levels (86). Spermatogenesis can be expected to be normal in CBAVD, so generally diagnostic biopsy is not indicated (92). In some cases, testicular biopsy may be indicated to differentiate between testicular and posttesticular causes. At least two-thirds of men with CBAVD have mutations of the cystic fibrosis transmembrane conductance regulator gene (CFTR). However, because many CFTR mutations are undetectable, CBAVD patients should be assumed to have a mutation and thus testing of the female partner’s carrier status should be performed (86).

Vasectomy Reversal and Treatment of Obstructive Azoospermia

Vasectomy can be reversed effectively using microsurgical vasovasostomy or vasoepididymostomy. These techniques can be used for epidymal obstructions (93). Patency and subsequent pregnancy rates approach 100% and 80%, respectively. Pregnancy typically occurs within 24 months of reversal (94). Rates of patency and pregnancy vary inversely with the length of time from vasectomy, particularly for reversal procedure performed after 15 years or more (93,94). Although 60% of reversal patients develop antisperm antibodies, these do not appear to affect fecundability. Following surgery, periodic semen analyses can identify reobstruction, which can range from 3% to 21% depending on which segments were anastomosed. For those patients with azoospermia 6 months after reversal, the procedure is considered a failure and testicular sperm aspiration with ICSI could be considered. However, repeat vasovasostomy is associated with patency rates of 75% and pregnancy rates of 43% (94).

Surgical Sperm Recovery for Intracytoplasmic Sperm Injection

Among the many surgical methods for sperm recovery, the most widely described are microsurgical epididymal sperm aspiration (MESA), percutaneous epididymal sperm aspiration (PESA), testicular sperm extraction (TESE), and percutaneous testicular sperm fine-needle aspiration (TESA, also called fine-needle aspiration, or FNA). Both MESA and TESE are open surgical procedures performed with an operating microscope and general or regional anesthesia, whereas the percutaneous procedures need only local anesthesia. The optimal choice for surgical sperm recovery method has not been determined and certainly varies based on patient history. Hematoma risk appears to be low regardless of method. Testicular atrophy is a rare complication of TESE and TESA even when biopsies
are obtained from multiple testicular sites (92).

With obstructive azoospermia, pregnancy rates using sperm retrieval and ICSI are 24% and 64%, respectively, and outcomes using either frozen-thawed or fresh sperm are comparable. Because MESA allows for diagnosis and possible reconstruction of ductal pathology and because it usually yields very large numbers of sperm, sperm cryopreservation and avoidance of repeat surgery may be possible (92). If repeat sperm retrievals are needed, the minimum interval between procedures is 3 to 6 months to allow for adequate healing (93).

For nonobstructive (testicular) azoospermia, epididymal aspiration is not an option. Although pregnancies have been reported following testicular sperm retrieval with nonobstructive azoospermia, the likelihood of retrieving sperm is low as are subsequent pregnancy rates (92,95). Patients with obstructive azoospermia must be counseled regarding the risk of transmitting genetic disorders to their offspring (47,86).

**Donor Insemination**

For men with azoospermia, couples with significant male factor infertility who do not desire ART, or women without a male partner who are seeking pregnancy, therapeutic donor insemination offers an effective option (96). In several prospective randomized or crossover trials, IUI was shown to be superior to intracervical insemination for donor insemination (68). In patients younger than 30 years of age who have no other infertility factors, delivery rates approach 90% after 12 cycles of IUI treatment with frozen sperm, so patients who do not conceive within 6 to 12 months should be assessed for female factors and encouraged to terminate treatment or proceed with alternative forms of therapy. The concomitant use of clomiphene citrate or gonadotropin (hMG) for controlled ovarian hyperstimulation (COH) did not result in higher fecundity rates in these patients (97). Psychological counseling should be offered because of the potential repercussions of using donor gametes (96).

**Donor Sperm Screening**

Although the use of fresh donor semen is associated with higher pregnancy rates than the use of frozen specimens, both the Centers for Disease Control and Prevention and the American Society for Reproductive Medicine recommend the use of frozen samples (96,98,99). This recommendation stems from the increasing incidence of human immunodeficiency virus (HIV) infection in the general population and the lag time between HIV infection and seroconversion. Currently, semen donors are screened for HIV infection, hepatitis B, hepatitis C, syphilis, gonorrhea, chlamydia, and cytomegalovirus infections, all of which may be transmitted through semen. All cryopreserved samples are quarantined for 6 months, and the donor is retested for HIV before clinical use of the specimen. Donors are likewise questioned about any family history of genetically transmitted disorders, including both Mendelian (e.g., hemophilia, Tay-Sachs disease, thalassemia, cystic fibrosis, congenital adrenal hyperplasia,
Huntington disease) and polygenic or multifactorial conditions (e.g., mental retardation, diabetes, heart malformation, spina bifida). Those with a positive family history of these conditions are eliminated as donor candidates (96).

Figure 32.4 Live births per embryo transfer comparing use of a patient’s own versus donor oocytes. (Adapted from CDC Reproductive Health. 2009 Assisted Reproductive Technology Success Rates. National Summary and Fertility Clinic Reports. http://www.cdc.gov/nccdphp/drh/art.htm.)
Female Age and Decreased Ovarian Reserve

**Decreased Fecundability**

Most women will experience a decline in fecundability as they age that is physiologic rather than pathologic. **This decline begins in the early 30s and accelerates during the late 30s and early 40s, reflecting declines in oocyte quantity and quality.** Among populations that do not practice contraception, fertility peaks at age 20, declines somewhat at age 32, steeply declines after the age of 37, and is rare after age 45 (100). Wives of azoospermic husbands who received donor IUI had cumulative pregnancy rates over 12 cycles of 74% (age <31 years), 62% (age 31 to 35), and 54% (age >35) (101). Chronologic aging of the endometrium does not seem to play an appreciable role in reduced fertility, given the excellent pregnancy and live birth rates using donor oocytes (Fig. 32.4) (102,103). IVF success rates similarly decrease with age and will be further discussed later in the chapter (100). Reproductive aging is related to the stock of primordial follicles that are established early in fetal life and decline to near zero at meno-pause (104).

**Spontaneous Pregnancy Loss**

Reproductive aging is associated with abnormalities in the oocyte meiotic spindles that lead to chromosome alignment errors and increase rates of conceptus aneuploidies, particularly trisomies. This serves to increase the risk for spontaneous pregnancy loss and thereby decrease live birth rates in older women (100,105). A large study based on the Danish national registry estimated the rates of clinically recognized spontaneous pregnancy loss for various age groups to be 13.3% (12 to 19 years), 11.1% (20 to 24 years), 11.9% (25 to 29 years), 15.0% (30 to 34 years), 24.6% (35 to 39 years), 51.0% (40 to 44 years), and 93.4% (older than 45 years) (106). In addition, using sensitive hCG assays in women during their reproductive years, 22% of all pregnancies were found to be lost before they could be clinically diagnosed (107).

**Ovarian Reserve**

Ovarian reserve refers to the size of the nongrowing, or resting, primordial follicle population in the ovaries. This, in turn, presumably determines the number of growing follicles and the “quality” or reproductive potential of their oocytes (105). Tests of ovarian reserve are often used, but the predictive values of these tests for fertility potential are limited, particularly when normal testing is found in older women and abnormal testing is documented in younger women. The tests appear to be better suited for determining how the ovaries will respond to pharmacologic doses of exogenous gonadotropins in terms of follicle count, the number of oocytes produced, serum estradiol levels during stimulation, the duration of stimulation, and the quantity of exogenous gonadotropins required in a given cycle (108). However, unlike age, the results of ovarian reserve testing are poorly predictive of pregnancy outcomes (109–111). **These tests appear to be more indicative of oocyte quantity rather than quality.**
Serum Day 3 Follicle Stimulating Hormone

As women age, FSH physiologically rises in the early follicular phase (cycle day 3), with levels of 5.74 IU/L at age 35 to 39 and 14.34 IU/L at age 45 to 59. Higher levels are seen after unilateral oophorectomy. In women in their 40s, levels greater than 20 IU/L are predictive of menopause. Because the incidence of abnormal values is lower in younger women, testing is typically performed for women aged 35 or older (108). In subfertile women with an FSH 8 IU/L or more, spontaneous pregnancy rates decrease by 7% per unit of FSH increase, with a 40% reduction at 15 IU/L and 58% at 20 IU/L (112). FSH levels vary widely by assay, laboratory, and population (109). Because of the poor sensitivity of high basal FSH values in determining fecundability, they should not be used as the sole basis for excluding women from consideration for ART (113). Likewise, the poor specificity of low basal FSH values in determining fecundability makes them unreliable when used to reassure patients, particularly those of increased reproductive age (109).

Basal Estradiol Level

Basal day 3 FSH is often combined with estradiol (E2) testing. Estradiol levels on day 3 of the menstrual cycle reflect follicular growth rather than the number of antral follicles (114). Elevations in FSH and decreases in inhibin B (see below) that accompany aging results in advanced follicular growth at the end of the preceding luteal phase. In response, early follicular E2 levels are typically higher in older women and in women with advanced reproductive aging (104).

Clomiphene Citrate Challenge Test

Clomiphene citrate is thought to have antiestrogenic effects on the hypothalamic–pituitary axis, resulting in a decrease in E2-mediated suppression of FSH production by the pituitary. The clomiphene citrate challenge test (CCCT) involves the measurement of serum FSH and estradiol on day 3 of the menstrual cycle, and again on day 10 after administration of clomiphene citrate (100 mg orally each day) from days 5 to 9. The CCCT has been reported to be more sensitive than basal FSH alone in identifying poor response to exogenous gonadotropins, but others report that the predictive values of the tests do not differ substantially (109,110).

Serum Inhibin B

Serum inhibin B is secreted by ovarian granulosa cells starting at the preantral follicle stage and therefore reflects the size of the growing follicular cohort (111). Reduced inhibin B levels are seen with aging even in normal fertile women (114). Inhibin B alone has poor predictive value for ovarian response but improves the predictive value when added to the CCCT (109,110). Unlike basal testing, levels of inhibin B measured on the 5th day of ovarian stimulation were predictive of live birth following IVF/ICSI (115).
Serum Antimüllerian Hormone

Antimüllerian hormone (AMH) is produced by the granulosa cells of preantral and small antral follicles (111,114). The serum level of AMH in women with normal cycles declines with age and becomes undetectable after menopause (114,116). AMH appears to be a good predictor of both excessive (>3.5 ng/mL) and poor (<1 ng/mL) IVF stimulation response and is strongly correlated to the antral follicle count (111,116,117). Unlike other serum markers, AMH can be measured at any time in the menstrual cycle (116).

Antral Follicle Count

Using transvaginal ultrasound in the early follicular phase, all ovarian follicles 2 to 10 mm are counted and the total for both ovaries is called the basal antral follicle count (AFC). The AFC correlates well with chronologic age in normal fertile women and appears to reflect what remains of the primordial follicular pool (104). Decreases in AFC with age are gradual rather than sudden (118). A total AFC less than 4 is predictive of poor response and higher cancellation rates with IVF (119,120).

Treatment of Diminished Ovarian Reserve

Treatments of diminished ovarian reserve include autologous IVF, use of donor oocytes or embryos, and adoption. Pretreatment of women with diminished ovarian reserve for 4 to 5 months with dehydroepiandrosterone (DHEA; 25 mg three times daily) has been described to improve oocyte yield and pregnancy rates with IVF (121–123).
Ovulatory Factor

Ovulatory factor accounts for 30% to 40% of all cases of female infertility. Initial diagnoses among women with ovulatory factor infertility may include anovulation (complete absence of ovulation) or oligo-ovulation (infrequent ovulation). Menstrual history may be suggestive if oligomenorrhea, amenorrhea, polymenorrhea, or dysfunctional uterine bleeding is present (124). Menstrual dysfunction is present in 18% to 20% of the general population (125). Figure 32.5 shows the fluctuations of E2, progesterone, FSH, and LH in a normal, 28-day ovulatory cycle. The normal length of the menstrual cycle in reproductive-age women varies from 21 to 35 days, with a mean of 27 to 29 days (126). Most of the variability in cycle length occurs during the follicular phase (127), but the luteal phase, often considered to be fixed at 14 days, can range from 7 to 19 days (128). Even women with regular monthly menses may have anovulation, although the presence of moliminal symptoms such as premenstrual breast swelling, bloating, and mood changes are much more suggestive of ovulatory cycles (125).

Figure 32.5 Relative hormonal fluctuations in a normal, ovulatory, 28-day menstrual cycle.

Methods to Document Ovulation

The “Fertile Window”

The fertile window is the 6 day interval ending on the day of ovulation, but not after ovulation. Sperm can survive for up to 6 days in well-estrogenized cervical mucus, but the egg may be fertilizable for less than a day. Daily intercourse during this window may increase the probability of conception (32,127). The average woman is fertile between days 10 and 17 of the menstrual cycle, but many women can conceive outside of this range (128). Therefore, if timed intercourse is too cumbersome, intercourse two to three times weekly throughout the menstrual cycle will likely result in at least some of those occasions falling within the fertile window (129). Duration of abstinence prior to the fertile window has not been established, although one author suggests 5 days (127).
Basal Body Temperature

This inexpensive method involves daily recording of oral or rectal temperature using a basal body temperature (BBT) thermometer before the patient arises, eats, or drinks. The secretion of progesterone following ovulation causes a temperature increase of about 0.5 to 1°F over the baseline temperature of 97°F to 98.8°F that is typically recorded during the follicular phase of the menstrual cycle. Ovulation is assumed after 3 consecutive days of raised temperatures. Charting of daily BBTs produces a characteristic biphasic pattern in women with ovulatory cycles (130). **Limitations to BBT include its inability to prospectively predict ovulation and its frequent false-negative results** (131). Smoking and irregular sleep patterns can interfere with accurate BBT testing (130).

Cervical Mucus

During the fertile window, cervical secretions at the vaginal introitus are slippery and clear, while secretions at other times of the menstrual cycle are dry and sticky (32,130). The volume of cervical mucus peaks 2 to 3 days prior to ovulation, thus identifying higher day-specific probabilities of conception (32).

Luteinizing Hormone Monitoring

At a mean time of 2 hours following the peak of the serum LH surge, urinary LH can be detected. Commercially available kits for documenting the LH surge are generally accurate, quick, convenient, and relatively inexpensive enzyme-linked immunosorbent assays (ELISA) that use 35 to 50 mIU/mL as their threshold for detection (132,133). **Once the LH surge is detected, ovulation may occur within the next 48 hours** (32,132,133). The positive-predictive and negative-predictive values for these kits have been described to be 92% and 95%, respectively (132,134). Because the duration of the surge may be less than 12 hours, twice daily testing may increase detection rates (133). However, the 2 days of highest probability of conception are the day of and the day prior to the LH surge, so this may actually lead to abstaining from intercourse during a potentially fertile time (127). False-positive rates occur in 7% of cycles, which may reflect urinary clearance of unsustained premature LH surges (32,131,135). The tests cannot be used in patients with irregular cycles (127).

Midluteal Serum Progesterone

When used to document ovulation, serum progesterone measurement should coincide with peak progesterone secretion in the midluteal phase (typically on days 21 to 23 of an ideal 28-day cycle or 7 days following the LH surge). **The lower limit of progesterone levels in the luteal phase varies among laboratories, but a level above 3 ng/mL (10 nmol/L) typically confirms ovulation.** However, interpretation of isolated luteal-phase measurements of serum progesterone is complicated by the frequent pulses that characterize the secretion of this hormone. Although ovulatory levels are often considerably higher than 3 ng/mL, low midluteal serum levels
of progesterone are not necessarily diagnostic of anovulation (124).

**Ultrasound Monitoring**

Ovulation is characterized both by a decrease in the size of a monitored ovarian follicle and by the appearance of fluid in the cul-de-sac using transvaginal ultrasound (124). **Follicles reach a preovulatory diameter of 17 to 19 mm in spontaneous cycles or 19 to 25 mm for clomiphene-induced cycles (136,137).** A combination of LH testing and ultrasound can be used, with LH kit testing starting when the ultrasound-measured follicle size reaches 14 mm (131). Ten percent of the cycles of normally fertile women may have a luteinized unruptured follicle, whereby progesterone is released and the luteal phase progresses normally without visible signs of follicle rupture when daily ultrasounds are performed from cycle days 10 to 20. This incidence is increased to 25% in women with unexplained infertility (138). **Because of the inconvenience and expense of serial measurements, ultrasound monitoring should be reserved for patients who fail less expensive methods for detecting ovulation or for certain types of ovulation induction (124).**

**Follow-Up Tests**

In women with absent or infrequent ovulation, serum FSH, prolactin, and thyroid-stimulating hormone (TSH) testing should be performed (124).

**Polycystic Ovarian Syndrome**

The most common cause of oligo-ovulation and anovulation—both in the general population and among women presenting with infertility—is polycystic ovarian syndrome (PCOS) (139). The diagnosis of PCOS is determined by exclusion of other medical conditions such as pregnancy, hypothalamic–pituitary disorders, or other causes of hyperandrogenism (e.g., androgen-secreting tumors or nonclassical congenital adrenal hyperplasia) and the presence of two of the following conditions (140):

- Oligo-ovulation or anovulation (manifested as oligomenorrhea or amenorrhea)
- Hyperandrogenemia (elevated levels of circulating androgens) or hyperandrogenism (clinical manifestations of androgen excess)
- Polycystic ovaries detected by ultrasonography

Documentation of elevated serum LH:FSH ratios and hyperinsulinemia are not required for either diagnosis or treatment of PCOS (139,140). Patients with PCOS should be counseled and screened regarding potential metabolic disease and obstetric complications prior to fertility treatment (141).

**Ovulation Induction in Women with Polycystic Ovarian Syndrome**

Despite the use of similar medications, the indications and goals of ovulation induction should be distinguished from those of superovulation. **The goal of ovulation induction refers to the therapeutic restoration of the release of one egg per cycle in a**
woman who either has not been ovulating regularly or has not been ovulating at all. In contrast, the explicit goal of superovulation is to cause more than one egg to be ovulated, thereby increasing the probability of conception in women with unexplained infertility (136).

Weight Loss
Obesity in PCOS patients is associated with poor infertility treatment outcomes (139,142–144), although the impact on pregnancy loss rates is less clear (141,142,145). Given that even a 5% weight loss may improve pregnancy rates, weight loss should be encouraged in all overweight and obese infertility patients (139). Generally, lifestyle modification is the first-line therapy, followed by pharmacologic treatment and weight-loss surgery (139). Lifestyle recommendations include a decrease in daily caloric consumption by 500 kcal and regular physical exercise, although the optimal regimen for the latter is unknown (139,146). Weight loss interventions should be undertaken prior to attempting conception in patients with excess body weight (139).

Clomiphene Citrate (Clomid, Serophene) Pharmacology
Clomiphene citrate is a weak synthetic estrogen that mimics the activity of an estrogen antagonist when given at typical pharmacologic doses for the induction of ovulation. It is cleared through the liver and excreted into the stool, with 85% clearance in 6 days. A functional hypothalamic–pituitary–ovarian axis is usually required for appropriate clomiphene citrate action. More specifically, clomiphene citrate is thought to bind and block estrogen receptors in the hypothalamus for prolonged periods, thereby decreasing the normal ovarian–hypothalamic estrogen feedback loop. This blockade increases GnRH pulsatility, leading to increased pituitary secretion of gonadotropins, which promote ovarian follicular development (136).

Clomiphene Citrate Outcomes
Clomiphene is considered a first-line treatment for anovulatory infertility (147). Over the course of 6 months, clomiphene is associated with 49% ovulation, 23.9% pregnancy, and 22.5% live birth rates in women with anovulatory infertility (142). Clomiphene effectiveness is decreased by obesity, increased age, and hyperandrogenic states (142,148,149). Side effects of clomiphene citrate include vasomotor flushes, mood swings, breast tenderness, pelvic discomfort, and nausea. In a minority of individuals, the antiestrogenic effects of clomiphene citrate at the level of the endometrium or the cervix may have adverse effects on fertility. In the presence of visual abnormalities, clomiphene citrate should be discontinued promptly. Multiple gestation rates with clomiphene citrate are approximately 8%, most of which are twins (136). Treatment should be limited to 6 ovulatory cycles or 12 total cycles (141,150,151).

Clomiphene Citrate Dosing
The drug is supplied in 50 mg tablets; the usual starting dose is 50 mg per day, but
patients who are very sensitive may respond to 12.5 to 25 mg per day. Therapy is typically begun within the first 5 days after the onset of a spontaneous or progesterone-induced menses and is continued for 5 days (i.e., treatment on days 2 to 6, 3 to 7, or 5 to 9 of the menstrual cycle) (136). It has been reported to be effective when started the day following progesterone withdrawal therapy, without waiting for menses (152). If ovulation does not occur at the initial dosage of clomiphene citrate, the dosage is increased in each subsequent cycle by 50 mg per day. Seventy-four percent of women will ovulate with 100 mg per day, the maximum dose approved by the U.S. Food and Drug Administration (153). However, some patients need higher doses, which have been safely given up to 250 mg per day (136). A novel stair-step method has been proposed, which increases the dose within a single cycle without intervening menses if there was no follicular response documented by ultrasound 4 to 5 days after the last pill (154). However, this particular protocol raises concern for unknown endometrial and embryonic effects (155).

Ovulation Monitoring during Clomiphene Citrate Therapy

If preovulation monitoring is not performed, patients should be instructed to have intercourse every 2 to 3 days following the last day of therapy and check a serum progesterone weekly for 5 weeks before inducing a withdrawal bleed or increasing the clomiphene citrate dose (142). Although no clear advantage has been demonstrated for any ovulation monitoring technique, regular contact should be maintained with patients to review response to therapy. The urinary LH surge may be detected 5 to 12 days after treatment is completed. When clomiphene is given cycle days 5 to 9, the surge typically occurs on cycle day 16 or 17 and can be confirmed by midluteal serum progesterone testing 7 days later. With ultrasound monitoring, treatment should be withheld if large cysts are seen on baseline testing. Following clomiphene, follicles typically reach a preovulatory diameter of 19 to 25 mm by ultrasound, but may be as large as 30 mm (136,137). A combination of LH testing and ultrasound can be used, with LH kits starting when the largest ultrasound-measured follicle reaches 14 mm in diameter (131).

Human Chorionic Gonadotropin

If a dominant follicle develops, but there is no spontaneous LH surge, human chorionic gonadotropin (hCG) can be used to induce final follicular maturation, with ovulation occurring approximately 40 hours following administration (136,156). Although administration of hCG at midcycle does not appear to improve conception chances in most infertility patients using clomiphene citrate, it may be useful for patients with known ovulatory dysfunction (157–159). The medication may be derived from urine (5,000 to 10,000 IU intramuscularly) or manufactured with recombinant technology (250 μg subcutaneously, equivalent to 5,000 to 6,000 IU urinary) (156).

Timing of Intrauterine Insemination
When IUI is added to the therapeutic protocol, insemination typically is performed 24 hours following the LH surge (157). However, given data that ovulation can occur much later than this, it is not surprising that no differences in pregnancy rates were found when IUI was performed between 24 and 60 hours following the LH surge (160). Although timing of IUI is typically performed 36 hours following hCG administration to coincide with follicle rupture when hCG is added to trigger ovulation, no significant differences in pregnancy or live birth rates are seen whether IUI is performed at 24 or 36 hours following the hCG trigger (161).

### Insulin Sensitizers

Insulin resistance is thought to play a central role in the pathogenesis of PCOS (Table 32.7). Metformin is an oral biguanide that is approved for the treatment of non–insulin-dependent diabetes and has been used in PCOS to increase the frequency of spontaneous ovulation. Metformin acts by several mechanisms, including inhibition of gluconeogenesis in the liver and increasing the uptake of glucose in the periphery (162). Although the literature is conflicting, larger studies have suggested that the live birth rate with metformin alone (7.2%) is lower than that achieved with clomiphene, and the combination does not confer additional benefit over clomiphene alone (142,163). Obese patients are less likely to respond to metformin (164). It remains unclear whether metformin decreases miscarriage rates in PCOS, although it appears to be safe when used during pregnancy (142,162). Risks of metformin include gastrointestinal upset and rare lactic acidosis, so it should be avoided in settings of hepatic and renal dysfunction and prior to surgery or use of contrast radiologic dye. Reported effective doses include 500 mg three times daily, 850 mg twice daily, or 1,000 mg twice daily (142,162). The medication is best tolerated when started at the lowest dose and increased gradually. Extended release formulations are associated with less gastrointestinal upset (142). Because regular ovulation may be delayed for 3 to 6 months or may not occur with metformin alone, patients may need medications to induce withdrawal bleeding to mitigate the risk of continued anovulation and endometrial hyperplasia (141). Thiazolidinediones, which include rosiglitazone
and pioglitazone, have been used for ovulation induction in PCOS patients (165–168). They have less associated gastrointestinal upset than metformin. All carry the risk of liver toxicity and, in the case of rosiglitazone, cardiovascular harm, and they are typically avoided during pregnancy (141).

**Dexamethasone**

Adjunctive oral dexamethasone may improve ovulation rates in patients resistant to clomiphene alone (147). These improvements have been reported even in the absence of adrenal hyperandrogenemia, so the mechanism of action remains unclear (169,170). Dose regimens have included 0.5 mg for 5 days starting on the first day of clomiphene, 0.5 mg for 6 weeks prior to starting clomiphene, and 2 mg for 10 days starting on the first day of clomiphene (169–172).

**Oral Contraceptive Pretreatment**

Administration of oral contraceptives for 2 months prior to beginning a cycle of clomiphene may improve ovulation and pregnancy rates in clomiphene-resistant patients, perhaps by improving a preexisting hyperandrogenic environment (147,173).

**Tamoxifen**

Tamoxifen is an oral antiestrogen similar in structure to clomiphene that is commonly used as an adjuvant therapy for breast cancer but has been used off-label to induce ovulation (174). Ovulation and pregnancy rates are similar with tamoxifen and clomiphene (147,174). Doses start at 20 mg per day for 5 days (similar in timing to clomiphene), and can be increased to 40 or 60 mg per day in subsequent cycles. The mechanism of action for tamoxifen in inducing ovulation appears to be similar to that of clomiphene, although tamoxifen exerts less negative endometrial effects (175).

**Aromatase Inhibitors**

These drugs include letrozole and anastrozole. Through their inhibition of aromatase-mediated conversion of androgens to estrogens and subsequent decreases in circulating estradiol, aromatase inhibitors have been approved for treatment of breast cancer. The off-label use of letrozole for ovulation induction in clomiphene-resistant patients was first reported in 2001 (176). Typical doses are 2.5 to 5 mg of letrozole or 1 mg of anastrozole daily for 5 days. Timing of administration is similar to that of clomiphene, although longer durations of 10 days have been reported (177,178). Letrozole appears to have less negative effects on endometrial development when compared to clomiphene (176). Although concerns have been raised regarding possible associations between fetal congenital anomalies and the use of aromatase inhibitors, no such increase was observed when letrozole was compared to clomiphene (179). Patients should be counseled regarding the absence of prospective, sufficiently powered studies to assess safety of off-label use of aromatase inhibitors for ovulation induction (141).
Gonadotropin Therapy

Anovulatory PCOS patients who fail to ovulate or conceive with oral agents should be considered for ovulation induction with exogenous gonadotropin injections. Evening medication administration allows for morning monitoring and midday decision making. Monitoring involves serum estradiol levels and transvaginal ultrasound measurements of follicle development. Typical protocols monitor at baseline, 4 to 5 days after treatment initiation, then every 1 to 3 days until follicular maturation (expected follicle growth is 1 to 2 mm daily after achieving 10 mm diameter) (180). Given the goal of promoting growth of a single mature follicle, low initial gonadotropin doses of 37.5 to 75 IU per day are generally recommended, with increases in doses by 50% of the previous dose after 7 days if no follicle greater than 10 mm is observed (141,180). Typical treatment duration is 7 to 12 days, but some patients require longer medications regimens for adequate stimulation. The maximum required gonadotropin dose seldom exceeds 225 units per day. Ovulation triggering with hCG is recommended for gonadotropin cycles and is used when one or two follicles are 16 to 18 mm in diameter and the E2 level per dominant follicle is 150 to 300 pg/mL. Ovulation can be expected 24 to 48 hours after the hCG trigger. GnRH agonists such as leuprolide (500 μg subcutaneously) can be used to trigger ovulation, but they require progesterone supplementation following administration. Intercourse should be recommended within 24 to 48 hours of ovulation triggering or IUI 24 to 36 hours after triggering (180). Testing for pregnancy should be performed 15 to 16 days after ovulation triggering and the cycle reviewed if pregnancy testing is negative. Gonadotropin dosage in future cycles should be altered if the prior response was inadequate or excessive.

Gonadotropin Preparations

Several gonadotropin preparations are available. Human menopausal gonadotropin (HMG) is derived from human urine and includes approximately equivalent FSH and LH (derived from hCG) activity of 75 IU each. Current formulations of HMG and FSH can be administered either subcutaneously or intramuscularly. FSH-only preparations may be derived either from urine or via recombinant methods and are packaged either as lyophilized powder or premixed-liquid cartridges/pens. With the exception of highly purified urinary FSH, which has an FSH activity of 82.5 IU per ampule, all other products contain 75 IU of gonadotropin when supplied in ampules. All preparations of FSH are highly purified, with minimal to no batch-to-batch variation and a high level of safety regardless of the derived source. Despite being differentially marketed as follitropin-α and -β, these recombinant FSH preparations still contain combinations of 1-α and 1-β glycoprotein chain. Rather, they differ in their posttranslational modifications and processes for purification. Recombinant LH is available in syringes delivering 75 IU (156). For PCOS patients, FSH alone (either recombinant or urinary) appears to be sufficient in the gonadotropin preparation, although LH is not harmful (180) (Table 32.8). Contraindications to gonadotropin therapy are listed in Table 32.9.

Table 32.8 Different Types of Available Gonadotropin Preparations
Table 32.9 Contraindications to Gonadotropins for the Treatment of Infertility in Women

1. Primary ovarian failure with elevated follicle-stimulating hormone levels
2. Uncontrolled thyroid and adrenal dysfunction
3. An organic intracranial lesion such as a pituitary tumor
4. Undiagnosed abnormal uterine bleeding
5. Ovarian cysts or enlargement not caused by polycystic ovary syndrome
6. Prior hypersensitivity to the particular gonadotropin
7. Sex hormone–dependent tumors of the reproductive tract and accessory organs
8. Pregnancy

Gonadotropin Outcomes

Cumulative live birth rates are similar when gonadotropins are compared to clomiphene for ovulation induction when the goal is monofollicular ovulation and a maximum of six ovulatory cycles is similarly recommended (141). When compared to other anovulatory patients, PCOS patients using gonadotropins are at higher risk for multiple gestations (36%), ovarian hyperstimulation syndrome (4.6%), and cycle cancellation (10%) because of their high numbers of baseline antral follicles (141,180, 181). Cancellation should be strongly considered in patients who reach E2 levels 1,000 to 2,500 pg/mL, have three or more follicles 16 mm or larger, or two or more follicles 16 mm or larger plus two or more follicles 14 mm or larger (141). Sequential use of gonadotropins and either clomiphene or aromatase inhibitors has been associated with lower gonadotropin requirements and lower cancellation rates and
treatment duration without compromising pregnancy rates. The addition of aromatase inhibitors is associated with a lower number of dominant follicles and lower maximum E2 levels (182–184).

Surgical Treatment

For clomiphene-resistant patients, surgical ovarian drilling has been performed as an alternative to the outdated ovarian wedge resection in an effort to decrease ovarian androgen-producing tissue and to promote ovulation without the risk of multiple pregnancy seen with gonadotropin administration (141,185). Drilling 3 to 15 puncture sites per ovary is typically performed via laparoscopy using electrocautery and diathermy or laser, although transvaginal ultrasound-guided and vaginal hydro-laparoscopy procedures have been reported (186–195). Successful drilling has been performed with the harmonic scalpel (190). Within 12 months after ovarian drilling, cumulative ovulation, clinical pregnancy, and live birth rates are 52%, 26% to 48%, and 13% to 32%, respectively. These outcomes are similar to those using gonadotropins, but ovarian drilling carries a lower multiple gestation rate. Outcomes are not significantly different when diathermy or laser are used for drilling, but they are compromised with patient age greater than 35 years or basal FSH greater than 10 mIU/mL (185,187). The risks of ovarian drilling include surgical complications, adhesions, recurrence of anovulation, and a theoretical risk of ovarian failure (185,196).

Ovulation Induction for Other Anovulatory Disorders

Hyperprolactinemia

Hyperprolactinemia can be associated with oligomenorrhea or amenorrhea and should be evaluated with pituitary magnetic resonance imaging (MRI) to exclude macroadenoma or other intracranial pathology (197). Dopamine agonists are first-line agents in otherwise asymptomatic oligoovulatiory or anovulatory patients to restore ovulation (197). Bromocriptine normalizes prolactin levels and induces ovulation in 80% to 90% of patients. It is taken two to three times daily, and most patients will respond to a total dose less than 7.5 mg daily. Side effects can be bothersome and include nausea, vomiting, postural hypotension, and headache. Cabergoline has similarly high efficacy and the advantage of a 0.25 mg twice-weekly dosing schedule and fewer side effects (198).

Hypogonadotropic Hypogonadism

Anovulation in the presence of low serum LH, FSH, and estradiol levels defines hypogonadotropic hypogonadism and reflects dysfunction within the hypothalamic–pituitary axis. Causes of hypogonadotropic hypogonadism, including craniopharyngiomas, pituitary adenomas, arteriovenous malformations, or other central space-occupying lesions, should be excluded using MRI. Stress, extreme weight loss, anorexia, excessive exercise, and low body mass index are all associated with functional hypothalamic suppression, so good nutrition and optimal body weight should be
encouraged to restore ovulation (197,199). Leptin is a hormone produced by peripheral adipocytes that reflects energy stores and is deficient in women with diet or exercise-induced amenorrhea (200). Exogenous leptin has been reported to restore ovulation in these women (200,201). Other conditions of hypothalamic dysfunction, such as congenital hypothalamic failure (Kallmann syndrome), can be treated using pulsatile GnRH therapy or gonadotropins. In these patients, both FSH and LH should be administered (197,202). Pulsatile GnRH agonist therapy (25 ng/kg every 60 to 90 minutes) simulates normal physiology and offers some advantages over gonadotropin injections, including fewer multiple gestations and less ovarian hyperstimulation syndrome (OHSS) while maintaining excellent pregnancy rates (202).

**Hypothyroidism**

The prevalence of hypothyroidism among mid-reproductive aged women is 2% to 4% and is mostly a result of autoimmune factors. Menstrual abnormalities, including those from anovulation, are present in 23% to 68% of overtly hypothyroid women and can be corrected with levothyroxine replacement. Subclinical hypothyroidism and the presence of antithyroid antibodies (even if euthyroid) are associated with increased rates of infertility and spontaneous pregnancy loss, although there exists a lack of consensus as to appropriate upper normal limits of TSH and selection bias limits interpretation. In any case, because even very mild or subclinical hypothyroidism can have adverse effects on fetal brain development and subsequent intelligence quotient, it is prudent to screen and treat women with thyroid hormone abnormalities before commencing infertility treatment (203).
Tubal Factor

Tubal factor accounts for 25% to 35% of infertility. Noninfectious causes for tubal factor include tubal endometriosis, salpingitis isthmica nodosa, tubal polyps, tubal spasm, and intratubal mucous debris (10). The incidence of tubal infertility has been reported to be 8%, 19.5%, and 40% after one, two, and three episodes of PID, respectively (204). Live birth rates are negatively affected by the severity of a single episode of PID (205). C. trachomatis and Neisseria gonorrhoeae are common pathogens associated with PID and infertility. M. hominis and U. urealyticum have been implicated in PID, but their contribution to infertility is less clear (17). Many patients with documented tubal damage have no history of PID and are presumed to have had subclinical chlamydial infections (206,207).

Hysterosalpingography

Hysterosalpingography (HSG) is performed after menses but prior to ovulation between cycle days 7 and 12 to avoid potential pregnancy and take advantage of the thinner proliferative phase endometrium. The patient is typically premedicated 30 to 60 minutes prior to the procedure with ibuprofen or related medication (208). Lidocaine injected intracervically may provide further pain relief (209). With the patient in the dorsal lithotomy position, either a metal cannula or a balloon catheter is inserted through the cervix and past the internal cervical os. Contrast dye is then injected under fluoroscopy to visualize the uterine cavity, fallopian tube architecture, and tubal patency (208,210). Certain disease processes, such as salpingitis isthmica nodosa, have a characteristic appearance on HSG, with typical cornual or isthmic honeycombing resulting from contrast-filled diverticular projections (211). Compared to laparoscopy, HSG has a sensitivity and specificity of 86.5% and 79.8% for bilateral tubal patency and 90% and 97% for bilateral tubal occlusion, respectively. The specificity of HSG remains high but the sensitivity drops for unilateral tubal patency (212).

Hysterosalpingography Risks

Although use of oil-based contrast has been associated with higher pregnancy rates following HSG when compared to water-based contrast (213,214), water-based contrast is generally preferred to avoid oil embolism or granuloma formation. Furthermore, patients should be screened for and pretreated with glucocorticoids if iodine allergy is found (210). The risk of PID after HSG is 0.3% to 3.1% overall but is greater than 10% in the setting of hydrosalpinges (215,216). Therefore, HSG should be avoided in the setting of known hydrosalpinges and/or current or suspected PID (208,216). The role of routine antibiotic prophylaxis for HSG is controversial, but in high-risk patients doxycycline could be considered (217). Recommended dosing is 100 mg twice daily, beginning the day before HSG and continuing for 3 to 5 days. If prophylaxis is not used and hydrosalpinges are noted on examination, postprocedure doxycycline treatment is recommended. Other rare complications of HSG include vascular intravasation, cervical laceration, uterine perforation, hemorrhage, vasovagal reactions, severe pain, and
allergic response to the contrast dye (208).

**Chlamydia Serology**

Chlamydia antibody testing appears to have comparable sensitivity and specificity to HSG but does not localize pathology and the utility of testing is controversial (211). It has been proposed that positive serologies in the setting of normal HSG should still prompt laparoscopy to rule out peritubal adhesions (207).

**Laparoscopy**

Laparoscopy is considered the gold standard for diagnosing tubal and peritoneal disease. It allows visualization of all pelvic organs and permits detection and potential concurrent treatment of intramural and subserosal uterine fibroids, peritubal and periovarian adhesions, and endometriosis. Abnormal findings on HSG can be validated by direct visualization on laparoscopy using chromopertubation, which involves the transcervical installation of a dye such as indigo carmine to directly visualize tubal patency and fimbrial architecture (212). However, even laparoscopy has been reported to have a false-positive rate of 11% for proximal tubal occlusion when resected tubal segments are examined pathologically (218).

**Other Diagnostic Modalities**

Falloposcopy is used in conjunction with hysteroscopy and allows direct fiberoptic visualization of tubal ostia and intratubal architecture for identification of tubal ostial spasm, abnormal tubal mucosal patterns, and even intraluminal debris causing tubal obstruction (218,219). At present, instrumentation availability and technical complications, including tubal perforation, limit its routine use (219). Alternatively, sonohysterography offers a much less invasive method of diagnosing fallopian tubal obstruction. The use of contrast media during sonohysterography is preferred to improve accuracy in documenting fallopian tubal patency, but these contrast agents are not available in the United States. As a substitute, the use of agitated saline (air-saline) during sonohysteroscopy provides good negative predictive value when compared to HSG or laparoscopy (220).

**Treatment of Tubal Factor Infertility**

As success rates for ART continue to improve, the indications for surgical approaches in the treatment of tubal infertility have become increasingly limited (221). Still, surgery can be effective in several situations and may be the optimal approach in some patients.

**Proximal Tubal Occlusion**

Proximal tubal catheterization and cannulation performed either via HSG or hysteroscopy can restore tubal patency in up to 85% of obstructions, although the reocclusion rate approaches 30%. The best candidates for proximal tubal catheterization or cannulation have muscle spasm, stromal edema, amorphous debris, mucosal
agglutination, or viscous secretions, while nonresponders include those with luminal fibrosis, failed tubal reanastamosis, fibroids, congenital atresia, or tuberculosis. Occlusion from salpingitis isthmica nodosa, endometriosis, synechiae, salpingitis, and cornual polyps only occasionally will respond to catheterization or cannulation (10). Catheterization involves passage of a soft catheter into the tubal ostia, while cannulation passes a guidewire thru the ostia and injects contrast media or colored dye. Tubal perforation, typically minor, occurs in 1.9% to 11% of cases (10,211,218). Catheterization under fluoroscopy during HSG is referred to as selective salpingography (222). Visualization of patency with the hysteroscopic approach can be accomplished using laparoscopy or ultrasound (10,218). Ongoing pregnancy rates following proximal tubal catheterization or cannulation are 12% to 44% regardless of hysteroscopic or HSG approach. If occlusion persists or recurs, IVF is usually recommended. Microsurgical tubocornual anastomosis is an option with small studies reporting pregnancy rates of up to 68% (10). This procedure typically is performed via laparotomy and involves excision of the tubal isthmus, followed by reimplantation of the residual tube into a new opening made through the uterine cornua (211).

Distal Tubal Occlusion (Excluding Sterilization or Hydrosalpinx)

Distal tubal disease and occlusion are causal in 85% of all tubal infertility and can be secondary to a variety of inflammatory conditions including infection, endometriosis, or prior abdominal or pelvic surgery (211,223). Patients younger than 35 years of age with mild distal tubal disease, normal tubal mucosa, and absent or minimal pelvic adhesions are the best candidates for corrective microsurgery (223). In vitro fertilization should be considered for older patients or those with diminished ovarian reserve, combined proximal and distal tubal disease, severe pelvic adhesions, tubal damage that is not amenable to reconstruction, or additional infertility factors (223,224). Fimbrioplasty involves lysis of fimbrial adhesions or dilation of fimbrial phimosis, whereas salpingostomy (also known as salpingoneostomy) involves the creation of a new tubal opening in an occluded fallopian tube (223). In well-selected patients, pregnancy rates are reported to be 32% to 42.2%, 54.6% to 60%, 30% to 34.6%, and 55.9% for adhesiolysis, fimbrioplasty, salpingostomy, and nonsterilization-related anastamosis, respectively (211,223). As a group, these procedures are associated with a 7.9% rate of subsequent ectopic pregnancy (223).

Sterilization Reversal

Twenty percent of women express regret following sterilization, and 1% to 5% of those will request reversal, often after a change in marital status. The technique for sterilization reversal involves microsurgical dissection of the occluded ends of the fallopian tube followed by a layered reapposition of the proximal and distal tubal segments. Surgical approaches include minilaparotomy, laparoscopy, and robotic-assisted laparoscopy (224,225). Pregnancy rates following microsurgical tubal reanastamosis for sterilization reversal are 55% to 81%, with most pregnancies occurring within 18 months of surgery (224). Ectopic pregnancy rates following the procedure are generally less than
10% but may approach 18% (223,226). The main predictors of success are age younger than 35 years, isthmic-isthmic or ampulo-ampullar anastamosis, final anastamosed tubal length greater than 4 cm, and less-destructive sterilization methods such as use of rings or clips (224,226). Unlike vasectomy reversal, the length of time between fallopian tubal sterilization and reversal does not seem to affect outcome. IVF should be considered in lieu of sterilization reversal for older patients or those with diminished ovarian reserve, severe pelvic adhesions, additional infertility factors, or prior unsuccessful reanastamosis (223,224).

Hydrosalpinx

Distal occlusion may lead to fluid buildup in the fallopian tube, causing a hydrosalpinx. Hydrosalpinx fluid impedes embryo development and implantation (211). A meta-analysis of 14 studies and 1,004 patients with hydrosalpinges concluded that IVF pregnancy rates were significantly lower in the presence of hydrosalpinges (227). Salpingectomy for hydrosalpinx prior to IVF significantly improves both pregnancy and live birth rates when compared to IVF performed with the fallopian tubes in situ, although laparoscopic tubal occlusion appears to be a reasonable alternative (228–230). There are significantly less outcome data on the use of transvaginal needle drainage and salpingostomy for treatment of hydrosalpinges prior to IVF (211).
Pathologies within the uterine cavity are the cause of infertility in as many as 15% of couples seeking treatment and are diagnosed in greater than 50% of infertile patients (231). Therefore, the evaluation of the couple with infertility should consistently include an assessment of the endometrial cavity. Uterine cavity abnormalities include endometrial polyps, endometrial hyperplasia, submucous myomas, intrauterine synechiae, and congenital uterine anomalies (232).

Diagnostic Imaging for Uterine Pathology

Hysteroscopy

Hysteroscopy is considered the gold standard for uterine cavity evaluation because it allows for direct visualization. The procedure involves insertion of an endoscope through the cervical canal into the uterine cavity and instillation of distension media to allow for visualization (231–233). Diagnostic hysteroscopy may be performed in the office using a small-diameter hysteroscope and saline distension, often without need for anesthesia (232). To optimize visualization of the endometrial cavity and avoid performing the procedure during early pregnancy, hysteroscopy is typically scheduled during the early- to midfollicular phase of the cycle. Disadvantages to the procedure include poor visualization when uterine bleeding is present and the inability to evaluate structures outside the uterine cavity, including those in the myometrium and adnexa. Office hysteroscopy is reported to have a 72% sensitivity for cavity abnormalities when compared to operative hysteroscopy using general anesthesia (231).

Hysterosalpingogram

Insofar as it allows assessment of both tubal and intrauterine pathology, HSG is a reasonable initial imaging technique to use in the basic infertility evaluation. Hysterosalpingogram shows the general configuration of the uterine cavity and indicates endometrial lesions as filling defects or irregularities of the intrauterine wall. Excessive contrast may lead to false-negative findings, which may account for the 50% sensitivity of HSG compared to hysteroscopy for endometrial polyps. Inability to discriminate air bubbles, mucous, and debris from true intracavitary pathology may account for HSG’s high false-positive rate when compared with hysteroscopy (232,233). Other drawbacks include patient discomfort, use of iodinated contrast, and radiation exposure (232).

Transvaginal Ultrasound

Compared to hysteroscopy, transvaginal ultrasound has a 75% positive predictive value and 96.5% negative predictive value for intracavitary polyps but a 0% positive predictive value for intrauterine adhesions. Similar to HSG, it has a sensitivity of 44% for uterine malformations (233). However, this may be improved significantly with the use of three-
Sonohysterography
Saline infusion sonography (SIS), synonymous with sonohysterography, involves the transcervical instillation of saline, often via a balloon catheter, during transvaginal ultrasound to distend the uterine cavity and delineate the endometrium. As with office hysteroscopy and HSG, SIS is performed during the follicular phase of the cycle and anesthesia typically is not required. Endometrial polyps appear as hyperechogenic pedunculated lesions, submucous fibroids have mixed echogenicity, and adhesions contain densely echogenic and cystic areas (234). Compared to hysteroscopy, SIS has 100% sensitivity, specificity, and positive and negative predictive values for uterine polyps (233). Because of a smaller volume of distension media used, SIS is generally better tolerated than HSG or hysteroscopy (231,234). Another advantage of SIS is the ability to evaluate the myometrium and the adnexa for fibroids or adenomyosis. When combined with three-dimensional technology, SIS is particularly good at assessing the overall uterine contour and delineating congenital anomalies such as septate uteri (234). Standard SIS has somewhat lower sensitivity of 77.8% in detecting uterine congenital anomalies when compared to hysteroscopy, but this is higher than both two-dimensional transvaginal ultrasound and HSG. Hysterosalpingogram and SIS perform similarly for intrauterine adhesions, each having approximately 50% positive predictive value and greater than 90% negative predictive value (233).

Magnetic Resonance Imaging
Although transvaginal ultrasound, HSG, SIS, and hystero-scopy may suggest congenital uterine anomalies, pelvic MRI is considered the gold standard for imaging and is particularly useful for diagnosing rudimentary uterine horns (235). Pelvic MRI has the best sensitivity and specificity for intramural and submucous myomas compared to pathologic examination and is especially useful for detecting large or multiple fibroids (236,237). MRI has been suggested as a tool to differentiate fibroids from adenomyosis, but routine substitution for ultrasound is not recommended (237,238).

Congenital Anomalies of the Uterus
Congenital uterine anomalies occur in 3% to 4% of women. This increases to 5% to 10% in women with early pregnancy loss and up to 25% in those with second and third trimester pregnancy losses (235). During female embryonic development, the paired paramesonephric or müllerian ducts elongate toward each other and fuse in the midline. This is followed by resorption of the intervening septum to form the upper vagina, cervix, uterus, and fallopian tubes by week 20 of gestation. Failure of any of these steps leads to absent uterine development or development of unicornuate, bicornuate, arcuate, didelphic, or septate uteri. Because of the proximity of the paramesonephric ducts to the urinary system, renal anomalies often coexist with müllerian anomalies. Appropriate urologic imaging should be performed whenever a müllerian
An anomaly is diagnosed (235,239). Uterine anomalies are more closely associated with pregnancy wastage and poor obstetric outcomes than with infertility, as the prevalence of congenital uterine defects is generally similar among fertile and infertile women. The exception to this is müllerian agenesis. Patients with müllerian agenesis can have genetically related children only through the use of IVF and a gestational carrier. The arcuate uterus is the mildest congenital uterine anomaly and typically live birth rates are comparable to those in women with normal uteri (235).

Surgical uterine repair to improve obstetric outcomes is controversial for most anomalies. However, rudimentary uterine horns require removal on diagnosis, and hysteroscopic metroplasty of the septate uteri significantly reduces the rates of pregnancy loss, but not infertility (235,240). The number of reproductive-age patients presenting with in utero exposure to DES is declining rapidly and will continue to decline in the future, because the substance was banned in 1971. Women whose mothers were exposed to DES have higher rates of uterine malformations (e.g., T-shaped uterus) and associated obstetric complications (235).

Acquired Abnormalities of the Uterus

Leiomyomas

Leiomyomas, also called myomas or fibroids, are benign monoclonal uterine myometrial tumors that affect 25% to 45% of reproductive-age women, particularly African Americans (241). The mechanisms by which fibroids cause infertility are unknown, but may involve altered uterine contractility, impaired gamete transport, or endometrial dysfunction (242). Among women with infertility and uterine leiomyomas, pregnancy rates are primarily affected by leiomyoma location (236,242). Subserosal fibroids do not appear to affect fertility or obstetric outcomes, while intramural (regardless of cavity distortion) and submucosal myomas are associated with lower implantation and live birth rates (236,242,243). It remains unclear whether the size of intramural fibroids determines pregnancy rates and obstetric outcomes, because lower or unchanged pregnancy rates have been reported among patients with fibroids of varying sizes including >2cm, >4cm, or 4–8 cm when compared to patients without fibroids (242).

Myomectomy

In women desiring fertility who require treatment for fibroids, myomectomy is the preferred approach, and uterine artery embolization is relatively contraindicated (242). Removal of cavity-distorting intramural and submucosal myomas is generally recommended prior to proceeding with infertility treatment. The utility of surgical removal of non-cavity-distorting intramural fibroids is presently unknown (236,242, 243). Myomectomy can be performed hysteroscopically, via laparotomy, laparoscopically (alone or with robotic assistance), or vaginally (237,241,244–246). Hysteroscopic removal is generally preferred for small submucous...
fibroids without intramural involvement, while use of the other methods generally depends on patient preference, operator skill, or the presence of other pelvic pathology (237,241,244,245). The utility of pretreatment with GnRH agonists prior to surgery is debatable. GnRH agonists may shrink larger fibroids (5 to 6 cm) enough to allow hysteroscopic resection and may decrease the risk of intraoperative blood loss and postoperative anemia. **Fluid overload and uterine perforation are the most common complications of hysteroscopic myomectomy, while bleeding and adjacent organ injury are more often associated with alternative approaches (237,241).** Fibroids that are located low on the uterus and posteriorly are less amenable to laparoscopic resection. Transmyometrial approaches raise concern for uterine rupture during pregnancy, although this risk appears to be very low (241).

**Endometrial Polyps**

The incidence of asymptomatic endometrial polyps among women with infertility has been reported to range from 6% to 8%, but may be as high as 32% (247–249). Risk factors for polyp development include obesity, unopposed estrogen exposure, and polycystic ovary syndrome. The mechanisms by which endometrial polyps may impair fertility are incompletely described but may relate to disordered endometrial receptivity (250). One report localized 32% of endometrial polyps in infertile women to the posterior uterine wall, indicated that 40.3% of patients had multiple polyps, and stated a 6.9% hyperplasia rate (251). Polypectomy is generally performed via curettage, blind avulsion, or hysteroscopic removal (249). **Although the efficacy of polypectomy prior to infertility treatment has not been clearly established, a prospective randomized trial showed a 2.1-fold higher rate of pregnancy among women who underwent the procedure prior to IUI (249,252).** Higher pregnancy rates have been noted for polyps removed from the uterotubal junction when compared to those removed from other locations (251). Smaller nonrandomized studies provide conflicting data on the negative fertility effects of polyps less than 1.5 to 2 cm (251,253,254).

**Intrauterine Synechiae or Asherman’s Syndrome**

Severe trauma to the basalis layer of the endometrium with subsequent tissue bridge formation leads to intrauterine synechiae or Asherman’s syndrome. Symptoms of severe disease include amenorrhea, menstrual irregularities, spontaneous abortion, and recurrent pregnancy loss. **The causes of intrauterine adhesions are often iatrogenic, with patients typically reporting intraoperative or postoperative complications of uterine evacuations for incomplete pregnancy loss, pregnancy termination, or postpartum hemorrhage.** Myomectomy, hysterotomy, diagnostic curettage, cesarean section, tuberculosis, caustic abortifacients, and uterine packing are less-common causes in Western countries (255). In developing countries, Asherman’s syndrome resulting from genital tuberculosis is quite common (256). **Hysteroscopic resection of synechiae is the preferred treatment to restore fertility in women with Asherman’s syndrome, and success rates are generally very high. Patients with genital tuberculosis have a very poor prognosis.** Postoperative prevention of
adhesion reformation disease may involve estrogen therapy alone for 1 month or in combination with intraoperative placement of an intrauterine device (such as a small Malecot catheter or pediatric Foley catheter) for 1 to 2 weeks. There is no standard regimen for estrogen therapy, but oral conjugated estrogens 2.5 mg daily overlapping with progestin or estradiol valerate 2 mg injections daily have been suggested (255,257).

Luteal-Phase Defect and Progesterone Supplementation

Mechanisms
The luteal phase is normally characterized by progesterone secretion by the corpus luteum and appropriate endometrial secretory transformation that allow for embryonic implantation in the endometrium and support of early pregnancy for the first 7 to 8 weeks of gestation (258,259). Luteal phase defect (LPD) is a failure to develop a fully mature secretory endometrium during the implantation window and is thought to account for 4% of infertility (260,261). Proposed mechanisms for LPD include inadequate production of progesterone following ovulation, improper GnRH pulsatility causing insufficient gonadotropin production during the LH surge, and inadequate endometrial responsivity to progesterone (260–262). ART or gonadotropin ovulation induction medications may induce iatrogenic LPD via disruption of granulosa cells from follicular aspiration and suppression of endogenous LH secretion through a combination of supraphysiologic estradiol levels and GnRH agonist or antagonist therapy (259,262).

Diagnosis
Diagnostic criteria for LPD have been varyingly defined, but have included a low mid-luteal phase serum progesterone levels of less than 5 to 10 ng/mL, a delay of 2 days or more in endometrial histology when compared to chronologic cycle day in two or more cycles, a BBT rise lasting less than 11 days, and a shortened luteal phase of less than 14 days (259–261). Unfortunately, the characteristic pulsatile secretion of progesterone during the luteal phase of the menstrual cycle combines with wide temporal variations (even within a 60- to 90-minute time span) to make interpretation of midlueal progesterone levels difficult (258). Similar rates of shortened luteal phase are found in fertile and infertile women, and there is significant variability of luteal phase length from cycle to cycle in an individual woman (261). Finally, there is significant interobserver variability in pathologic interpretation of endometrial biopsies from infertile women, and out-of-phase biopsy results poorly discriminate between fertile and infertile women (263,264).

Treatment
Progesterone therapy is considered standard practice during ART cycles, but is more controversial during non-ART fertility treatments (258,259,262). When used, progesterone supplementation can be administered via oral, vaginal, or
Intramuscular routes. Intramuscular progesterone is dosed at 25 to 50 mg daily. Most products are delivered in oil, and caution should be used to ascertain the presence of sesame or peanut allergies. Oral micronized progesterone is associated with erratic absorption and decreased bioavailability, so it is typically administered via an off-label delivery route—vaginally 200 to 600 mg daily, and often in divided doses. The side effects of this delivery route, however, can include vaginal discharge and irritation. Other vaginal preparations include a once-daily gel and a 100 mg insert that is given two to three times daily. **There remains no consensus regarding the superiority of vaginal versus intramuscular administration.** Progesterone therapy typically begins 3 to 4 days following the hCG trigger or LH surge and, if pregnancy occurs, continues for at least 8 to 9 weeks of gestation (258,259,262). Although some progestins can stimulate the androgen receptor, there is no evidence of teratogenicity with the progesterone supplementation described herein (258).
Pelvic Factor

Endometriosis

Endometriosis affects 6% to 10% of all women during their reproductive years but is present in 25% to 50% of infertile women (212,265). It is characterized by the presence of endometrial tissue growing outside the uterine cavity and is found primarily on the peritoneum, ovaries, and rectovaginal septum (265). Fecundability rates in affected patients are estimated at 2% to 10% per month (266).

Possible mechanisms for infertility among women with endometriosis include anatomic distortion from adhesions or fibrosis and the known presence of inflammatory mediators that exert toxic effects on gametes, embryos, tubal fimbria, and eutopic endometrium (265,266). Laparoscopy for direct visualization remains the mainstay in the diagnosis of endometriosis. The disease is staged laparoscopically according to the Revised American Society for Reproductive Medicine’s classification, with stages III and IV (moderate to severe) including ovarian endometriomas, dense tubal or ovarian adhesions, and/or cul-de-sac obliteration (265).

However, laparoscopy can miss deep disease that may better be detected by ultrasound (i.e., endometriomas) and rectovaginal examination (267). It is unclear whether the presence of endometriosis negatively affects IVF outcomes, although some reports indicate a worse prognosis for more severe disease (stages III and IV) (221,268).

Endometriosis Infertility Management

Hormonal suppression of endometriosis typically has a minimal benefit for endometriosis-related infertility (265). In minimal to mild disease, laparoscopic ablation appears to significantly improve pregnancy rates when compared to diagnostic laparoscopy alone, although there remains some dissent (267,269). One major randomized trial reported 31% versus 17% pregnancy rates over 3 years with a subsequent meta-analysis supporting these findings (265,266,270,271). Although authors have estimated that eight laparoscopies involving treatment of mild or minimal endometriosis would need to be performed for each pregnancy gained, that number is likely to be much higher given that not everyone who undergoes laparoscopy will have endometriosis (267,270). The benefit of surgical management of endometriosis is even less clear for moderate to severe disease, although removal of endometriomas may be indicated prior to IVF when they would interfere with oocyte retrieval (265–267). Endometrioma resection during IVF or ICSI treatment is associated with decreased ovarian function in up to 13% of cases (272,273). Furthermore, 40% of endometriomas recur postoperatively, and conflicting reports exist that show increases and decreases in pregnancy and live birth rates after surgery (267,272,273). Therefore, IVF is considered a reasonable first-line therapy for endometriosis-associated infertility because of the short time to pregnancy and avoidance of surgery (221).

Adhesions
Adhesions may result from sharp, mechanical, or thermal injury, infection, radiation, ischemia, dessication, abrasion, or foreign body reaction. Adhesiolysis improves pregnancy rates by 12% at 1 year and by 29% at 2 years in infertile women with adnexal adhesions. Use of adhesion barriers reduces adhesion formation following laparoscopy and laparotomy, but there is no evidence to date for improvement in pregnancy rates (274,275).
Unexplained Infertility

Thirty percent of couples are diagnosed with unexplained infertility, in which the basic infertility evaluation reveals normal semen parameters, evidence of ovulation, patent fallopian tubes, and no other obvious cause of infertility. Patients with unexplained infertility may be reassured that even after 12 months of failed attempts, 20% will conceive in the following 12 months and over 50% in the following 36 months. This suggests that in couples with the good prognostic factors of female age less than 30, less than 24 months of infertility, and a previous pregnancy in the same partnership, unexplained infertility may merely reflect the lower extreme of normal fertility. It is likely that current technology is limited in terms of diagnosing all causes for infertility, and the utility of evaluations other than basic testing in an infertile couple has yet to be proven (2,150,276).

Proposed Mechanisms for Unexplained Infertility

Luteinized Unruptured Follicle Syndrome

This condition involves luteinization of a follicle that has failed to rupture and release its oocyte, leading to a normal menstrual cycle but infertility. It is thought to occur in up to 25% of patients with unexplained infertility, more than twice the incidence in fertile women (138). The diagnosis may justify the use of IVF whereby follicles are aspirated and oocyte are retrieved and fertilized in vitro.

Immunologic Factors

Although serum antiphospholipid antibodies and antithyroid antibodies are more prevalent among patients with unexplained infertility than among fertile women, the presence of antiphospholipid antibodies has not been found to adversely affect IVF outcomes, so screening is discouraged (277,278). The association between the presence of antithyroid antibodies and infertility is inconsistent, so screening is not recommended (279–282). Unexplained infertility has been associated with antisperm antibodies, but the extent to which these antibodies affect fertility treatment outcomes and whether IUI, ICSI, or glucocorticoids should be used remains unclear (280,282,283). A similar lack of consensus exists concerning the assessment of peripheral natural killer cell number and/or activity in infertility patients (276,282).

Decreased Endometrial Perfusion

Using ultrasound-based endometrial Doppler studies, women with unexplained infertility have been shown to exhibit abnormal endometrial perfusion when compared to fertile women, but, at present, there is no direct link to fertility treatment outcomes and no recommendations to act on these findings (284).

Infection
C. trachomatis and related clinical and subclinical infections have been discussed in the “Tubal Factor” section. To date, no consistent associations have been reported between chlamydial species, M. hominis, and unexplained infertility in men or women (207,285,286). U. urealyticum and M. genitalium, however, may be more of a concern (287). Prophylactic doxycycline (100 mg twice daily for 4 weeks) given to infertile couples improved pregnancy rates only for those couples in which the male partner was able to clear a ureaplasma infection (288). Antimicrobial prophylaxis is often given for ART, but it is not clear the extent to which clearance of these organisms improves pregnancy rates (287,289).

**Undiagnosed Pelvic Pathology**

Following a negative infertility workup, laparoscopy has been proposed to evaluate for peritubal adhesions and endometriosis. However, there is a lack of consensus as to the frequency of these abnormalities in women with unexplained infertility, and many practitioners will forgo laparoscopy in lieu of a few cycles of less invasive interventions in such patients (290–292).

**Occult Male or Oocyte Factors**

Occult male factor despite normal semen analysis and oocyte factors, such as premature zona hardening, mitochondrial dysfunction, and/or aberrant spindle formation, has been suggested as a mechanism for unexplained infertility (293).

**Treatment of Unexplained Infertility**

It is reasonable to discuss no intervention or expectant management with younger patients presenting with unexplained infertility. Some patients will want to proceed with diagnostic (and potentially therapeutic) laparoscopy. Typical interventions proceed stepwise with superovulation (first with clomiphene or letrozole for three to four cycles, then gonadotropins for three to four cycles) combined with intrauterine insemination, followed by ART (294). ART options for unexplained infertility include conventional IVF, split IVF/ICSI, and full ICSI, even though no male factor has been identified. Risks with clomiphene, letrozole, and non-ART gonadotropins, as well as gonadotropin preparations, have been discussed above.

**Baseline Ovarian Cysts**

Prior to beginning therapy, a baseline ultrasound may be performed on cycle day 2 or 3 during menses (or following GnRH agonist suppression) to confirm an optimally thin (<4 mm) endometrium and quiescent ovaries. With clomiphene citrate cycles, the presence of ovarian cysts on a baseline scan was associated with decreased rates of ovulation but not of pregnancy, although cyst size was not predictive of response (295). Ovarian cysts on baseline evaluation have been associated with decreased pregnancy rates in ovulation induction cycles employing gonadotropins (296). In IVF patients, **functional (estrogen-producing) cysts are seen in 9.3% of women following GnRH agonist**
suppression (297). Although nonfunctional ovarian cysts up to 5.3 cm did not affect IVF outcomes, functional ovarian cysts (mean diameter 2 cm and baseline estradiol 180 pg/mL) have been associated with increased gonadotropin requirements (dosing and duration), higher cancellation rates, fewer retrieved oocytes, poorer embryo quality, and lower pregnancy rates per cycle (9.6% vs. 29.7% in cyst-free cycles) (297,298). Ovarian cysts greater than 10 mm that are seen on the baseline scan tend to resolve spontaneously within 1 to 2 months, and oral contraceptive administration does not appear to hasten their resolution (299). However, oral contraceptive pretreatment prior to GnRH agonist cycles is associated with decreased risk of cyst formation (300). Functional cyst aspiration prior to gonadotropin stimulation, which is commonly performed to expedite initiation of treatment, did not improve IVF outcomes in one large study (297).

Superovulation (Controlled Ovarian Hyperstimulation)

Unlike ovulation induction, in which the goal is to stimulate the release of a single oocyte in a women who was not previously ovulating, the explicit goal of superovulation (for non-ART or ART purposes) is to cause more than one egg to be ovulated, thereby increasing the probability of conception in women with unexplained infertility (136). In most superovulation protocols, a baseline scan is performed on day 2 of the menstrual cycle to assess antral follicle count and the presence or absence of ovarian cysts. Baseline estrogen and progesterone levels are typically obtained on this day (301). Starting daily doses in superovulation cycles are higher for both clomiphene (100 mg for 5 days) and gonadotropins (150 to 300 IU daily) than those used for ovulation induction (111,301,302). Superovulation with clomiphene is otherwise conducted as described above for ovulation induction. When gonadotropins are used for normal responders with unexplained infertility, FSH doses of 225 IU and 300 IU lead to similar outcomes with IVF (111). The maximal gonadotropin dosage is typically 450 IU per day because higher dosages do not increase ovarian response (301). In most superovulation protocols, gonadotropins are started on day 2 or 3 of menses (301–303). The starting dose of gonadotropins is maintained each day until cycle day 6 or 7 (stimulation day 4 or 5), when the serum estradiol level and transvaginal ultrasound are first measured to document ovarian response (111,302,303). Gonadotropin dosage is increased by 50 to 100 IU per day every 2 to 4 days until a response is evident (304). Estradiol levels typically double every 48 hours, with follicle growth of 1 to 2 mm daily after a 10 mm diameter is reached (305). Triggering of ovulation typically occurs when at least two follicles have reached an average diameter 17 to 18 mm and the endometrial thickness is 8 mm or more (111,302,303,306–308). For non-ART cycles, cancellation should be strongly considered for E2 levels 1,000 to 2,500 pg/mL, for three or more follicles 16 mm or more, or for two or more follicles 16 mm or more plus two or more follicles 14 mm or more (141). Ultrasound monitoring of IVF cycles without estradiol levels can be considered (309).

Treatment Outcomes
It should be noted that pregnancy rates in unexplained infertility patients vary widely among studies, even when the same treatments are used, perhaps as a result of heterogeneity in treatment protocols and patient age. Interpretation of data on the use of clomiphene in patients with unexplained infertility is particularly difficult because the studies are heterogeneous and their results conflicting (150,151). One meta-analysis of 1,159 participants with unexplained infertility involving seven randomized controlled trials of clomiphene citrate with and without IUI indicated no improvement in pregnancy or live birth rates when compared to no treatment or placebo (151). Still, oral therapies continue to be used, and clomiphene and letrozole have recently been shown to have comparable efficacy when combined with IUI for treating unexplained infertility, with pregnancy rates approximately 18% per cycle (310). Combined therapy with gonadotropins and IUI is more likely to result in pregnancy (9% per cycle) than either superovulation (4%) or IUI (5%) alone (302). Laparoscopy to treat minimal or mild endometriosis is associated with live birth rates similar to those in patients with unexplained infertility who receive COH/IUI (70% over four cycles) (311).

In women over the age of 40, non-ART therapies are much less effective and IVF should be offered as an initial or early treatment option (312). Pregnancy rates per cycle for unexplained infertility in women who are less than 40 years old have been grouped by treatment modality and reported as follows: (i) clomiphene/IUI 7.8%, (ii) gonadotropin/IUI 9.8%, and (iii) IVF 30.7% (313). The use of ICSI or splitting sibling oocytes between IVF and ICSI has been proposed as an approach to unexplained infertility patients to diagnose and treat underlying occult male or oocyte factors (293,314). Although ICSI does improve fertilization rates and reduce fertilization failure, no differences have been noted in pregnancy or live birth rates when comparing IVF to ICSI for unexplained infertility (314,315).

Cost-Effectiveness

According to computerized decision-tree modeling, laparoscopy followed by expected management for unexplained infertility may be cost-effective when compared to no intervention, non-ART treatment, or IVF (294). Given that 15 gonadotropin/IUI cycles are needed to produce one additional pregnancy when compared to intracervical insemination alone, IVF seems a reasonable option (150). In Massachusetts, where insurance companies are required to cover infertility treatment, the cost-effectiveness of IVF in the treatment of unexplained infertility was determined. Couples were randomized to accelerated treatment with three cycles of clomiphene citrate/IUI followed by up to six cycles of IVF if no pregnancy occurred (n = 256) versus conventional treatment with clomiphene/IUI for three cycles, then injectable gonadotropins/IUI for three cycles, then IVF for six cycles (n = 247). Median time to pregnancy was 8 months in the accelerated versus 11 months in the conventional treatment groups. The authors used an average cost per cycle with clomiphene/IUI of $500, with gonadotropin/IUI of $2,500, and assuming IVF costs were less than $17,749 per cycle. They reported that the accelerated treatment protocol resulted in a savings of $2,624 per couple and lowered the per delivery charges by $9,856 compared to
conventional treatment regimens. The study concluded that couples with unexplained infertility who have not achieved pregnancy after three cycles of clomiphene/IUI should proceed directly to IVF (313).
Assisted Reproductive Technologies

Process of Assisted Reproductive Technologies

ART include IVF, ICSI, gamete intrafallopian transfer (GIFT), zygote intrafallopian transfer (ZIFT), cryopreserved embryo transfers, and the use of donor oocytes. Because of improved success rates associated with IVF-embryo transfer, the performance of GIFT and ZIFT has declined in the United States, so this review will focus primarily on IVF and ICSI (316). Both processes involve:

- Prevention of a premature LH surge
- Follicle growth
- Pretreatment
- Adjunctive medications
- Oocyte maturation/ovulation triggering
- Oocyte retrieval
- Luteal support
- Fertilization by IVF or ICSI
- In vitro embryo culture
- Transfer of fresh embryos
- Cryopreservation of surplus embryos
- First trimester pregnancy monitoring

Prevention of Premature Luteinizing Hormone Surge

Luteinizing Hormone surge and Premature Luteinization

Without GnRH agonist or antagonist suppression, LH surges occur in IVF cycles resulting from high estradiol levels in the early follicular phase. This, in turn, results in a lower oocyte yield and reduced pregnancy rates (317). Spontaneous ovulation prior to oocyte retrieval is reported to occur in 16% of nonsuppressed IVF cycles (318). The premature LH rise typically occurs after 5 to 7 days of stimulation (317). In contrast, premature luteinization is a somewhat misleading term that refers to a rise in serum progesterone (cutoffs vary from 0.8 to 2 ng/mL) observed on the day of hCG administration and occurs in the setting of low LH levels secondary to gonadotropin-suppressive medications (319). The incidence of premature luteinization has been estimated at 6% to 7% when the progesterone cutoff level is set at greater than 1.5 ng/mL, but it may be as high as 35%. Mechanisms underlying premature luteinization may include incomplete pituitary desensitization, increased granulosa cell receptor sensitivity to LH secondary to aggressive COH or innately poor responders, and/or the presence of multiple follicles each producing a normal amount of progesterone consistent with the late follicular phase (319,320). Although the literature on this subject remains inconsistent, the negative effects of premature luteinization have been attributed to endometrial advancement rather than
Methods proposed to address premature luteinization have included earlier triggering with hCG, less aggressive stimulation protocols, cryopreservation of embryos (freeze-all), and administration of the antiprogestin mifepristone at the time of hCG (320,322).

**GnRH Agonists**

Native GnRH is rapidly degraded in the circulation. Commercial preparations of GnRH agonists consist of decapeptides similar to GnRH but for modification at two amino acid residues, which increase both the half-life and the receptor binding affinities (323). Over the course of 10 to 14 days, agonists initially bind to and upregulate pituitary GnRH receptor activity, leading to a flare response of increased gonadotropin secretion. This is followed by receptor desensitization (depleted gonadotropin pools along with rapid uncoupling of the GnRH receptor from its regulatory protein and loss of signal transduction) that suppresses circulating levels of pituitary gonadotropins and, with high doses and prolonged use, eventually decreases GnRH receptor numbers (301,317,323–325). Therefore, prolonged use of GnRH agonists induces a menopause-like state characterized by low estradiol levels and accompanied by common side effects such as hot flashes and moodiness. The flare effect may cause ovarian cyst formation as described in the “Unexplained Infertility” section of this chapter (301). GnRH agonists are commercially available for either depot or daily use and can be administered intranasally (buserelin and nafarelin) or by intramuscular or subcutaneous injection (leuprolide, triptorelin, or buserelin). Intranasal preparations have lower absorption rates when compared to injectable agonists and are associated with milder suppression (326). Typical starting daily doses of leuprolide are 1 mg, 0.5 mg, or 25 μg (microdose) (324).

**Gonadotropin-Releasing Hormone Agonist Protocols**

Some of the more commonly used ART medications and protocols are summarized in Fig. 32.6 and Table 32.8. In the long protocol, a GnRH agonist is started in the luteal phase (day 21) of the previous cycle. This diminishes the GnRH agonists flare effect and suppresses endogenous FSH and dominant follicle selection to promote synchronous follicular growth (317). After 10 to 14 days of GnRH agonist administration, a pelvic ultrasound and estradiol level are used to confirm suppression and gonadotropin stimulation begins. The GnRH agonist is continued (the dose may be halved or unchanged) throughout the cycle until the hCG trigger (317,324). Mean serum progesterone levels on the day of hCG administration using the long protocol are reportedly 0.84 ng/mL (320). The long protocol provides for better oocyte yields and pregnancy rates in normal responders when compared with shorter protocols that use later administration or early cessation of agonists (317). Shorter protocols using lower GnRH agonist doses have been advocated for poor responders in whom excessive suppression may be undesirable, perhaps from direct negative effects of the agonist on the ovary (324). However, long protocols, particularly those using single-dose depot rather than daily GnRH agonist formulations, are
associated with higher gonadotropin dose and duration, which themselves have been associated with lower pregnancy rates (327–329). Alternatively, GnRH microdose flare protocols have been developed that may improve oocyte yield in poor responders. Microdose flare regimens involve pretreatment with 14 to 21 days of combination oral contraceptives. Four days following the cessation of the oral contraceptive pills, a microdose (leuprolide 25 μg) of agonist is added in the early follicular phase to take advantage of the agonist flare effect. Gonadotropin stimulation is initiated 1 to 2 days later while continuing the agonist (324).

Gonadotropin-Releasing Hormone Antagonists

GnRH antagonists (cetrorelix and ganerelrix) were developed by modifying the GnRH decapeptide at six positions. They compete with endogenous GnRH for binding to pituitary GnRH receptors. Because they have no agonistic activity, GnRH antagonists lead to almost immediate suppression of FSH and LH and do not require the additional time for pituitary down-regulation that characterizes the GnRH agonists. With prolonged use, GnRH antagonists down-regulate GnRH receptors (323). At this time, the only delivery method available for GnRH antagonist is subcutaneous injection, although orally active agents are in development. GnRH
antagonists can be given as 0.25 mg daily doses or as a single 3 mg dose with no
difference in outcome (325). The time between daily injections should not exceed 30
hours (301). With single dose regimens, avoidance of multiple injections is attractive, but
additional small doses starting 4 days after initial dose are required in 10% of cycles
(325). Use of GnRH antagonists in ART protocols is typically begun on day 4 to
7 of stimulation. This timing balances the risk for premature LH surges with the
need for initiation of endogenous FSH-mediated follicular recruitment and
endogenous estradiol production prior to administration (301,317,325).

Gonadotropin-Releasing Hormone Antagonists Fixed versus Flexible
Protocols
Several GnRH antagonist protocols have been developed for use in ART cycles. **Fixed
protocols involve starting the antagonist on day 4, 5, 6, or 7 of stimulation
regardless of follicular response** (301,308,317,325). Flexible protocols were
developed to reduce gonadotropin stimulation dose and duration (317). **In flexible
protocols, varying thresholds have been described for antagonist initiation. These include addition of the antagonist when the leading follicle has reached
12 to 16 mm in average diameter or when the estradiol level has risen above
600 pg/mL (303,307,317,324,325).** When flexible protocols are used, pregnancy rates
are similar when antagonist is initiated on day 4 or 5 of stimulation but drop significantly
when antagonist is initiated after day 6. This suggests that rapid follicular growth may be
more important in preventing LH surges and improving pregnancy rates than the day the
antagonist is initiated (303). Fixed initiation of a GnRH antagonist on day 6 of stimulation
has been associated with higher pregnancy rates when compared to flexible protocols in
one meta-analysis involving four randomized trials; however, **the true superiority of
one approach over the other remains to be determined** (303,324,325). Diminished estradiol levels can be expected following GnRH antagonist
administration, but this does not appear to affect follicular growth (308). The
addition of exogenous FSH or LH does not appear to be necessary (301,324,325).

Gonadotropin-Releasing Hormone Agonists Compared with Antagonists
Because there is no pituitary desensitization period required when GnRH antagonists are
used in ART, cycles can begin more quickly than those that employ GnRH agonists (301).
**Antagonists are associated with lower duration of stimulation, lower
stimulation dose, and reduced rates of ovarian hyperstimulation syndrome
(330).** Antagonists are often used in the absence of pretreatment with oral
contraceptives. Initiation of antagonist cycles therefore relies on the start of spontaneous
menses, often making scheduling easier for GnRH agonist cycles (331). Study and
protocol heterogeneity make it difficult to detect consistent differences in IVF pregnancy
outcomes after GnRH agonist and antagonist cycles (330,332). **A Cochrane review of
27 randomized controlled trials indicated that while the number of good
quality embryos produced for transfer are similar, clinical pregnancy rates are
higher by 4.7% in agonist compared to antagonist cycles. They concluded that for every 21 couples, one additional pregnancy would be gained by using a GnRH agonist protocol. The number of oocytes retrieved and the live birth rates favored agonist usage (330).

**Follicular Growth**

**Follicular Recruitment**

Although the inciting stimulus is unclear, cohorts of small antral follicles (<2 mm) become responsive to FSH stimulation only after 45 days of initial growth. They are then considered recruitable and begin to slowly enlarge in the late luteal phase of the cycle preceding ovulation. Once the antral follicle grows beyond 10 mm, FSH induces the appearance of LH receptors on the granulosa cells. At that point, somewhat contrary to the 2-cell-2-gonadotropin model, LH can exert FSH-like actions on the granulosa cell, including stimulation of aromatase. With complete absence of endogenous LH, such as that seen with hypothalamic hypogonadism, exogenous FSH produces fewer preovulatory follicles, inadequate estradiol, lower ovulation rates, and thinner endometrium when compared to ovaries stimulated with exogenous HMG (FSH and LH). Therefore, in the setting of normal hypothalamic function, it seems likely that even with suppressive therapy, enough endogenous LH is present to synergize with exogenous FSH to provide adequate stimulation for recruitment (326).

**Follicular Waves**

Seventy-five percent of unstimulated human menstrual cycles have two waves of follicular development: one major wave in which a dominant follicle is selected to the detriment of other follicles and one minor wave during which all follicles undergo atresia. When progesterone is available to block LH, the first wave is typically minor and occurs one day after ovulation in the previous cycle. The subsequent major wave occurs around the time of menses, with the dominant follicle being selected by its ability to reach a diameter of 10 mm by cycle day 6 or 7, which coincides with an estradiol rise that inhibits FSH. One-quarter of cycles will exhibit an additional wave that occurs 2 days prior to menses and may be minor or major. If the dominant follicle regresses or is removed, a new follicular wave begins 2 days later. In light of this, future efforts toward greater synchrony during stimulation might include ablation of the early dominant follicle using aspiration or administration of exogenous estrogen and progesterone during the follicular phase (333).

**Controlled Ovarian Hyperstimulation**

The goal of gonadotropin stimulation for ART is the synchronous growth of dominant follicles in quantities greater than that associated with non-ART therapy. FSH is the key hormone in this regard (111). Gonadotropin preparations are described in the “Ovulatory Factor” section, while dosing and the relevance of baseline ovarian cysts are described in the “Unexplained Infertility” section. ART pregnancy outcomes are not affected by
the source of FSH, the delivery system, or the route of administration (156). In one recent report, women who were predicted to be normal responders using 225 to 300 IU of FSH required 11 days of stimulation, had 11 to 13 follicles 15 mm or larger on the day of hCG trigger, had a peak E2 level of approximately 2,100 pg/mL, and had 10 to 11 oocytes retrieved, of which 82% to 83% were mature (111). Most investigators suggest that the optimal number of retrieved oocytes in a given cycle is between 5 and 15, and the optimal level of estradiol at the time of hCG administration is between 70 and 140 pg/mL per oocyte or follicle (306,329). It should be noted that the utility of estradiol monitoring during ART is controversial, and that ultrasound monitoring alone may be adequate to maximize pregnancy and live birth rates (309). Cycle cancellation in normal responders occurs in up to 6% of the cycles because of inadequate response and 1.5% of cycles for excessive response (111). Cycle cancellation increases with older age and decreased ovarian reserve, but is reportedly decreased by 2% for every additional 100 IU gonadotropins used (328). There appears to be no benefit of exceeding a total daily gonadotropin dose of 450 IU in any patient (301).

Follicle-Stimulating Hormone versus Human Menopausal Gonadotropin

Higher androgen and lower progesterone levels on the day of hCG trigger are observed when HMG is used for stimulation rather than FSH alone, indicating a more favorable endocrine profile with HMG (334). Concern has been raised that exogenous LH might be needed to address the sudden decrease in endogenous LH that is associated with GnRH antagonist use and the possible excess endogenous LH suppression in long GnRH agonist protocols (326). However, there is no consensus as to whether the addition of LH to exogenous FSH improves pregnancy and live birth outcomes in women with normal hypothalamic function (156,335,336).

Less Aggressive Stimulation

Although it reduces cancellation rates, each additional 100 IU of gonadotropins is correspondingly associated with a 2% lower rate of clinical pregnancy and live birth (328). This seems to support the findings of premature luteinization and lower pregnancy rates when more aggressive FSH stimulation protocols are used (320). When comparing normal responders using a flexible antagonist protocol and a fixed FSH dose of 150 IU (mild) to those using conventional FSH doses, implantation rates were maximized when a median of 5 oocytes were retrieved in the mild stimulation group, while 10 oocytes were necessary in the conventional dose group. Outcomes were compromised when more than eight oocytes were obtained in the mild group, and only the high dose group experienced poorer outcomes with low oocyte yield. Pregnancy rates seem to level off or decrease when stimulation is pushed beyond a certain threshold, but this threshold is unknown (329).

Pretreatment

Combined oral contraceptives (OCs) are commonly taken for 14 to 28 days
prior to GnRH analogues to ease cycle scheduling, synchronize follicular development, further prevent LH surges, reduce the incidence of ovarian cysts, and reduce cancellation rates resulting from hyperstimulation (331,337,338).

Patients can begin OCs anytime between days 1 and 5 of menses (337). For antagonist cycles, COH begins 2 to 5 days after stopping OCs (irrespective of menses) (331). During long GnRH agonist protocols, the agonist overlaps the final 5 days of OC use, followed by initiation of COH on the second or third day of withdrawal bleeding (300,338). As previously discussed, microdose flare protocols involve pretreatment with 14 to 21 days of OC, followed 4 days later by a microdose of agonist. COH typically starts 1 to 2 days later (324). The progestins norethindrone acetate 10 mg orally daily, medroxyprogesterone acetate 10 mg orally daily, or a single intramuscular dose of progesterone (not specified) can be used in place of an OC in ART cycles, but recommendations on the duration of treatment and the timing of initiation vary widely: a duration of 5 to 20 days and initiation anytime between days 1 and 19 of menses have been reported. A dose of 4 mg of daily micronized 17β estradiol or estradiol valerate has been used in lieu of OCs in ART cycles, with initiation between cycle days 15 and 21 and a duration of 10 to 15 days. Although OC pretreatment for antagonist cycles has been shown to increase both the duration of stimulation and the amount of medication used, its effect on pregnancy rates is controversial (331,337). OC pretreatment during GnRH agonist cycles is associated with higher pregnancy rates than those in cycles without pretreatment (300). Progestin and estradiol pretreatment do not affect live birth rates in either agonist or antagonist cycles (337).

Adjunctive Medications

Prenatal vitamins should be given to all infertility patients beginning at least 1 month prior to initiation of infertility treatment. Although aspirin is commonly used during IVF regimens, recent studies have failed to demonstrate beneficial changes in pregnancy rates (339,340). Antimicrobial prophylaxis using doxycycline or azithromycin for both partners is often given during ART cycles, particularly those involving assisted hatching procedures, although these medications have not been clearly associated with improved pregnancy rates (287,289,341). Glucocorticoids given to women during the peri-implantation period may improve pregnancy rates in women with autoimmune disease, those undergoing assisted hatching or frozen/thaw embryo transfers, and in women of advanced maternal age (341). Metformin may limit ovarian hyperstimulation (OHSS) in PCOS patients, but shows no benefit for pregnancy or live birth rates (342).

Oocyte Maturation/Ovulation Triggering

Physiology of Oocyte Maturation

Prior to maturation, oocytes are arrested in the prophase stage of meiosis I, also known as the germinal vesicle (343,344). Meiosis I oocytes must reach at least the early antral
folicle stage to respond to FSH and be competent to resume meiosis. In vivo, LH receptors on the follicle are induced by FSH during later stages of follicular development (345). Therefore, only fully grown oocytes respond to the LH surge in vivo to begin the cytoplasmic and nuclear maturation that are required for developmental progression toward the metaphase stage of meiosis II. At this point, the developmentally competent oocyte will extrude the first polar body, the oocyte-cumulus complex will detach from the ovarian wall, ovulation will occur, and fertilization is possible (343–346).

Oocyte Maturation during Assisted Reproductive Technology Cycles

Because spontaneous LH surges occur inconsistently during non-ART gonadotropin cycles and are suppressed in ART cycles, hCG has been used to trigger ovulation. In combination with its long half-life, homology between hCG and LH (identical α subunits) allows for cross-reactivity with the LH receptor and induction of final oocyte maturation and ovulation (347). hCG is derived from urine (5,000 to 10,000 IU intramuscularly) or through recombinant technology (250 μg subcutaneously, equivalent to 5,000 to 6,000 IU of intramuscular urinary product) (156). The half-life of hCG is 2.32 days, compared to 1 to 5 hours for LH (347). **Ovulation is typically triggered when at least two follicles are 17 to 18 mm or larger in average diameter (but <24 mm) and the endometrial thickness is 8 mm or more (111,302,303,306–308,348).** Similar clinical outcomes have been noted when 5,000 IU or 10,000 IU of hCG (349) and urinary or recombinant preparations are used for triggering (348,350). If there is concern for ovarian hyperstimulation syndrome (OHSS, see below), GnRH agonists can be substituted for hCG to trigger ovulation in antagonist protocols or recombinant LH can be substituted for hCG in agonist protocols; however, both protocols are associated with decreased pregnancy rates in nondonor ART cycles (347,351).

Oocyte Retrieval

Oocyte retrieval is performed via transvaginal ultrasound-guided needle puncture into each follicle followed by aspiration of follicular fluid. Either general anesthesia or intravenous conscious sedation may be used (352). Prophylactic antibiotics such as ceftriaxone are recommended at the time of retrieval (353). The vaginal preparation can be performed either with sterile saline alone or with povidone iodine followed by vigorous saline flushing (354,355). **The highest oocyte yield is obtained when oocyte retrieval is performed 36 to 37 hours after the hCG injection.** Earlier retrieval (35 hours) is associated with a much lower oocyte yield, and later retrieval risks ovulation; spontaneous follicular rupture appears to occur at a mean of 38.3 hours following hCG administration (348).

Luteal Support

The rationale and regimens for luteal phase support with progesterone are discussed in the “Uterine Factors” section. The timing for luteal progesterone support varies, but lower
pregnancy rates have been noted with initiation prior to oocyte retrieval or later than 5 days following retrieval (356,357). Luteal phase estradiol supplementation is not necessary (358,359).

**Fertilization by In Vitro Fertilization or Intracytoplasmic Sperm Injection**

Following semen collection and sperm processing (described in the “Male Factor” section), sperm are incubated in media for 3 to 4 hours to promote sperm capacitation and the acrosome reaction. Before fertilization, retrieved oocytes are cultured in media. Conventional IVF involves insemination concentrations of 100,000 to 800,000 motile sperm/mL per oocyte with each oocyte in a small droplet of media under oil (9,360,361). For every three cycles done for severe male factor, the use of ICSI prevents one case of fertilization failure when compared to conventional IVF (9). The indications for and the procedure and risks of ICSI are discussed under “Male Factor.”

**In Vitro Embryo Culture**

**Embryo Development**

*Initial embryo development is typically assessed 15 to 20 hours after insemination or ICSI, when fertilization is characterized by the presence of two pronuclei and the extrusion of the second polar body* (9,361,362). Embryos are examined again for cleavage after 24 to 30 hours of culture (9). The first embryo cleavage occurs approximately 21 hours after fertilization, and subsequent divisions occur every 12 to 15 hours up to the eight-cell stage on the 3rd day of embryo development (363). Compaction to form the 16-cell morula occurs on the 4th day of embryo development, and differentiation of the inner cell mass and trophectoderm to form a blastocyst (containing a fluid-filled area called a blastocele) is completed by the 5th or 6th day (364,365).

**Culture Environment**

*Sequential media systems are preferred during embryo culture to adjust for each stage of embryo development.* Prior to compaction, the embryo is under genetic control of the oocyte, it uses a pyruvate-based metabolism, it requires at least a few amino acids, and it prefers a relatively oxygenated environment (though much lower than atmospheric oxygen) similar to that found in the fallopian tube. Following compaction, amino acid needs increase (stable dipeptide glutamine instead of glutamine will avoid toxic ammonium buildup), the embryonic genome is activated, and metabolism requires both glucose and a very low oxygen environment similar as that found in the uterus (363,366). Supplementation of culture media with hyaluron and albumin is beneficial in postcompaction media preparations (363).

**Extended Culture to Blastocyst**
Although precompaction human embryos can survive when placed in the uterus, the uterine cavity is a nonphysiological location for them, and there is greater uterine pulsatility during this period that may cause the embryos to be expelled. **Therefore, the blastocyst stage represents a more physiologic time for embryo transfer.** Since nearly 60% of morphologically normal cleavage embryos but only 30% of blastocysts are chromosomally abnormal, extended culture allows for better selection of embryos with improved quality (364,367).

**Blastocyst versus Cleavage Transfer Outcomes**

Comparisons involving equal numbers of transferred embryos demonstrate that blastocyst transfer is associated with lower implantation failure, a higher pregnancy rate, and a 7% higher live birth rate than cleavage stage transfer. This is of particular interest in programs that offer elective single embryo transfer (364,367,368). Given that blastocyst formation rates range from only 28% to 60%, disadvantages of extended culture include the possibility that no embryos will survive to transfer (8.9% vs. 2.8% for cleavage transfer) and a reduced opportunity for embryo cryopreservation. Monozygotic twinning rates may be higher with blastocyst culture, although this has not been a consistent finding (364,369).

**Criteria for Extended Culture**

There are no established guidelines or criteria that determine when to utilize extended culture. Varying suggestions include maternal age 42 or younger with five or more two pronuclear stage (2PN) embryos on postretrieval day 1; maternal age of 40 or younger and three or more good-quality day 3 embryos having 4 to 10 cells with less than 15% fragmentation; maternal age of 41 to 42 or younger and four or more good-quality day 3 embryos having 4 to 10 cells with less than 15% fragmentation; and age less than 37 with four or more morphologically good embryos on day 3, or four or more embryos with 6 cells and less than 10% fragmentation (362,364,370).

**Embryo Transfer**

**Embryo Morphology**

Embryo morphology guides the choice of embryo for transfer. Pronuclear embryos are assessed by their distribution and number of nucleoli, the position of the second polar body relative to the first, and cleavage rates (abnormal rates are too fast, too slow, or arrested) (365). Preferred cleavage stage embryos have a normal developmental pattern characterized by early cleavage on day 1, four cells on day 2, and eight cells on day 3. Embryo fragmentation should be 10% or less, the blastomere size should be regular, and there should be no multinucleation (362). The Gardner and Schoolcraft system for scoring blastocysts uses a scale from 1 (worst) to 6 (best), with grades 1 to 3 indicating growth of the blastocele until it completely fills the embryo. Grade 4 blastocysts are expanded with a larger blastocele volume and a thinning zona
pellucida. The trophectoderm in a grade 5 blastocyst is starting to hatch though the zona, and the grade 6 blastocyst has completely escaped or hatched from the zona. The inner cell mass is graded A to C based on tightness and cellularity (A is best), and the trophectoderm is assessed from A to C based on cohesiveness and cellularity (A is best) (361).

**Number of Embryos to Transfer**

High-order multiple pregnancy (three or more fetuses) increases complications for mothers and fetuses, so guidelines have been developed to minimize this adverse outcome (371). Single embryo transfer should be considered for patients younger than age 35, particularly those undergoing their first ART cycle who have a large quantity of good quality embryos or patients who have conceived in a prior cycle. Otherwise, transfer should be limited to two embryos in women under 35 years of age. For older women, the maximum number of transferred cleavage-stage embryos should be three in women aged 35 to 37, four in women aged 38 to 40, and five in women older than 40 years of age. Because of their high implantation potential, no more than three blastocysts should be transferred to any woman regardless of her age. Limits on the number of embryos transferred when the embryos were created from donor oocytes should be based on the age of the donor, rather than the recipient (371).

**Transfer Procedure**

The goal of transcervical embryo transfer is to atraumatically deliver the embryos to an optimal intrauterine location for implantation. Implantation is more likely after an easy transfer using a soft catheter and when fundal contact is avoided (353). Trial transfer, although not required, allows advance preparation such as cervical dilation or placement of a traction stitch, although uterine position and depth can be different at the time of the actual procedure. When performed at the time of embryo transfer, trial transfer should not go past the internal os. Trial transfer can be combined with an afterloading technique in which the outer sheath of the transfer catheter is left in place and the transfer catheter is threaded through the trial transfer sheath and into the uterus, although there is no advantage when compared to routine transfer (353,372). Soft catheters such as those made by the Cook or Wallace companies are preferred to rigid catheters to minimize prostaglandin release after cervical and/or endometrial trauma (353). The utility of cervical mucus removal prior to embryo transfer in improving embryo delivery remains controversial (353,372). Although intrauterine infections decrease pregnancy rates, the efficacy of antibiotic administration at the time of transfer is not clear. During a conventional embryo transfer, embryos are suspended in 20 μL of media at the tip of a syringe with air on either side of the fluid. This creates an air–fluid interface easily seen with ultrasound. Abdominal ultrasound visualization during embryo transfer is useful to ensure deposit of the embryos 1.5 to 2 cm from the uterine fundus. Once the embryos are deposited, the inner and outer sheath should be removed as a unit to avoid suction within the device (353). No changes in patient position are necessary (372). Following transfer, the catheter is
checked for retained embryos. If present, retained embryos should be transferred because there is no detriment in pregnancy rates (353).

Figure 32.7 Regimens of ovarian stimulation and hormone replacement used to synchronize the development of ovarian follicles in the oocyte donor and the endometrial cycle in the recipient. hCG, human chorionic gonadotropin; OCP, oral contraceptive pill; GnRH-a, gonadotropin releasing hormone antagonist; TVA, ultrasound-guided transvaginal aspiration of oocytes. Philadelphia, PA: Current Sciences Group, 1998, with permission.)

Cryopreservation of Embryos
Embryo cryopreservation at the pronuclear, cleavage, and blastocyst stages has allowed for multiple transfer cycles from a single oocyte retrieval. Because transfer of cryopreserved embryos is less expensive than a second fresh cycle, overall fertility treatment costs can be optimized. Embryo cryopreservation can be considered as a means to prevent ovarian hyperstimulation syndrome. Techniques for embryo cryopreservation include slow freezing and rapid freezing or vitrification. Slow freezing protocols use lower concentrations of cryoprotectants but are more time-consuming when compared to vitrification, which uses high-concentration cryoprotectants for rapid cooling and is less expensive. Embryo thawing is accomplished by brief exposure to air and warm water followed by rehydration (373). Although pregnancy rates for freeze/thaw transfer (FET) cycles using the two cryopreservation methods are similar, vitrification is associated
with higher postthaw embryo survival (93% vs. 76% with slow freezing) (374). Infant outcomes are reassuring for slow freezing but are more limited for the newer technique of vitrification (375). Overall, use of **frozen embryos results in lower pregnancy rates when compared to fresh transfer cycles, but this may be a result of embryo selection (the best embryos are typically used for fresh transfer and lesser quality embryos are frozen)** (373,376). Frozen transfer outcomes are heavily dependent on the characteristics of the fresh cycle that generated the frozen embryos; excellent pregnancy rates are noted when the fresh cycle resulted in conception or when all the embryos were frozen from the fresh cycle (376).

**Endometrial Preparation for Frozen Embryo Transfer**

When FET is combined with a recipient’s natural cycle, no exogenous treatment is given, and transfer is timed to spontaneous ovulation. In medicated FET cycles, estradiol supplementation begins in the early follicular phase and is continued for 13 to 15 days (373). Multiple estradiol preparations have been described for use in FET cycles, but none has been proven superior (377). Transvaginal ultrasound is used to assess endometrial thickness during estrogen therapy, and estrogen administration continues until an optimal thickness of greater than 8 mm is reached (373). Progesterone supplementation begins 48 to 72 hours prior to transfer when cleavage-stage embryos are used and 6 to 7 days prior to transfer when blastocysts will be thawed (373,377). Again, several progesterone preparations have been described for use in FET cycles, but none has been proven superior (discussed in the “Uterine Factors” section). GnRH agonists are commonly used during medicated cycles to prevent premature LH surges that might adversely affect endometrial maturation (377) (Fig. 32.7).

**First-Trimester Pregnancy Monitoring**

The production of hCG by the blastocyst can be detected as early as 7 days posttransfer, and serum quantitative hCG levels may be obtained 11 to 14 days following embryo transfer (373,378). A serum threshold of 200 mIU/mL of hCG measured 12 days after transfer is 92% and 80% predictive of ongoing pregnancies for day 3 and day 5 embryos, respectively, with levels normally rising approximately 40% per day. If normally rising hCG levels are detected, transvaginal ultrasound is planned at 6 to 7 weeks of gestation to determine the location of the pregnancy, the number of gestational sacs, and pregnancy viability (378).

Assisted Reproductive Technology Success Rates

Since 1992, all clinics performing ART in the United States have been required to submit annual success rates to the Centers for Disease Control and Prevention (379). Success rates of IVF vary from program to program. The most comprehensive assessment of the efficacy of ART programs in North America comes from the database of the Society for Assisted Reproductive Technology (SART). Information on SART and registered ART clinics are accessible by the public online. Because ICSI and IVF rates are similar, statistical analyses combine them for the annual SART reports. IVF success rates are largely dependent on maternal age, and data from recent studies, including those from SART, are summarized in Table 32.10 (380). SART statistics should not be used to compare IVF clinics since success rates are largely dependent on patient demographics, including the cause of infertility, which will be different for each individual clinic. Lifestyle factors affecting IVF success are discussed under “Causes of Infertility.” Since SART does not publish success rates for non-ART cycles, it can often be helpful for physicians to assist patients in comparing the success rates for clomiphene, gonadotropins, and IVF, although rates vary widely between studies (Table 32.11).

A new approach to predicting live birth probabilities focuses on the use of machine learning or the mining of clinic-specific IVF outcomes data to provide a personalized per-cycle prognosis that pertains to the clinical scenario of each patient (381). Briefly, a live birth prediction model was developed by boosted tree analysis of baseline clinical data, uterine response to a patient’s first IVF treatment, and embryo developmental parameters, with no preselection of prognostic factors. The model predicted live birth outcomes in a subsequent IVF treatment cycle. Validation by an independent dataset and comparison with a control model that is based on chronological age alone showed that the boosted tree model was more than 1,000 times better in fitting new data and improved discrimination (i.e., the ability to discern among patients with different prognoses) by receiver–operator curve analysis. Approximately 60% of patients were found to have significantly different predicted live birth probabilities when compared to the use of age categories. Further testing across different clinics will be required to determine whether this approach may be generally valid and applicable. Nevertheless, the nonredundant and unique contribution of the patient’s age to predicting outcomes was found to be limited if data pertaining to the response to gonadotropins and embryo development in the first IVF treatment were available. These findings may move prognostic counseling away from an age-centric paradigm and toward a more objective extraction of predictive value from simultaneous analysis of a wide array clinical factors.

Table 32.11 Fertility Treatment Success Rates
Cessation of Therapy

Patients must be accurately informed of estimated success rates and reasonable expectations for all therapeutic interventions. Patients with a very poor prognosis have a 2% to 5% chance of achieving a live birth with fertility therapy, and those with a futile prognosis have a 1% or less chance. Refusing or limiting therapy may be justified if the risk of intervention outweighs the potential benefits (382).
Third Party Reproduction

When gametes and the ability to gestate a pregnancy are compromised through circumstances or disease, other reproductive options can be considered. **These include use of donor sperm** (discussed in “Male Factor”), donor oocytes, donor embryos, a gestational carrier, or a combination of these approaches. In contrast to donor gametes (sperm or oocytes), the decision to donate embryos is typically made after the embryos have been generated and there is a known surplus. A gestational carrier receives and gestates birth embryos created from the intended mother’s oocytes. Patients who choose to utilize a gestational carrier may have irreparable uterine factor infertility or suffer from medical conditions that contraindicate pregnancy. In true surrogacy, the birth mother is the genetic mother but not the intended mother. Legal and psychosocial counseling are suggested for all parties embarking on any form of third party reproduction.

**Donor Oocyte**

Patients with ovarian failure, poor oocyte quality, poor ovarian response to stimulation, or failed fertilization or implantation after multiple ART cycles may be candidates to receive donated oocytes. A female same-sex couple may choose to have one partner undergo IVF and place the resulting oocytes fertilized with donor sperm into the other partner (383). **At present, donor oocytes must be used to create embryos during the retrieval cycle, because oocyte freezing is considered experimental** (384). With carefully selected donors, live birth rates per cycle of donor oocyte IVF are 50% to 60% regardless of the recipient’s age (Table 32.10). However, recipients must be aware that advanced recipient age is associated with higher risk for preeclampsia, diabetes, and cesarean section (385–387). Oocyte donors must endure all the interventions and risks of the ART process described herein except for embryo transfer and luteal support. Because of the intensity of therapy and the potential infectious disease and genetic risks for donor, recipient, and the resulting offspring, oocyte donors must be screened for infectious and heritable disorders similar to those performed for sperm donors (see “Male Factor”) and undergo meticulous informed consent and a comprehensive psychosocial evaluation. Oocyte donors may be anonymous or known to the recipient (96). Oocyte recipients undergo endometrial preparation (as described in the “Process of Assisted Reproductive Technologies” section), but GnRH analogues are not required if there is no endogenous ovarian function. Recipients may initiate progesterone one day prior, on the same day, or one day after the donor’s oocyte retrieval, but a randomized trial found lower pregnancy rates when progesterone was initiated prior to the retrieval (377). Other topics, such as methods for donor recruitment and financial compensation for the donor, are much more challenging issues (388).
Complications of Assisted Reproductive Technology

Cycle Cancellation
Cycle cancellation in normal responders occurs in up to 6% of cycles because of inadequate stimulation response and in 1.5% of cycles because of excessive response (111). In 0.2% to 7% of retrievals, no oocytes will be obtained. Two proposed explanations include human error during the administration of hCG and early oocyte atresia despite normal follicular response (346).

Oocyte Retrieval
The risks of oocyte retrieval include bleeding requiring transfusion, injury to adjacent structures requiring laparotomy, formation of a pelvic abscess leading to loss of reproductive function despite prophylaxis, and risks related to anesthesia (389).

Multiple Gestation
As the majority of ART cycles involve the transfer of more than one embryo, multiple gestation occurs at higher rates than the 3% rate for spontaneous conception. This has social, medical, emotional, and financial ramifications (379,380). Although the majority of complications of multiple gestations occur with high-order (three or more) multiples, twins have increased risks for low birth weight, preterm birth, and neurologic deficits when compared to singletons (380,390). Despite this, 20% of infertile patients view multiple pregnancy as a desired outcome. Because most patients lack insurance coverage for IVF, patients may push their physicians to take greater risks when deciding on the number of embryos to transfer (379). The multiple pregnancy risk is higher in patients under the age of 35 who are undergoing IVF because their embryos are typically of better quality and implantation rates are higher, but multiple pregnancy can occur at any reproductive age (371). From 1998 to 2007, the overall twinning rate in ART cycles remained stable at 29% to 32%, but the rate of high-order multiples decreased from 6% to 2%. In 2007, the live birth rates for twins and triplets or more for women under the age of 35 who underwent ART in the United States were 33.2% and 3.5%, respectively. Women aged 43 or 44 had twinning live birth rates of 10.6% and triplet or more live birth rates of 0.8% (380). Most multiple pregnancies arising from ART are dizygotic, but monozygotic twinning occurs in 3.2% of IVF cycles (compared to a background rate of 0.4%) (379). Concerns have been raised that monozygotic twinning might increase after blastocyst culture, but this finding has not been consistent (364,369). With increasing adherence to guidelines suggesting limitations on the number of embryos to transfer in a given ART cycle (discussed in “Process of Assisted Reproductive Technologies”) and improved implantation rates that allow single embryo transfer, the multiple pregnancy rates associated with ART should continue to decrease.

Selective Reduction
Ten percent of multifetal pregnancies spontaneously lose at least one gestational sac during the first trimester. This loss rate increases to 21% in women older than 35 years of age. The spontaneous reduction rate to twins or singletons is much higher for triplets (14%) than for quadruplets (3.5%) (391,392). **Selective pregnancy termination or multifetal reduction may be an option for some patients in whom spontaneous reduction does not occur by 11 to 13 weeks.** This involves first karyotyping each fetus through transabdominal chorionic villous sampling to preferentially reduce those that are abnormal, then injecting potassium chloride into the heart of the targeted fetus. Although selective reduction carries a 3% to 7% risk of losing the entire pregnancy when performed prior to 19 weeks, this is still lower than the 15% chance of spontaneously losing an entire triplet pregnancy (390,393). Selective fetal reduction is typically considered for triplet or higher pregnancies, but even reduction from twins to singletons may have benefit (390).

**Ectopic and Heterotopic Pregnancy**

Up to 3.4% of ART pregnancies are ectopic (implantation outside the uterus) and require treatment with either surgery or methotrexate. **The absence of an intrauterine pregnancy on transvaginal ultrasound evaluation in conjunction with a maternal serum hCG level above a threshold of 1,500 mIU/mL suggests the diagnosis** (394,395). Heterotopic pregnancy involves concurrent intrauterine and ectopic pregnancy, usually within the fallopian tube, but ovarian implantations have been reported (395,396). The incidence of heterotopic pregnancy, which is normally rare, is particularly high (1%) after IVF treatment. Multiple gestation, smoking, previous tubal surgery, and prior PID are potential risk factors in addition to ART. As with standard ectopic pregnancies, pain and bleeding are the most common presenting findings with heterotopic pregnancies. Heterotopic pregnancies are most often diagnosed in the first 5 to 8 weeks of gestation using laparoscopy or laparotomy. **Only 26% of heterotopic cases can be diagnosed with transvaginal ultrasound, possibly as a result of difficulties in sonographic interpretation in the presence of concomitant ovarian hyperstimulation.** After treatment of a heterotopic gestation with laparoscopy, laparotomy, or ultrasound-guided injection of potassium chloride into the extrauterine pregnancy, the overall delivery rate for the intrauterine pregnancy is nearly 70% (395).

**Ovarian Hyperstimulation Syndrome**

**OHSS is a medical complication that is both completely iatrogenic and unique to stimulatory infertility treatment** (397). Its symptoms are the result of ovarian enlargement and fragility, extravascular fluid accumulation, and intravascular volume depletion. Proposed mechanisms for the characteristic fluid shifts that accompany OHSS include increased protein-rich fluid secretion from the stimulated ovaries, increased renin and prorenin within follicular fluid, and increased capillary permeability mediated by angiotensin. **Vascular endothelial growth factor (VEGF), whose expression in granulosa cells and serum is augmented by hCG, and a**
variety of other inflammatory cytokines have been implicated in the pathogenesis of this disease (398). Two distinct patterns of OHSS onset have been described. Early OHSS occurs 3 to 7 days following the hCG trigger and is associated with the administration of exogenous hCG. Late onset disease occurs 12 to 17 days after the hCG trigger; it is the result of endogenous hCG secretion from the pregnancy and tends to be more severe with multiple gestation. Pregnancy outcomes are inconsistently affected by the presence of OHSS, with higher rates of biochemical losses but similar rates of clinical losses when compared to patients without OHSS (399).

**Severity Classification**

Mild OHSS (grades 1 and 2) is associated with high serum estradiol levels and ovarian enlargement to less than 5 cm and has minimal clinical significance. Grade 3 moderate OHSS is accompanied by mild abdominal distention and has minimal clinical significance (397). Grade 3 OHSS occurs in one-third of all COH cycles (398). Grade 4 moderate OHSS is accompanied by gastrointestinal upset and ovarian enlargement to 5 to 12 cm (397). The presence of fluid shifts from intra- to extravascular spaces are the hallmark of severe disease, and grade 5 OHSS includes tense ascites or hydrothorax. Grade 6 OHSS is accompanied by hemoconcentration, coagulation abnormalities, respiratory failure, and renal dysfunction (397). Other markers of severe OHSS include hyponatremia, hyperkalemia, elevated liver function tests, and an elevated white blood cell count (397, 398). Concerning symptoms for severe disease include rapid weight gain (≥2 lb per day), increased measurable abdominal girth, hypotension, tachypnea, tachycardia, oliguria, and severe abdominal pain. The latter symptom is suggestive of ovarian cyst rupture or hemorrhage (398).

**Risk Factors**

Mild OHSS occurs in 13.5% of clomiphene cycles, but more severe disease is rare. With gonadotropin injections, the incidence of moderate disease is 3% to 6% and severe OHSS occurs in 0.1% to 2% of patients. Polycystic ovary syndrome, polycystic ovarian morphology with attendant elevated antimüllerian hormone levels (>3.36 ng/mL), and previous episodes of OHSS are major risk factors for the disease; the impact of young age and lean body mass is controversial (351, 398, 400). Estradiol levels greater than 800 pg/mL on day 9 of stimulation have been associated with a 55.8% risk for the development of OHSS (severity not specified). Estradiol concentrations of greater than 3,500 pg/mL and greater than 6,000 pg/mL at the time of hCG trigger were associated with severe OHSS in 1.5% and 38% of patients, respectively. During antagonist cycles, the presence of 13 or more follicles at 11 mm or greater average diameter was predictive of the development of OHSS. More than 20 preovulatory follicles were associated with a 15% incidence of severe OHSS. When 20 to 29 oocytes were collected at retrieval, 1.4% of patients developed severe OHSS; this raised to 22.7% with 30 or more oocytes (400).

**Management**
If outpatient management is appropriate, the patient should be instructed to limit her activity, to weigh herself daily, and to monitor her fluid intake (at least 1 L per day of mostly electrolyte-balanced fluid) and output. Daily follow-up by telephone or visit is important and the patient should be reassessed if she notes worsening of the symptoms or if her weight gain increases to more than 2 lb per day. **Indications for hospitalization include an inability to tolerate oral hydration, hemodynamic instability, respiratory compromise, tense ascites, hemoconcentration, leukocytosis, hyponatremia, hyperkalemia, abnormal renal or liver function, and decreased oxygen saturation.** Fluid intake and urine output need to be carefully measured, and admission to an intensive care setting can be considered if the patient has hyperkalemia, renal failure, respiratory failure, or thromboembolic disease. Although intravenous fluids may worsen ascities, they are essential to correct hypovolemia, hypotension, electrolyte abnormalities, and oliguria. Albumin 25% can be dosed 50 to 100 mg intravenously every 4 to 12 hours if further intravascular volume expansion is needed. Diuretics can be considered to improve weight gain and oliguria only after hypovolemia has been corrected. Thromboembolic prophylaxis should be given. Single or repeated transvaginal or transabdominal ultrasound-guided paracentesis may relieve pain, hydrothorax, or persistent oliguria. Rapid large-volume fluid removal can be considered, as compensatory fluid shifts are unlikely to occur in this typically young healthy population as long as the patient is carefully monitored (398).

**Prevention**

No method will prevent OHSS completely, but steps can be taken to decrease risk. Careful gonadotropin stimulation for monofollicular development is discussed under “Ovulatory Factor.” For ART, **stimulation protocols for high-risk patients include lower initial COH doses of 150 IU and GnRH antagonists for LH surge prevention, which reduce the total dosage and duration of gonadotropin stimulation** (401,402). Reintroduction of GnRH antagonists following retrieval may be of benefit (351).

Decreasing the dose of hCG to reduce the incidence of OHSS is controversial (401,402). Exogenous recombinant LH is available for COH, but the dose required to trigger ovulation has not been established (402). **The very short half-life of endogenous LH may in turn reduce the incidence and/or severity of OHSS** (351). GnRH agonists can be used instead of hCG during antagonist cycles to induce an endogenous LH surge. As GnRH agonist triggers are associated with lower pregnancy rates, these may be a better option for oocyte donors or for patients who are not planning a fresh embryo transfer (351,402).

Coasting may be considered when estradiol levels are less than 4,500 pg/mL and/or there are 15 to 30 mature follicles present. **During coasting, gonadotropin stimulation is withheld and estradiol levels are checked daily** (351). An initial rise of estradiol is typically observed within the first 48 hours of the coast, but the levels should subsequently plateau or decrease (402). The patient may then be triggered when serum
estradiol levels fall to less than 3,500 pg/mL. If GnRH agonists are used for initial LH surge suppression, switching to an antagonist during the coast has been associated with improved outcomes (351).

The cycle should be cancelled and the trigger withheld if there are greater than 30 mature follicles, the coast duration is more than 4 days, or if estradiol levels rise to more than 6,500 pg/mL during coasting (351,402).

The adjunctive use of metformin is associated with decreased OHSS rates in PCOS patients (342). Cabergoline, a dopamine agonist that inhibits VEGF production, decreased OHSS rates when given at 0.5 mg daily for 7 or 8 days following retrieval. Long-term use of cabergoline may be associated with valvular heart disease (351,401,402). Albumin given at oocyte retrieval does not appear to decrease subsequent rates of OHSS (401).

Cryopreservation of all embryos without transfer will prevent late onset OHSS (402), but pregnancy outcomes vary for frozen/thaw transfers and early onset OHSS may still occur (401,402). More information on embryo crypreservation can be found in the “Process of Assisted Reproductive Technologies” section.

In vitro oocyte maturation completely obviates the need to stimulate the ovaries with gonadotropins. During in vitro oocyte maturation cycles, immature follicles are aspirated following hCG administration, and the retrieved oocytes are grown in vitro until mature. Mature oocytes are then fertilized by insemination or ICSI. Randomized trials are still needed to further evaluate this technique (403).

**Risk of Cancer after Fertility Therapy**

Infertility by itself is a predisposing factor for ovarian cancer and breast cancer (404,405). Although treatments that promote incessant ovulation and elevated estrogen levels offer biologic plausibility for further increased cancer risk, data regarding the impact of infertility therapy on neoplasias have been inconsistent and conflicting (406). A retrospective cohort study of women in the United States found no association between prior use of clomiphene or gonadotropins and subsequent development of ovarian or breast cancer, although the authors suggested that very high doses or long duration of administration may warrant closer attention (404,405). A large British cohort of women with ovulatory disorders who were given ovulation-stimulation drugs did not find evidence to suggest causation for cancer of the breast, ovary, colon, skin, or thyroid. However, there was a dose–response relationship between the development of uterine cancer and prior use of clomiphene, particularly with a lifetime exposure of 2,250 mg or more (406).

**Stress**

Stress, as manifested by anxiety or depression, is thought to be increased among women experiencing infertility (407). Stress is the most common reason for patients, even
those with insurance coverage, to terminate fertility treatment (408). However, it is not clear whether stress worsens infertility, nor is there clear evidence that psychological treatment improves fertility (407). If psychological disorders are present, treatment should be offered regardless of fertility status.
Preimplantation Genetic Diagnosis

The primary indication for preimplantation genetic diagnosis (PGD) is to improve the chances of having healthy infants in families at high risk for a specific genetic disease (409). Following embryo biopsy, genetic testing can be performed on a blastomere (cell from day 3 embryo), polar body, or on blastocyst trophectoderm prior to transferring the embryo. Aneuploidy in embryos most commonly affects chromosomes X, Y, 13, 14, 15, 16, 18, 21, and 22. Fluorescence in situ hybridization (FISH) is a technique that assesses aneuploidy, translocation, other structural chromosomal defects and sex chromosome content (410). FISH is technically limited by the number of distinct chromosomes that can be evaluated, which results in an inherently high false-negative rate. Newer methods are being developed that assess the entire genome using comparative genomic hybridization or DNA microarrays (411). One-quarter of the cases of PGD are performed for single gene disorders, most commonly myotonic dystrophy, Huntington disease, cystic fibrosis, fragile X syndrome, spinal muscular atrophy, tuberous sclerosis, Marfan syndrome, thalassemia, and sickle cell anemia. Because polymerase chain reaction (PCR) is required for single gene disorder diagnosis, ICSI is performed during ART to avoid contamination from sperm bound to the zona pellucida. PGD can be used for HLA antigen tissue matching in an effort to produce a child whose cord blood or stem cells could potentially help an existing affected child. Disadvantages to PGD include decreased postbiopsy embryo survival, requirements for extended culture with an associated possibility that no embryos will be available for transfer or cryopreservation, false-positive and false-negative testing results, and controversies regarding disposition of nontransferred embryos (409,410). **PGD is not synonymous with preimplantation genetic screening (PGS), which is performed in couples without known chromosomal anomaly, mutation, or other genetic abnormality.** Although it seems intuitive that replacing only euploid embryos should improve pregnancy and live birth rates in patients with advanced age, recurrent pregnancy loss, or implantation failure, study outcomes have not been consistent (409,410,412–415).
Preservation of Fertility in Cancer Patients

Improved cancer treatments such as chemotherapy, surgery, and radiotherapy have greatly enhanced survival, such that many cancer survivors contemplate parenthood. Unfortunately, those life-saving treatments can diminish fertility potential in both men and women. Cancer itself does not usually affect oocytes, but certain chemotherapeutic drugs or radiation damage may adversely affect ovarian reserve and uterine function, particularly in older women (416). Ovarian transposition prior to radiation therapy seems to be effective in preserving ovarian function (417). It is unclear whether ovarian suppression with GnRH analogues or oral contraceptives before or during chemotherapy or radiation is beneficial. If time allows prior to commencement of cancer treatment, women can undergo IVF with embryo cryopreservation (oocyte and ovarian tissue preservation are not routine). In women with cervical cancer, radical trachelectomy allows for retention of the uterus, those with uterine cancer may respond to progestin therapy in lieu of hysterectomy, and some ovarian tumors are amenable to unilateral oophorectomy if future fertility is desired. In men, cancer directly affects gametogenesis, and cancer treatments cause more fertility damage when given at younger ages. Semen and sperm cryopreservation prior to cancer treatment are often recommended for fertility preservation in men (416).

Isolated spontaneous pregnancy loss is remarkably common. Recurrent pregnancy loss affects between 1 in 300 and 1 in 100 couples. After several pregnancy losses, there remains a greater chance of having a viable birth than another loss, even without treatment. Prognosis can improve dramatically with treatment of a known underlying etiology for recurrent pregnancy loss.

Parental chromosomal abnormalities and the antiphospholipid syndrome (APS) are the only undisputed causes of recurrent pregnancy loss. Other well-described causes include anatomic, endocrine, thrombotic, and possibly other immunologic factors.

The state of coagulability is a fine balance between pro- and antithrombotic pathways. The hypercoagulability of pregnancy can be attributed to increases in prothrombotic factors and decreases in those that inhibit coagulation. The immunologic interactions at the maternal–fetal interface reflect the presence of unique cellular constituents combined with the actions of steroid hormones, protein hormones, and metabolic factors.

Evaluation of patients with recurrent pregnancy loss should include a detailed patient and family history, an examination focused on endocrine and anatomic abnormalities, and laboratory studies limited to evaluation of treatable etiologies.

Monitoring early pregnancies in recurrent pregnancy loss patients should include ultrasound, β-human chorionic gonadotropin levels if indicated, frequent visits with psychological support, and the karyotypic analysis of tissues from any pregnancy losses.

In treating recurrent pregnancy loss, evidence supports repairing anatomic abnormalities, correcting preexisting endocrine disorders, and treating APS.
and other thrombophilic disorders. Advances in the ability to document and diagnose early pregnancy reveal that spontaneous pregnancy loss is a common event. Spontaneous pregnancy loss is, in fact, the most common complication of pregnancy. Approximately 70% of human conceptions fail to achieve viability, and an estimated 50% are lost before the first missed menstrual period (1). Most of these pregnancy losses are unrecognized. Studies using sensitive assays for human chorionic gonadotropin (hCG) indicate that the actual rate of pregnancy loss after implantation is 31% (2). Loss occurs in 15% of pregnancies that are clinically recognized before 20 weeks of gestation from last menstrual period (3,4).

Traditionally, recurrent abortion has been defined as the occurrence of three or more clinically recognized pregnancy losses before 20 weeks from the last menstrual period. Using this definition, recurrent pregnancy loss occurs in approximately 1 in 300 pregnancies (2). Clinical investigation of pregnancy loss, however, may be initiated after two consecutive spontaneous abortions, especially when fetal heart activity is identified before any of the pregnancy losses, when the women is older than 35 years of age, or when the couple has had difficulty conceiving (5). A study of over 1,000 patients with recurrent pregnancy loss reported no difference in the prevalence of abnormal results for evidence-based and investigative diagnostic tests when the diagnostic workup was initiated after two versus three or more losses (6). If clinical intervention is undertaken in the form of investigation after two spontaneous abortions, approximately 1% of pregnant women will require evaluation (3). Even with a history of recurrent pregnancy loss, a patient is more likely to carry her next pregnancy successfully to term than to miscarry. For patients with a history of recurrent pregnancy loss, the risk of subsequent pregnancy loss is estimated to be 24% after two clinically recognized losses, 30% after three losses, and 40% to 50% after four losses (7). These data make clinical study of recurrent pregnancy loss and its treatment difficult because very large groups of patients must be studied to demonstrate the effects of any proposed therapeutic intervention.
Parental chromosomal abnormalities and thrombotic complications of the antiphospholipid antibody syndrome (APS) are the only undisputed causes of recurrent abortion. However, collectively these abnormalities account for less than 10% to 15% of recurrent pregnancy losses. Although the exact proportion of patients diagnosed with a particular abnormality may vary among the populations studied, other associations have been made with anatomic abnormalities (12%–16%), endocrine problems (17%–20%), infections (0.5%–5%), and immunologic factors, including those associated with the APS (20%–50%). Other miscellaneous factors have been implicated and account for approximately 10% of cases. Among women aged 35 or greater who experience recurrent pregnancy loss, spontaneous fetal chromosomal abnormalities are likely to be responsible for the vast majority of losses (8). Even after a thorough evaluation, the potential cause remains unexplained in about one-third to one-half of all cases of recurrent loss (Table 33.1) (3,6,9).

The timing of fetal demise provides etiologic clues and its documentation is important in investigations into causes and treatments for recurrent pregnancy loss. The vast majority of preclinical and early clinical pregnancy losses are the result of de novo fetal aneuploidy. This is also thought to be the cause of anembryonic pregnancy losses, whereas pregnancy losses occurring after 10 weeks of fetal development are much less likely to derive from fetal aneuploidy. Pregnancy losses resulting from de novo fetal aneuploidy, whether early and undocumented or documented through evaluation of chromosomal content in fetal tissues, cloud the results of many published studies. Their presence or absence must be documented in all investigations on recurrent pregnancy loss patients and their potential as a confounding factor discussed. The timing of fetal demise and tissue chromosomal analysis of any collected fetal tissues should be carefully weighed when diagnostic and therapeutic investigations into causes of recurrent pregnancy loss are being considered.

### 2. Humoral mechanisms
- a. Antiphospholipid antibodies
- b. Antithyroid antibodies
- c. Antisperm antibodies
- d. Antithrophoblast antibodies
- e. Blocking antibody deficiency

### Thrombotic factors
1. Heritable thrombophilias
   - a. Single gene defects (e.g., MTHFR, factor deficiencies)
   - b. Antibody-mediated thromboses (APS, anti-β2G1) Most are included among other categories (e.g., immune, genetic)

### Other factors
1. Altered uterine receptivity (integrins, adhesion molecules)
2. Environmental
   - a. Toxins
   - b. Illicit drugs
   - c. Cigarettes and caffeine
3. Placental abnormalities (circumvallate, marginate)
4. Maternal medical illnesses (cardiac, renal hematologic)
5. Male factors
6. Exercise
7. Dysynchronous fertilization

TH, T helper; MTHFR, methylene tetrahydrofolate reductase; APS, antiphospholipid antibody syndrome.
Genetic Factors
The most common inborn parental chromosomal abnormalities contributing to recurrent abortion are balanced translocations (11–14), in which one parent carries an overall normal gene content, but has a piece of one chromosome inappropriately attached to another. Depending on the nature of the translocation (reciprocal or Robertsonian), the gametes produced by the translocation carrier will be normal (reciprocal only), balanced, or unbalanced for the translocated DNA. When fertilized by a chromosomally normal gamete, the resulting embryos may be chromosomally normal (reciprocal only) or may be balanced or unbalanced carriers of the translocation. Most gametes and embryos with abnormal chromosomal status will not survive. Of those that do, live offspring will either be carriers of a balanced translocation or, for Robertsonian translocations, be monosomic or trisomic for the translocated chromosomal DNA.

Among the possible chromosomal monosomies, only that of the X chromosome typically permits viable offspring. On careful examination, however, many of these offspring may, in fact, exhibit mosaicism. Embryonic chromosomal monosomy may be particularly prevalent among patients with histories of recurrent pregnancy loss who are undergoing in vitro fertilization (IVF) (15). Compared with monosomies, chromosomal trisomies (e.g., trisomy 13, 18, and 21) appear to be tolerated a bit more readily, although mosaicism also may be implicated with these abnormalities.

Neither family history alone nor a history of prior term births is sufficient to rule out a potential parental chromosomal abnormality. Whereas the frequency of detecting a parental chromosomal abnormality is inversely related to the number of previous spontaneous losses, the chance of detecting a parental chromosomal abnormality is increased among couples who have never experienced a live birth (13). Abnormalities also may be detected upon parental karyotype analysis of some couples with a history of spontaneous abortions interspersed with stillbirths and live births (with or without congenital anomalies). Ultimately the use of parental karyotyping as a screening modality to evaluate the structural chromosomal etiologies of recurrent pregnancy loss may become insufficient. Evidence now suggests that, in some cases, paternal chromosomal abnormalities may be isolated within a particular fertilizing spermatozoon (16,17). Aneuploid spermatozoa may be particularly motile (18). Other structural chromosome anomalies, such as inversions and insertions, may also contribute to recurrent abortion, as can chromosomal mosaicism and single gene defects. X-linked disorders uncommonly result in recurrent abortion of male rather than female offspring (19).

Thrombophilias
There is a great deal of interest in the role of inherited thrombophilias in recurrent pregnancy loss (20–22). This heterogeneous group of disorders increases venous or arterial thrombosis. Their associations with pregnancy loss remains controversial and is attributed to hypothetical alterations in placental growth and development, particularly to
alterations in placental vascular development (23–28). Abnormal placental vascularization and inappropriate placental thrombosis would link these thrombophilic states to pregnancy loss. Although some thrombophilic states may be acquired, most are heritable. Those heritable thrombophilias most often linked with reference to recurrent pregnancy loss include activated protein C resistance associated with mutations in factor V, deficiencies in proteins C and S, mutations in prothrombin, and mutations in antithrombin III.

Like spontaneous pregnancy loss, inherited and combined inherited or acquired thrombophilias are also surprisingly common. Greater than 15% of whites carry an inherited thrombophilic mutation (21). The most common of these are the factor V Leiden mutation, a mutation in the promoter region of the prothrombin gene and mutations in the gene encoding methylene tetrahydrofolate reductase (MTHFR). These disorders are present in their heterozygous state in approximately 5%, 2% to 3%, and 11% to 15% of healthy white populations, respectively (22,29–31). These common mutations are associated with mild thrombotic risks. It remains controversial whether homozygous MTHFR mutations are associated with vascular disease at all (32). In contrast, more severe thrombophilic deficiencies, such as those of antithrombin and of protein S, are much less common in the general population. These epidemiologic data support the hypothesis that a selective genetic advantage may accompany carriage of common heritable thrombophilias. To this point, women with activated protein C resistance because of the factor V Leiden mutation have reduced blood loss at delivery and factor V Leiden carriage is reported to improve pregnancy rates in intracytoplasmic sperm injection or IVF, suggesting a positive role in implantation (33,34). It is important to note that the above epidemiology of factor V Leiden mutations is specific to white populations. Factor V Leiden and prothrombin gene mutations are rare in African and Asian populations, despite similar incidence of venous thromboembolic events (35–38). Protein C, protein S, and antithrombin mutations are the most important risk factors for venous thromboembolic events among many Chinese and other Asian populations (39). These ethnographic differences are important considerations when faced with decisions concerning diagnostic testing in patients with a history of recurrent fetal loss.

The proposed mechanistic basis for the association between adverse fetal outcomes and heritable thrombophilias has focused on impaired placental development and function, secondary to venous and/or arterial thrombosis at the maternal–fetal interface. These findings have been noted in the placentas of women with adverse fetal outcomes and known inherited thrombophilias and have been demonstrated in patients with similar outcomes, but lacking inherited thrombophilic risk (40–44). Discussions of placental thrombosis as causal in early pregnancy losses (<10 weeks gestation) are particularly contentious, citing an elegant series of experiments demonstrating that maternal blood flow into the intervillous spaces of the human placenta does not occur until approximately 10 weeks of gestation (45–48). Prior to establishment of intervillous circulation, nutrient transfer from maternal blood to fetal
tissues appears to be dependent on transudation that, in turn, relies on flow through the uterine vasculature. This suggests that maternal or fetal thrombotic episodes in the developing placental vasculature could be equally devastating prior to or after the establishment of intervillous circulation near 10 weeks of gestation. Very early pregnancy losses (biochemical, anembryonic) and known aneuploid fetal losses are unlikely to be altered by the presence of, or treatment for, an underlying thrombophilic state.

The coagulation system relies on a complex cascade of prothrombotic enzymatic activations (often via serine proteases) in delicate balance with antithrombotic pathways. Although pregnancy is most simply described as prothrombotic, the alterations in the coagulation system associated with pregnancy may be described as a state of compensated disseminated intravascular coagulation (DIC) (49). Human hemochorial placentation is unique and inherently unstable. Placental development involves invasion into the maternal decidua and its vasculature and requires precise control of hemostasis and fibrinolysis. Delicate control mechanisms exist locally within the placenta and globally within the pregnant woman (50). Hormonal and related physiologic changes characteristic of pregnancy affect important components of the clotting cascade, the fibrinolytic cascade, and platelet physiology.

Figure 33.1 The clotting cascade. Physiologic clotting is initiated by endothelial cell damage or abnormal exposure of negatively charged phospholipids to serum and blood components. Procoagulant pathways in black are part of the clotting cascade and are prothrombotic. Both lead to activation of cascades of proteolytic enzymes and cleavage of clotting factors. The extrinsic and intrinsic pathways are initiated by distinct mechanisms. They merge at the activation of factor X to form the common pathway. For all coagulation factors, the subscript letter “a” denotes the activated form of the factor.

Clot formation can be initiated through two pathways, called the extrinsic and intrinsic clotting cascades (Fig. 33.1). Both respond to blood vessel damage and the release of tissue factor (TF). Tissue factor is a glycoprotein expressed on the surface of cells surrounding blood vessels. It is not expressed on the endothelium of the
blood vessel itself, so exposure of blood to TF is a sensitive indicator of vascular damage. The extrinsic clotting cascade begins with the interaction of newly released TF with factor VII of the clotting cascade. The complex formed by TF and factor VII can either activate factor X directly or activate factor X via the intrinsic pathway. In the intrinsic pathway, the TF/factor VII complex activates factor IX to factor IXa (activated factor IX). Factor IXa then complexes with factor VIIIa. In combination, factors IXa and VIIIa activate factor X. Activation of factor XII after binding to negatively charged surfaces can also initiate the intrinsic pathway. Via this route, activated factor XII cleaves factor XI, generating factor XIa. Factor XIa can act as an alternate activator of factor IX. Extrinsic and intrinsic clotting cascades converge in the activation of factor X to factor Xa. Activated factor X (Xa) catalyzes the conversion of prothrombin (factor II) to thrombin (factor IIa). This conversion depends on the presence of activated factor V, which is factor Va. Thrombin, in turn, converts fibrinogen to fibrin, an essential building block for stable clot formation. Thrombin also activates factor XIII, which, in turn, crosslinks fibrin monomers and thereby stabilizes the fibrin clot.

**Figure 33.2 Physiologic mechanisms that counteract the clotting cascade.** The procoagulant cascade is inhibited by several physiologic mechanisms. The balance between pro- and antithrombotic pathways determines the state of coagulability. Antithrombotic mechanisms include the action of antithrombin (AT) and of proteins C and S. The sites of inhibition by these substances are depicted by an “X.” Plasminogen activator inhibitors-1 and -2 (PAI-1 and PAI-2) indirectly inactivate plasmin. Plasmin plays an important role in the dissolution of coagulated blood. For all coagulation factors, the subscript letter “a” denotes the activated form of the factor. FSP, fibrin split products; FDP, fibrin degradation products.

To avoid uncontrolled thrombosis in response to tissue damage or alternate activation of the coagulation cascade, a number of antithrombotic control mechanisms are activated in conjunction with clot formation (Fig. 33.2). Important to this discussion are antithrombin (formerly antithrombin III), protein C, and protein S. Proteins C and S are vitamin K–dependent factors that are activated upon clot
Formation. Activation is initiated by complexes of thrombomodulin and thrombin at sites of endothelial damage. Complexes of activated protein C and S inactivate factors Va and VIIIa, thereby inhibiting their associated procoagulant activities. Antithrombin is a serine protease inhibitor that binds irreversibly to serine proteases. Proteases that bind antithrombin include factors IXa, Xa, XIa, and XIIa. Antithrombin also accelerates dissociation of factor VIIa/tissue factor complexes, thereby inhibiting intrinsic and extrinsic clotting pathways at their points of initiation. Finally, as its name suggests, antithrombin binds to and inhibits thrombin (factor IIa). Fibrinolysis also acts to delimit uncontrolled coagulation (Fig. 33.3). Mechanisms for fibrinolysis include cleavage of the fibrin clot by plasmin and the formation of fibrin degradation products (FDPs; or fibrin split products [FSPs]). Plasmin activity is, in turn, controlled by plasminogen activator inhibitors (e.g., PAI-1).

Figure 33.3 Alterations in coagulation and fibrinolysis during normal pregnancy. Pregnancy is a state of hypercoagulability. Levels of factors VII, VIII, X, and XII are elevated throughout pregnancy, levels of factors II, V, and XIII rise in the first trimester, then return to normal values. The antithrombotic activity mediated by protein S decreases in pregnancy. The placenta produces plasminogen activator inhibitor-2 (PAI-2). For all coagulation factors, the subscript letter “a” denotes the activated form of the factor. FSP, fibrin split products; FDP, fibrin degradation products.

Prothrombotic changes associated with pregnancy include increases in the amounts and/or activities of factors in the clotting cascade and decreases in those counteracting clotting. The former includes pregnancy-associated elevations in factors VII, VIII, X, XII, von Willebrand’s factor, and fibrinogen levels (49,51,52). All rise throughout gestation. Factor II, factor V, and factor XIII levels also rise early in pregnancy, but return to normal levels after the first trimester (49,53). Normal pregnancy has been associated with the development of activated protein C resistance (acquired APCR, see below) via mechanisms that remain unclear (54). Changes in balancing antithrombotic control mechanisms during pregnancy also favor clot formation. The
activities of protein C and antithrombin remain fairly constant during the course of pregnancy. Protein S activity significantly decreases in conjunction with pregnancy-induced increases in the production of C4b-binding protein, a complement factor-binding protein that complexes with protein S, making it unavailable for interaction with activated protein C. This increased binding does not fully explain the level of decrease in protein S activity during pregnancy (55).

Figure 33.4 Homocysteine metabolism. Dietary methionine is metabolized either to cysteine or back into methionine. Homocysteine, a prothrombotic metabolite, is an intermediate in this process. Conversion of homocysteine to methionine requires transfer of a methyl group from 5-methyltetrahydrofolate. The conversion of folate to 5-methyltetrahydrofolate is a multistep process requiring vitamin B₂ as a cofactor for the enzyme, methylene tetrahydrofolate reductase (MTHFR). Vitamin B₁₂ is a required cofactor for the enzyme methionine synthase. Vitamin B₆ is also required for metabolism of sulfur containing amino acids such as methionine.

Fibrinolysis is impaired during pregnancy, with decreases in fibrinolytic activity beginning at approximately 11 to 15 weeks of gestation (49). A significant factor in this impairment is a marked decrease in plasmin activity, resulting from placental production of the plasmin inhibitor PAI-2 (56,57). In conjunction with these changes, however, FDP levels are seen to rise in pregnancy, beginning at approximately 20 weeks of gestation, and continue their rise throughout pregnancy (49,56). In normal pregnancy, platelet function and turnover is unchanged. In the third trimester, platelet number typically decreases as the result of increased platelet consumption. This benign gestational thrombocytopenia can reach levels less than 80 × 10⁹/L (58). Taken together, pregnancy-associated alterations in the amounts and activities of prothrombotic clotting factors, anticoagulant control mechanisms, and fibrinolysis support the determination of human pregnancy as a state of compensated DIC. Although these changes reverse during the 4 to 6 weeks following delivery, the vascular damage associated with delivery is an additional significant risk factor for thrombosis, making the immediate
postpartum period an important continuation of the prothrombotic state associated with pregnancy (49,58).

Circulating homocysteine is derived from dietary methionine. Homocysteine, in turn, is metabolized either into cystathionine or back into methionine (Fig. 33.4). The latter process involves the enzyme methionine synthase. Methionine synthase requires donation of a methyl group from 5-methyltetrahydrofolate to produce methionine, and the enzyme MTHFR is involved in the production of 5-methyltetrahydrofolate from dietary folate sources (20). The nutritional supplements folic acid, vitamins B₂, B₆, and vitamin B₁₂ are all required for proper metabolism of homocysteine; therefore, their deficiency is associated with acquired elevations in circulating homocysteine levels (21,29,59). Although heritable deficiencies in the enzymes required for metabolism of homocysteine have been described for the pathways leading to cystathionine formation and those involved in reconversion to methionine, mutations in MTHFR have received the most attention (20,59–61). Point mutations in MTHFR are surprisingly common, are associated with hyperhomocysteinemia, and are linked to thrombosis (22,29,59–61).

Those heritable thrombophilias most often linked to recurrent pregnancy loss include hyperhomocysteinemia, activated protein C resistance associated with mutations in factor V, deficiencies in proteins C and S, mutations in prothrombin, and mutations in antithrombin. These inherited disorders are mainly autosomal dominant and display a wide variation in prevalence and in the severity of morbidity associated with gene carriage. The latter two characteristics have direct reciprocal correlations in white populations. In agreement with general thrombotic risk data, carriage of combinations of two or more inherited thrombophilic defects has particularly strong association with adverse pregnancy outcome (22,24,30,62). Acquired thrombophilias associated with recurrent pregnancy loss include hyperhomocysteinemia and activated protein C resistance. The vast majority of the data linking thrombophilic states to recurrent fetal loss consist of small- to moderate-sized prevalence studies (62–70). Recent attempts to pool these data into meta-analyses have led to more informed recommendations on the testing of patients presenting with recurrent pregnancy loss (71–73). Taken together, these studies suggest that testing for the factor V Leiden mutation, protein S levels, prothrombin promoter mutations, homocysteine levels, and global activated protein C resistance is of use in white patients with a history of repetitive first or second trimester losses. These recommendations do not apply to patients who are nonwhite. Data directly linking hyperhomocysteinemia, folic acid, vitamin B₁₂, and MTHFR mutations to recurrent pregnancy loss have been contradictory (41,43,60–62,65,66,68). Studies have evaluated pooled data from previous investigations (one via meta-analysis) and show these disorders to be linked to risk for recurrent pregnancy loss (72).
Anatomic Abnormalities

Anatomic abnormalities of both the uterine cervix and the uterine body have been associated with recurrent pregnancy loss (74,75). These anatomic causes may be either congenital or acquired. During development, the uterus forms via the apposition of a portion of bilateral hollow tubes called the müllerian ducts. The dissolution of the walls of these ducts along their site of apposition allows formation of the intrauterine cavity, the intracervical canal, and the upper vagina. Congenital uterine anomalies may, therefore, include incomplete müllerian duct fusion, incomplete septum resorption, and uterine cervical anomalies. Although the causes underlying many of the congenital anomalies of the female reproductive tract are unclear, it has been well documented that prenatal exposure to maternally ingested diethylstilbestrol (DES) results in complex congenital uterine, cervical, and vaginal changes.

Historically, all congenital reproductive tract abnormalities have been linked to both isolated spontaneous pregnancy loss and to recurrent pregnancy loss, although the presence of an intrauterine septum and prenatal exposure to DES demonstrate the strongest associations (76–78). Women with an intrauterine septum may have as high as a 60% risk for spontaneous abortion (79). Uterine septum–related losses most frequently occur during the second trimester (80). However, if an embryo implants into the poorly developed endometrium overlying the uterine septum, abnormal placentation and resultant first trimester losses may occur (81). The most common uterine congenital anomaly associated with in utero DES exposure is hypoplasia, which may contribute to first- or second-trimester spontaneous abortions, incompetent cervix, and premature labor (82,83). Congenital anomalies of the uterine arteries also may contribute to pregnancy loss via adverse alterations in blood flow to the implanted blastocyst and developing placenta (84).

Acquired anatomic anomalies have likewise been linked to both isolated and recurrent pregnancy losses. These abnormalities include such disparate conditions as intrauterine adhesions, uterine fibroids, and endometrial polyps. Endometrium that develops over an intrauterine synechiae or over a fibroid that impinges in the intrauterine cavity (submucous) may be inadequately vascularized (85). This may promote abnormal placentation for any embryo attempting to implant over such lesions. Although data supporting these concepts are limited, this abnormal placentation may lead to spontaneous pregnancy loss. Less clear is the association between intramural fibroids and recurrent pregnancy loss, but it is suggested that large (>5 cm) intramural fibroids are associated with pregnancy loss and that removal improves outcomes (78,86) (see Chapter 15).
Endocrine Abnormalities
The endocrinology of normal pregnancy is complex. Because spontaneous pregnancy is critically dependent on appropriately timed endocrinologic changes of the menstrual cycle, it is not surprising that those endocrine abnormalities that ultimately alter pregnancy maintenance may mediate their effects during the follicular phase of the cycle in which conception occurs, or even earlier. Modifications in follicular development and ovulation, in turn, may be reflected in abnormalities of blastocyst transport and development, alterations in uterine receptivity to the implanting blastocyst, and improper functioning of the corpus luteum. Beginning with ovulation and lasting until approximately 7 to 9 weeks of gestation, maintenance of early pregnancy depends on the production of progesterone by the corpus luteum. Normal pregnancies are characterized by a luteal–placental shift at about 7 to 9 weeks gestation, during which the developing placental trophoblast cells take over progesterone production and pregnancy maintenance (87). Spontaneous pregnancy losses occurring before 10 weeks of gestation may result from a number of alterations in normal progesterone production or utilization. These include failure of the corpus luteum to produce sufficient quantities of progesterone, impaired delivery of progesterone to the uterus, or inappropriate utilization of progesterone by the uterine decidua. Pregnancy failures may also occur near the time of the expected luteal–placental shift if the trophoblast is unable to produce biologically active progesterone following demise of the corpus luteum.

Endocrinologic factors associated with recurrent abortion include luteal phase insufficiency, diabetes mellitus, hypersecretion of luteinizing hormone (LH), thyroid disease, and, potentially, insulin resistance and polycystic ovarian syndrome, hyperprolactinemia and decreased ovarian reserve. Luteal phase insufficiency or luteal phase defects (LPD) are characterized by inadequate luteal milestones and most likely relate to adverse pregnancy outcome via inadequate or improperly timed endometrial development at potential implantation sites. An elegant description of abnormalities at the site of implantation, which may be responsible for some cases of recurrent pregnancy loss, describes impaired decidualization of the endometrium as a mechanism for natural selection of human embryos (88). LPD has many causes, some of which are associated with hypersecretion of luteinizing hormone. Although the mechanism underlying the association of elevated LH levels with recurrent pregnancy loss is incompletely understood, abnormal LH secretion may have direct effects on the developing oocyte (premature aging), on the endometrium (dyssynchronous maturation), or both. Many patients with elevated LH levels also display physical, endocrinologic, and metabolic characteristics of polycystic ovarian syndrome (PCOS). Some studies report ovarian radiologic evidence of PCOS in as many as 40% to 80% of recurrent pregnancy loss patients (89,90). In addition to inappropriately elevated LH levels, PCOS patients are frequently obese and often have elevated circulating androgen levels. Although not undisputed, both changes have been linked to recurrent pregnancy loss, and elevated androgen levels have been shown to
adversely affect markers of uterine receptivity in women with a history of recurrent pregnancy loss (89–92).

**Many women with PCOS have metabolic alterations in glycemic control characterized by insulin resistance.** This too may be directly or indirectly related to adverse pregnancy outcome, and it may explain increases in the rate of spontaneous pregnancy loss among women with type 2 diabetes mellitus (93). Women with overt insulin-dependent diabetes mellitus (IDDM) appear to exhibit a threshold of pregestational glycemic control above which spontaneous pregnancy loss is increased (94,95). In fact, hyperglycemia has now been directly linked to embryonic damage (96). In cases of advanced IDDM with accompanying vascular complications, compromised blood flow to the uterus may be mechanistically involved in subsequent pregnancy loss.

**Patients with thyroid disease often have concomitant reproductive abnormalities, including ovulatory dysfunction and luteal phase defects. In addition, the metabolic demands of early pregnancy mandate an increased requirement for thyroid hormones. It is therefore not surprising that hypothyroidism has been associated with isolated spontaneous pregnancy loss and with recurrent pregnancy loss (97).** The definition of hypothyroidism is itself now under scrutiny with many investigators suggesting that cutoff thyroid-stimulating hormone (TSH) values during pregnancy should be less than 2.5 mIU/mL (98). Others have suggested even lower TSH cutoff values (99). Although it has long been debated whether clinically euthyroid patients with antithyroid antibodies have higher rates of miscarriage and recurrent pregnancy loss, thyroid hormone supplementation was shown to reduce miscarriage in infertility patients with positive antithyroid antibodies undergoing IVF (100–106). The mechanism for an association between antithyroid antibody positivity and recurrent pregnancy loss remains unclear; however, these antibodies could be markers of more generalized autoimmunity or may predict an impaired ability of the thyroid gland to respond to the demands of pregnancy.

Two additional endocrinologic abnormalities have been linked with recurrent pregnancy loss, although support for these associations and their mechanistic pathways remains shrouded in controversy. The relationship of hyperprolactinemia with recurrent pregnancy loss continues to be debated. Animal models suggest that elevated prolactin levels may adversely affect corpus luteal function; however, this concept is not well supported in humans (107,108). Some have suggested that elevated prolactin levels may promote pregnancy wastage via direct effects on the endometrium or indirect immunomodulatory mechanisms (88,109). Most recently, attempts have been made to correlate markers of ovarian reserve (day 3 follicle-stimulating hormone, day 3 estradiol, response to the clomiphene challenge test) with recurrent pregnancy loss (89,110,111). At present, no consensus exists concerning this potential association.
Maternal Infection

The association of infection with recurrent abortion is among the most controversial and poorly explored of the potential causes for pregnancy loss. Reproductive tract infection with bacterial, viral, parasitic, zoonotic, and fungal organisms have all been linked theoretically to pregnancy loss; however, mycoplasma, ureaplasma, chlamydia, and β-streptococcus are the most commonly studied pathogens (112,113). More recent data have directly addressed the roles of some of these proposed organisms in recurrent pregnancy loss. One prospective comparison trial involving 70 recurrent pregnancy loss patients reported no elevations in any markers for present or past infection with Chlamydia trachomatis when compared with controls (114). In contrast, a very large, prospective trial demonstrated a link between the detection of bacterial vaginosis and a history of second trimester pregnancy loss among 500 recurrent pregnancy loss patients (115). The risk of bacterial vaginosis detection was also positively correlated with cigarette smoking in this study.

The etiologic mechanism linking specific organisms to either isolated or recurrent pregnancy loss remains unclear and must certainly differ among infectious organisms. Certain viral organisms, such as herpes simplex virus (HSV) and human cytomegalovirus (HCMV) can directly infect the placenta and fetus (116,117). The resulting villitis and related tissue destruction may lead to pregnancy disruption. Another theoretic possibility warranting study is that infection-associated early pregnancy loss may result from immunologic activation in response to pathologic organisms. A large body of evidence supports the role of this mechanism in adverse events later in gestation, such as intrauterine growth restriction, premature rupture of membranes, and preterm birth (118,119). Alternatively, mechanisms that protect the fetus from autoimmune rejection also may protect virally infected placental cells from recognition and clearance. This could potentially promote periods of unfettered infectious growth for some of the pathogenic organisms gaining entry to the reproductive tract (120).
Immunologic Phenomena

During the past decade, there has been extensive information published concerning the possible immunologic causes and treatments of recurrent pregnancy loss. **There is a lack of consensus as to the mechanisms and the impact of therapeutic intervention because the detection of a therapeutic effect is difficult in the absence of very large studies.** This situation reflects the fact that many recurrent pregnancy loss patients present after their index pregnancy has expired but prior to its being expelled. In these cases, the physiologic immune reaction to the presence of nonviable tissue may mask any alternative, underlying immune causes for the demise itself. Finally, it is very likely that there are a wide variety of immune alterations that may result in the same end point—isolated or recurrent pregnancy loss. This latter theory is certainly supported by a now classic review article that lists 10 fairly well-supported immune mechanisms that are each potentially important in pregnancy maintenance (121) (Tables 33.1 and 33.2).

**Table 33.2 Concepts in Reproductive Immunology**
Before launching into the most commonly accepted causes of immune-mediated pregnancy loss, a brief review of some of the important concepts in basic immunology is warranted. Although these descriptions are presented in general terms, and are further defined in Chapter 6, they should serve as useful reference for the ensuing information.

Immune responses classically are divided into innate and acquired responses. Innate responses represent the body’s first line of defense against pathogenic invasion. They are rapid and are not antigen specific. Cell types and mechanisms
typically considered vital to innate immunity include complement activation, phagocytosis by macrophage, and lysis by natural killer (NK) and natural killer T (NKT) cells and possibly by TCR γδ+ T cells (see below). **Acquired immune responses, in contrast, are antigen specific and are largely mediated by T cells and B cells. Acquired responses can be further divided into primary (response associated with initial antigen contact) and secondary (rapid and powerful amnestic responses associated with subsequent contact to the same antigen).**

Antigen specificity is generally regulated by two sets of genes in the major histocompatibility complex (MHC), located on chromosome 6 in humans. **MHC class I molecules** (HLA-A, -B, and -C) are present on the surface of nearly every cell in the human body and are important in defense against intracellular pathogens, such as viral infection and oncogenic transformation. MHC class I molecules act as important ligands for both the T-cell receptor on CD8+ cytotoxic/suppressor T cells and for a variety of receptors on NK cells (122). **MHC class II molecules** (HLA-DR, HLA-DP, and HLA-DQ), in contrast, are present on the surface of a limited number of antigen-presenting cells, including dendritic cells, macrophage and monocytes, B cells, and tissue-specific cells such as the Langerhans cells in the skin. These molecules are important in defense against extracellular pathogens, such as bacterial invaders. The major ligand for MHC class II is the T-cell receptor on CD4+ T-helper cells.

**One very important concept in immunology that has particular application to pregnancy is that of immune tolerance.** The passage of bone marrow–derived T cells through the fetal thymus during early development has been well described. During this developmental interval, the T cells encounter a process termed thymic education. During thymic education, T cells that express either the CD4 or the CD8 coreceptor are chosen, and autoreactive cells are effectively eliminated. In short, this education promotes T-cell tolerance, allowing selection and survival only of those T cells that recognize non-self and will not react against self. Recently, a subpopulation of CD4+ T cells has been described that, like all activated lymphocytes, strongly express CD25 on their cell surface (123). These CD4, CD25+ cells are more specifically identified by the intracellular presence of the forkhead box P3 (Fox P3) transcription factor and have been called regulatory T lymphocytes (Treg cells). Treg cells, when activated by autoantigens, can suppress activated inflammatory cells. They secrete regulatory cytokines, including interleukin-10 (IL-10) and transforming growth factor-β (TGF-β) (123–125). They may have particular importance in avoidance of tissue destruction associated with inflammation, possibly with applications to tolerance. In an abortion-prone murine model, adoptive transfer of Treg cells from normal pregnant mice into abortion-prone animals prevented immune-mediated pregnancy wastage (126). In pregnant women, Treg cells suppress autologous mediated peripheral blood mononuclear cell (PBMC) secretion of the inflammatory cytokine, interferon-γ (IFN-γ) when challenged by paternal or unrelated PBMCs (127).

These immunologic characteristics were thoroughly described and investigated for the immune effector cells populating the peripheral immune system. The peripheral immune
system consists of the spleen and peripheral blood, and it is generally responsible for protection against blood-borne pathogens. Pathogens that enter the host via the extensive surface areas of the lacrimal ducts, respiratory system, gastrointestinal tract, mammary ducts, and genitourinary tract encounter a very distinct and important immune environment—that of the mucosal immune system. Although the mucosal immune system may be primarily responsible for the initial protection against most exogenous pathogens, an understanding of its immune characteristics lags far behind that of the peripheral immune system. Insight into the specific characteristics of immunity within the reproductive tract is even further limited.

**Cellular Immune Mechanisms**

Many of the immune theories surrounding the causes of isolated and recurrent spontaneous pregnancy losses have stemmed from attempts to define immunologic rules as they apply specifically to the mucosal reproductive tract. Four main questions summarize much of the theoretical thinking surrounding pregnancy maintenance and reproductive immunology:

Which immune cells populate the reproductive tract, particularly at implantation sites?  
How do these cells arrive at this mucosal immune site and are they educated in the same way as those populating the periphery?  
How do the characteristics of antigen presentation differ at the maternal–fetal interface?  
What regulatory mechanisms specifically affect reproductive tract immune cells?

**Resident Cells**

Immune cells populating the reproductive tract exhibit many characteristics that distinguish them from their peripheral counterparts. In particular, the human endometrium is populated by T cells, macrophage, and NK-like cells, but very few B cells are present. The relative proportions of these resident cells vary with the menstrual cycle and change dramatically during early pregnancy. In fact, surrounding the time of implantation, one particular cell type comprises between 70% to 80% of the total endometrial lymphocyte populations (128,129). This cell type is called a variety of names, including decidual granular lymphocytes (DGLs), large granular lymphocytes (LGLs), and decidual NK cells. This heterogeneity of names reflects the fact that this particular cell type differs from similar cells isolated from the periphery, although most believe it to be an NK cell variant. While the majority of peripheral NK cells have low cell surface expression of CD56 (CD56\textsuperscript{dim}) and express high levels of CD16, the immunoglobulin receptor responsible for NK-mediated, antibody-dependent cellular cytotoxicity, those in the uterine decidua and at the placental implantation site, are largely CD56\textsuperscript{bright} and CD16\textsuperscript{dim} or CD16− (130). If these unusual endometrial cells are considered NK cells, the implantation site represents the largest accumulation of NK cells in any state of human health or disease. The true function of these cells remains unclear, but their remarkable abundance at the maternal–fetal interface compels further study. These decidual NK cells display fairly poor cytotoxic function but are robust cytokine
secretors (131,132). The balance of activating and inhibitory receptors expressed on their cell surfaces determines their ultimate killing versus secretion patterns (133,134). Increases in killer-type activating receptors in comparison to inhibitory receptors were found among patients with a history of recurrent pregnancy loss (135,136). Other immune cells have been described in the periphery as having the characteristics of both NK cells and T cells. These NKT cells demonstrated a role in pregnancy loss in animal models (137). They are present in the decidua in humans and may play an important immunoregulatory role at this site (138).

In the peripheral immune compartment, the vast majority of T cells express a T-cell receptor comprised of an αβ heterodimer (TCRαβ+). In addition to TCRαβ+ T cells, the human reproductive tract also is populated by a subset of T cells with a distinctive T-cell receptor comprised of the γδ heterodimer (TCRγδ+), and the numbers of these cells increases in early pregnancy (139–141). TCRγδ+ T cells appear to fulfill functions quite distinct from their αβ+ counterparts; functions that may include direct, non-MHC restricted recognition of antigens within tissues (142). TCRγδ+ T cells may fill a protective niche that is either missed or poorly covered by B cells and TCRαβ+ T cells. The role and importance of TCRγδ+ cells in the reproductive tract and, more particularly, in pregnancy maintenance deserves further attention.

Treg cells are also of the “suppressor” functional phenotype. In pregnant mice and women, these specialized CD4+ cells are systemically expanded in an alloantigen independent fashion and can suppress adverse maternal responses to the fetus (143) and to self (144).

The human decidua contains characteristic immune effector cells. Most investigations into whether alterations in these cells (including T cells, decidual NK cells, and NKT cells) determine pregnancy outcome are hampered by insufficient patient numbers to allow meaningful conclusions. These immune cell populations are reported to be altered in recurrent pregnancy loss patients but not in patients experiencing isolated spontaneous pregnancy losses (141,145–147).

**Immune Cell Education and Homing to the Reproductive Tract**

The implanting fetus represents the most common model of allograft acceptance. How the maternal immune system avoids rejection of the implanting fetus in an uncomplicated pregnancy invokes the presence of some manifestation of immune tolerance. This, in turn, begs the questions of how the resident decidual immune effector cells are selected and educated, how they home to reproductive sites, and how they are maintained once they reach this destination. Animal studies have suggested that the rules for selection and maintenance of these cells, in terms of their requirement for MHC and their education within the thymus, may be distinct from those governing either peripheral immune cells or cells within other mucosal sites, including the intestine (148). It appears the human reproductive tract displays similar characteristics—the immunophenotypes of immune cells populating the human reproductive tract are distinct from both the periphery and from other mucosal sites
The education of TCRγδ+ cells populating epithelial sites may occur outside the thymus and might involve mechanisms that substitute for or modify interaction with MHC (141,151). The development of MHC specificity among NK cells is presently being carefully dissected in animal models with the hope that these investigations will shed light on similar processes in humans and, more specifically, on the selection and maintenance characteristics of decidual NK cells (133,134,152,153).

It is becoming increasingly evident that the cells populating mucosal immune tissues select these sites through interactions between cell surface molecules on the immune cell (integrins) and cell surface molecules on the endothelial cells of blood vessels within the mucosal tissues (e.g., selectins). This cellular recruitment process, called homing, has been most thoroughly described for the intestine (154,155). Both murine and human reproductive tract tissues express these integrin or vascular ligand pairs (155–157). The extension of these findings to pregnancy maintenance will be useful (158,159). Solving the mechanisms of selection, education, and maintenance of reproductive tract immune effector cells is of paramount importance. Until we understand these vital processes in the normal state, we cannot define the effects that alterations will have on human disease nor can we develop therapeutic interventions.

**Antigen Presentation at the Maternal–Fetal Interface**

Historically, it was proposed that one method by which the implanting trophoblastic allograft potentially could avoid immune detection by the maternal host would be by making itself antigenically invisible. It could downregulate its expression of the MHC-encoded transplantation antigens (some of which would be of paternal origin) and thereby avoid recognition as non-self. Although current knowledge of immunology renders this theory obsolete, the implanting fetus does utilize this strategy to some extent (160). It is certainly true that placental trophoblast cells do not express MHC class II molecules (161,162).

Unlike nearly every other cell in the human body, trophoblast cells do not express the classical MHC class I transplantation antigens HLA-A and -B. Rather, a subpopulation of placental cells, specifically the extravilous cytotrophoblast cells, express the classical MHC class I HLA-C products, and the nonclassical HLA-E and -G products (120,163–167). These extravilous cytotrophoblast cells are of particular interest because they are characterized by remarkable invasive potential (168,169). These cells move from the tips of the anchoring villae of the human placenta, invading deeply into the maternal decidua, and can replace cells within the walls of decidual arterial vessels (168–170). Although the invasive characteristics of extravilous cytotrophoblast may reflect non-MHC–related mechanisms, including well-described integrin switching, the intimate contact of these fetal-derived cells with maternal immune effector cells certainly exposes the fetus to recognition as nonself (171).

It is not known why all placental cells downregulate expression of HLA-A and -B, whereas invasive extravilous cytotrophoblast express HLA-C, -E, and -G. This area of investigation is ripe with hypotheses and study. Because NK cells of the innate immune system
recognize and kill cells that express no MHC, the complete downregulation of MHC should cause trophoblast cells to act as targets for those NK cells that are pervasive at sites of implantation (134,160). In addition to possible protection from direct NK cell–mediated killing, the expression of HLA-C, -E, and -G by trophoblast cells may serve a variety of alternate purposes. NK cell receptor-mediated interactions with extravillous cytotrophoblast MHC products modulate cytokine expression profiles at the maternal–fetal interface (131,132). MHC expression aids in decidual and vascular invasion by the trophoblast, an activity essential for proper placental development (172). Whereas definitive correlations between placental MHC class I expression patterns and recurrent pregnancy loss have not been reported, trophoblast expression of HLA-G was linked to other disorders of placental invasion, such as preeclampsia (172,173). Genetic mutations at the HLA-G locus have also been linked to recurrent pregnancy loss in some, but not all studies (174–177). Finally, soluble or secreted trophoblast MHC products may aid in the development of maternal immune tolerance toward the placenta (178). Soluble HLA-G was shown to suppress T lymphocyte and NK cell function and to induce the expansion of Treg cells in humans (179).

Aberrant expression of class II MHC determinants, or enhanced expression of MHC class I on syncytiotrophoblast occurring in response to IFN-γ (180) could mediate pregnancy loss by enhancing cytotoxic T-cell attack (181). This theory appears unlikely, because the expression of classical MHC antigens does not seem to be induced on aborted tissues from women experiencing one or more pregnancy losses (181). Finally, MHC class II genotypes appear to affect susceptibility to a variety of diseases, including diabetes and other autoimmune diseases. A similar link between MHC class II typing and adverse pregnancy outcome was reported for recurrent pregnancy loss (182,183).

Regulation of Decidual Immune Cells
The characteristics of the interactions between decidual immune effector cells and the implanting fetus may be determined by factors other than those already mentioned. Local regulation of the cells that populate the human decidua will further modify the effects of selection, maintenance, and homing, as well as the distinctive characteristics of antigen presentation at the maternal–fetal interface. As might be predicted, these regulatory effects are often targets for investigative efforts, because they may offer more direct insight into potential therapies for immune-mediated disorders of pregnancy maintenance. Three such regulatory mechanisms will be discussed here: (i) alterations in T-helper cell phenotypes, (ii) reproductive hormones and immunosuppression, and (iii) tryptophan metabolism.

As discussed in Chapter 6, antigen-stimulated immune responses involving CD4+ T cells can be divided into two major classes: T helper 1 (TH1) responses and T helper 2 (TH2) responses. This subclassification may be overly simple, but it has been useful in broadly defining types of immune responses based on the characteristics of the CD4+ cells present, as well as their associated cytokines. The production of these responses rests on
the environment in which relatively undifferentiated CD4+ TH0 cells become differentiated. Thus, TH0 cells exposed to IFN-γ become TH1-type cells, and those exposed to IL-4 become TH2-type cells (184). TH1 responses are associated with inflammation and primarily involve IFN-γ and IL-12, as well as IL-2, and tumor necrosis factor-β (TNF-β). TH2 cells responses are associated with antibody production and the cytokines IL-10, IL-4, IL-5, and IL-6 (184–186). Although TNF-α can be secreted by both TH1 and TH2 cells, it is most often a characteristic of TH1 response (187,188).

A reciprocal regulating relationship exists between TH1 and TH2 cells and cytokines, with one response supporting its own persistence while averting conversion to the other (189–191).

One additional T-helper cell subset, TH17 cells, has been recently distinguished, although many of their proinflammatory effects were previously attributed to TH1 cells (192). TH17 cells preferentially produce IL-17 family cytokines (including IL-17A and IL-17F), which upregulate stromal IL-8 and IL-6 and cause local neutrophilic inflammation. These cells are important in sustaining the inflammatory response and are closely associated with several autoimmune diseases (193).

Extending these immune regulatory phenomena to pregnancy, the type of CD4+ cellular response to the implanting fetus is controlled not only by the types of cells (e.g., T-helper cells) in the decidua, but also by the cytokine environment at the maternal–fetal interface. As mentioned previously, the human endometrium and decidua are replete with immune and inflammatory cells capable of cytokine secretion (194–196). Cytokines may affect reproductive events either directly or indirectly, depending on the specific cytokines secreted, their concentrations, and the differentiation stage of potential reproductive target tissues. It is well documented that TH1-type cytokines can be harmful to an implanting embryo (197,198). Further, most agree that some patients with recurrent pregnancy loss exhibit a dysregulation of their T-helper cellular immune response to antigens at the site of implantation, with typical shifts toward TH1 inflammatory responses (199,200). Depending on the individual series, 60% to 80% of nonpregnant women with a history of otherwise unexplained recurrent spontaneous abortion have been found to have evidence of abnormal in vitro TH1 cellular immune responses. Fewer than 3% of women with normal reproductive histories demonstrate these responses (199,201). Rather, most women with normal pregnancies have a TH2 immune response to trophoblast antigens (199). It has only been recently that the TH17 concept has been applied to pregnancy (202). In humans, a single study demonstrates an increase in the number of TH17 cells in the decidua and peripheral blood of women with otherwise unexplained recurrent pregnancy loss (203). Mechanistically, a dysregulation of TH17 cell control by Treg cells may lead to adverse pregnancy outcomes (204).

Methods for the documentation of cytokine dysregulation among recurrent pregnancy loss patients also varies among investigators; some groups have confirmed this abnormality within the endometrium or among immune cells isolated from the decidua of these patients (205–208). Others use peripheral blood lymphocytes (PBLs) from women with a
history of recurrent pregnancy loss and stimulate them in vitro with trophoblast antigens \(199,209\). One study documented aberrant cytokine secretion when PBLs from recurrent pregnancy loss patients were stimulated in vitro by HLA-G bearing cells, whereas another study demonstrated that decidual and peripheral immune cells exhibit a shift toward the TH2 phenotype when exposed to HLA-G \(210,211\). Whether peripheral cytokine levels reflect T-helper cell dysregulation at the maternal–fetal interface and whether this dysregulation affects peripheral as well as local immune response during pregnancy remains controversial \(212,213\). Finally, as with all immune theories, there seems to be significant redundancy in the necessity for particular cytokines and soluble immunoregulatory factors at the site of implantation. To date, animal models with directed gene deletions have shown few of these factors to be absolutely essential to pregnancy maintenance (e.g., leukemia inhibitory factor [LIF]) \(214,215\).

Although many mechanisms are aimed at avoiding maternal immune recognition of the implanting fetus, research in both humans and animals indicates that immune responses to fetal antigens can be detected \(216–218\). Thus, the regulation of this response at the maternal–fetal interface may be critical. The concept that successful pregnancy requires some form of generalized suppression of maternal immune response is supported by reports that failure to downregulate maternal responses to recall antigens, such as tetanus toxoid and influenza, is associated with poor pregnancy outcome among recurrent pregnancy loss patients \(219\). Treg cells appear important in this respect (see above). So too do reproductive hormones. Reproductive hormones have dramatic effects on peripheral cell-mediated immunity, as demonstrated by well-documented and notable gender differences in immune responsiveness \(220\). The levels of these potentially immunosuppressive hormones are quite elevated in pregnant women. The fact that the levels of these hormones at the maternal–fetal interface may be far above those in the maternal circulation during pregnancy may explain an apparent inconsistency: overall immune responsiveness during pregnancy appears to change little, while local suppression at the maternal–fetal interface may be vital \(221\).

It has been suggested that the immunosuppressive effects of progesterone within the reproductive tract are at least partially responsible for the maintenance of the semiallogeneic implanting fetus \(222\). In vitro studies have shown that progesterone mediates its suppression of T-cell effector function by altering membrane-resident potassium channels and cell membrane depolarization. This action, in turn, affects intracellular calcium signaling cascades and gene expression and may be mediated by nonclassical steroid receptors or may not involve a receptor at all \(223–225\). Progesterone-mediated changes in T-cell gene expression have been associated with the development of TH2-type T-helper cell responses and with increased LIF expression \(208,226\). Because a shift in the intrauterine immune environment from TH2 to TH1 has been linked with early spontaneous pregnancy loss, the elevated intrauterine concentrations of progesterone characteristic of early pregnancy may promote an immune environment favoring pregnancy maintenance \(199,208\). To this
point, in vitro evidence indicates that progesterone can inhibit mitogen-induced proliferation of and cytokine secretion by CD8+ T cells and can alter the expression of a transcription factor that drives the development of TH1 cells (227,228).

Levels of estrogen also rise dramatically during pregnancy, and attention has focused on the role of estrogen in immune modulation. A group of animal studies showed that estrogens improve immune responses in males after significant trauma and hemorrhage, suppress cell-mediated immunity after thermal injury, and protect against chronic renal allograft rejection (229–231). In vitro, estrogens appear to downregulate delayed-type hypersensitivity (DTH) reactions and promote the development of TH2-type immune responses, particularly at the elevated estrogen concentrations typical of pregnancy (232,233).

One additional regulatory mechanism proposed for the induction of maternal tolerance to the fetal allograft involves the amino acid tryptophan and its catabolizing enzyme indolamine 2,3 dioxygenase (IDO). The IDO hypothesis of tolerance in pregnancy rests on data that indicate that T cells need tryptophan for activation and proliferation (234), and that local alterations in tryptophan metabolism at the maternal–fetal interface could either activate or fail to suppress maternal antifetal immunoreactivity (235). Studies in mice have shown that the inhibition of IDO leads to loss of allogeneic, but not syngeneic, fetuses, and that this effect is mediated by lymphocytes (236). Further support lies in studies demonstrating that hamsters fed diets high in tryptophan have increased rates of fetal wastage (237). Extending this theory to humans requires further investigation. However, the demonstration of IDO expression in human uterine decidua, and the documentation of alterations in serum tryptophan levels with increasing gestational age during human pregnancy both support further interest in this potential local immunoregulatory mechanism (238,239).

Endometriosis is the growth of both endometrial glands and stroma outside of the intrauterine cavity. Although associations between the development of endometriosis and immunologic abnormalities are now being defined, the link between endometriosis and recurrent pregnancy loss remains contentious (240,241). The occurrence of recurrent pregnancy loss in the presence of endometriosis certainly would involve the interaction of complex mechanisms, some of which may involve cellular or humoral immune dysfunction (242,243).

**Humoral Immune Mechanisms**

Humoral responses to pregnancy-specific antigens exist, and patients with recurrent pregnancy loss can display altered humoral responses to endometrial and trophoblast antigens (Table 33.2) (199,244). Nevertheless, most literature surrounding humoral immune responses and recurrent pregnancy loss focus on organ nonspecific autoantibodies associated with the antiphospholipid antibody syndrome (APS). Historically, these immunoglobulin-G (IgG) and IgM antibodies were considered as directed against negatively charged phospholipids. Those phospholipids most often
implicated in recurrent pregnancy loss are cardiolipin and phosphatidylserine. However, antiphospholipid antibodies often are directed against a protein cofactor, β2 glycoprotein 1, which assists antibody association with the phospholipid (245–249). Antiphospholipid antibodies were originally characterized by prolonged phospholipid-dependent coagulation tests in vitro (activated partial thromboplastin time [aPTT], Russell Viper Venom time) and by thrombosis in vivo. The association of these antiphospholipid antibodies with thrombotic complications has been termed the antiphospholipid syndrome, and although many of these complications are systemic, some are pregnancy specific—spontaneous abortion, stillbirth, intrauterine growth retardation, and preeclampsia (250,251). A reassessment of the criteria used to diagnose APS resulted in additions to the prior Sapporo criteria for diagnosis of APS and continues to include adverse pregnancy outcomes. These criteria, which have been validated clinically, are as follows (251–253).

For a patient to be diagnosed with antiphospholipid antibody syndrome, one or more clinical and one or more laboratory criteria must be present:

Clinical
One or more confirmed episode of vascular thrombosis of any type:
Venous
Arterial
Small vessel
Pregnancy complications:
Three or more consecutive spontaneous pregnancy losses at less than 10 weeks of gestation with exclusion of maternal anatomic and hormonal abnormalities and exclusion of paternal and maternal chromosomal abnormalities
One or more unexplained deaths of a morphologically normal fetus at or beyond 10 weeks of gestation (normal fetal morphology documented by ultrasound or direct examination of the fetus)
One or more premature births of a morphologically normal neonate at or before 34 weeks of gestation secondary to severe preeclampsia or placental insufficiency

Laboratory
Testing must be positive on two or more occasions with evaluations 12 or more weeks apart:
Positive plasma levels of anticardiolipin antibodies of the IgG or IgM isotype at medium to high levels
Positive plasma levels of lupus anticoagulant
Anti-β2 glycoprotein-1 antibodies of the IgG or IgM isotype in titers greater than the 99th percentile

The presence of antiphospholipid antibodies (anticardiolipin or lupus anticoagulant) and anti-β2 glycoprotein-1 antibodies during pregnancy is a major risk factor for an adverse pregnancy outcome (245,246,254). In a large
A number of mechanisms have been proposed by which antiphospholipid antibodies might mediate pregnancy loss (256). Antibodies against phospholipids could increase thromboxane and decrease prostacyclin synthesis within placental vessels. The resultant prothrombotic environment could promote vascular constriction, platelet adhesion, and placental infarction (257–259). Alternatively, in vitro evidence from trophoblast cell lines indicates that IgM action against phosphatidylserine inhibits formation of syncytial trophoblast (260). Syncytialization is required for proper placental function. One study demonstrated that both extravillous cytotrophoblast and syncytiotrophoblast cells synthesize β2 glycoprotein-1, the essential cofactor for antiphospholipid antibody binding (261). Although it gives insight into pathophysiology, the prognostic value of serum levels of specific antibodies against β2 glycoprotein-1 with respect to pregnancy outcome among recurrent pregnancy loss patients is contentious and may be poorer than that of standard anticardiolipin antibodies (262–264). Some have proposed that sera from antibody positive recurrent pregnancy loss patients is particularly adept at inhibiting trophoblast adhesion to endothelial cells in vitro (265). Others noted rapid development of atherosclerosis in the decidual spiral arteries of patients who test positive for antiphospholipid antibody (266). Finally, still others have demonstrated that levels of the placental antithrombotic molecule—annexin V—are reduced within the placental villa from those women with recurrent pregnancy loss who are antiphospholipid antibody positive (267). However, placental pathologic evidence supporting causal involvement of the antiphospholipid antibody syndrome in pregnancy loss often is equivocal. The characteristic lesions for this syndrome (placental infarction, abruption, and hemorrhage) are typically missing in women with antiphospholipid antibodies, and these same pathologic lesions can be found in placentae from women with recurrent abortion who do not have biochemical evidence of antiphospholipid antibodies (256,268–270).

One additional group of autoantibodies that have been linked to recurrent pregnancy loss is the antithyroid antibodies (ATA). Although the data remain somewhat controversial, several investigators demonstrated an increased prevalence of these antibodies among women with a history of recurrent pregnancy loss, even in the absence of thyroid endocrinologic abnormalities (98–199,102,103,271–273).

Other antibody-mediated mechanisms for recurrent abortion have been proposed, including antisperm and antitrophoblast antibodies, as well as blocking antibody deficiency. Although each hypothesis has minimal relevance to recurrent pregnancy loss, their discussion is warranted because therapies aimed at these disorders persist. Historically, the blocking antibody deficiency hypothesis has received the most attention (112,181). This hypothesis is based on a supposition that blocking factors (presumably antibodies) were required to prevent a maternal, cell-mediated,
antifetal immune response that was believed to occur in all pregnancies. It was therefore proposed that, in the absence of these blocking antibodies, abortion occurred (273). This supposition was not consistently substantiated (274,275). For instance, maternal hyporesponsiveness in mixed lymphocyte culture with paternal stimulator cells was originally proposed to identify women with deficient blocking activity (273). Investigations based on this type of testing were continued by those who proposed that parental HLA sharing resulted in a predisposition to blocking antibody deficiency (276,277). These reports were of limited sample size, were retrospective in nature, and lacked population-based controls. One prospective, population-based control study conclusively demonstrated that HLA heterogeneity was not essential for successful pregnancy (278). However, follow-up studies showed that, in the exceedingly rare case of complete sharing of the entire HLA region, spontaneous pregnancy losses do increase (279). This particular 10-year prospective trial concluded that HLA typing is of no use in outbred populations, because only isolated and significantly inbred populations have such HLA homogeneity. Further evidence refuting the blocking antibody hypothesis for recurrent abortion comes from reports of successful pregnancies among women who do not produce serum factors capable of mixed lymphocyte culture inhibition and also among women who do not produce antipaternal cytotoxic antibodies (273,274). Those mixed lymphocyte culture results that demonstrate hyporesponsiveness in some recurrent pregnancy loss patients are now believed to represent the effect of the pregnancy loss rather than the cause of recurrent abortion (217,273–275).

One final theory that emerged from the blocking antibody investigations involved a novel HLA-linked alloantigen system. The finding that polyclonal rabbit antisera could recognize both lymphocytes and trophoblast cells suggested the existence of trophoblast–lymphocyte cross-reactive alloantigens (called TLX) (280). These TLX were, in turn, linked to maternal blocking antibody deficiency and recurrent pregnancy loss. The TLX hypothesis only has historical relevance. The theory was invalidated when TLX was found to be identical to CD46, a complement receptor that is thought to protect the placenta from complement-mediated attack (281). CD46 was not a novel alloantigen. It can be found on a wide variety of cells, thus explaining the cross-reactive nature of the original rabbit antisera.

It is important to conclude this in-depth discussion of the immune-mediated mechanisms of isolated and recurrent pregnancy loss by suggesting that pregnancy may not require an intact maternal immune system. Supporting this concept are data showing that agammaglobulinemic animals and women can successfully reproduce (282). Further, viable births also occur among women with severe immune deficiencies and in murine models that lack T and B cells (severe combined immunodeficiency [SCID] mice) and those that display a congenital absence of their thymus (nude mice). Still, immune factors may play important roles in a significant proportion of patients with recurrent pregnancy loss, and their presence is the subject of abundant research. Until this role is better defined, an understanding of contemporary immunologic hypotheses fosters the informed consideration of novel findings.
Male Factors

Most publications that review testing and treatment for recurrent pregnancy loss couples, including this chapter, recommend only a single test for the male partner in the couple—a peripheral blood karyotype. The role of the male partner in the etiology of recurrent pregnancy loss is understudied, but there is a growing body of literature suggesting that the development and validation of novel testing and treatment regimens for the male may prove beneficial (283,284). Detailed peripheral chromosomal testing of men whose partners experienced recurrent pregnancy loss revealed an increased incidence of Y chromosome microdeletions when compared to male partners in fertile and infertile couples (285). Small studies demonstrated that male partners in couples experiencing recurrent pregnancy loss have an increased incidence of sperm chromosomal aneuploidy, particularly sex chromosome disomy, when compared to fertile men (16,286). The addition of specialized testing to a standard semen analysis among men in couples with recurrent loss revealed reductions in sperm functional testing (hypo-osmotic swelling, acrosome status, nuclear chromatin decondensation) and increased DNA fragmentation and lipid peroxidation when compared to fertile men or historical controls (287–289). The latter results suggest that these men may have abnormal levels of reactive oxygen species in their semen or that their sperm cells are particularly sensitive to these compounds. To this point, paternal carriage of the MTHFR C677T mutation and hyperhomocysteinemia were associated with both DNA damage and recurrent pregnancy loss (290). A single, small, uncontrolled treatment study using antioxidants among male partners in recurrent pregnancy loss couples who had high levels of sperm DNA damage or semen lipid peroxidation suggested favorable treatment outcomes (288).
Other Factors

It is increasingly evident that the implantation of the blastocyst within the uterine decidua involves an exquisitely scripted crosstalk between embryo and mother. Alterations in this dialogue often result in improper implantation and placental development. For instance, recurrent pregnancy loss has been linked to a dysregulation in the expression patterns of vascular endothelial growth factors (VEGFs) on the developing placenta and their requisite receptors within the maternal decidua (291). Cellular and extracellular matrix adhesion properties may also be involved in this dialogue. The concept of uterine receptivity has been emboldened by the description of endometrial integrins and the timing of integrin switching during implantation (292). Others have reported decreased levels of endometrial mucin secretion and reductions in the endometrial release of soluble intercellular adhesion molecule I among women with histories of recurrent pregnancy loss (293,294). Programmed cell death (apoptosis) may also play an essential role in normal placental development. Alterations in two important apoptotic pathways—Fas-Fas ligand and bcl2—have both been linked to recurrent pregnancy loss and poor pregnancy outcome (121,295).
Environmental Factors

A variety of environmental factors have been linked to sporadic and recurrent early spontaneous pregnancy loss. These are difficult studies to perform, because, in humans, they all must be retrospective and all are confounded by alternative or additional environmental exposures. Nevertheless, the following factors have been linked to pregnancy loss: exposure to medications (e.g., antiprogestogens, antineoplastic agents, and inhalation anesthetics), exposure to ionizing radiation, prolonged exposure to organic solvents, and exposure to environmental toxins, especially bisphenol-A and heavy metals (296–299). The latter two exposures have been demonstrated to have both endocrine and immune effects that could lead to poor placentation and subsequent pregnancy loss (300,301). Associations between spontaneous pregnancy loss and exposures to video display terminals, microwave ovens, high-energy electric power lines, and high altitudes (e.g., flight attendants) are not substantiated (302,303). There is no compelling evidence that moderate exercise during pregnancy is associated with spontaneous abortion. In the absence of cervical anatomic abnormalities or incompetent cervix, coitus does not appear to increase the risk for spontaneous pregnancy loss (304,305). Exposure to three particular substances—alcohol, cigarettes, and caffeine—deserves specific attention. Although some conflicting data exist, one very large epidemiologic study has shown that alcohol consumption during the first trimester of pregnancy, at levels as low as three drinks per week, is associated with an increased incidence of spontaneous pregnancy loss (306–308). Cigarette smoking has also been linked to early spontaneous pregnancy loss; however, this is also not without controversy (309–311). Alcohol and tobacco intake in the male partner correlates with the incidence of domestic violence, which in turn is associated with early pregnancy loss (312). Finally, recent evidence adds to a growing body of literature that suggests consumption of coffee and other caffeinated beverages during early pregnancy is linked to adverse pregnancy outcome (309,313). The most publicized recent report casts doubt on the definition of a lower limit for safe use of caffeine in the first trimester of pregnancy (309). Obesity, stress at work, and use of nonsteroidal anti-inflammatory agents during early pregnancy have all been linked to an increased rate of isolated spontaneous pregnancy loss (314–317).
Preconception Evaluation

Investigative measures that are potentially useful in the evaluation of recurrent spontaneous abortion include obtaining a thorough history from both partners, performing a physical assessment of the woman (with attention to the pelvic examination), and a limited amount of laboratory testing (Table 33.3).
History
A description of all prior pregnancies and their sequence as well as whether histologic assessment and karyotype determinations were performed on previously aborted tissues are important aspects of the history. **Approximately 60% of abortuses lost before 8 weeks of gestation were reported to be chromosomally abnormal; most of these pregnancies are affected by some type of trisomy, particularly trisomy 16** ([318,319]). **The most common single chromosomal abnormality is monosomy X (45X), especially among anembryonic conceptuses** ([320]). Aneuploid losses are particularly prevalent among women with recurrent pregnancy loss who are over the age of 35 ([8]). Although somewhat controversial, the detection of aneuploidy in miscarriage specimens may be less when the couple experiencing recurrent abortions is euploidic. Alternatively, some investigators have suggested that, because aneuploidy is common among miscarriage specimens from patients experiencing both isolated and recurrent spontaneous pregnancy losses, if aneuploidy is documented in fetal tissues from a recurrent pregnancy loss patient, this loss does not affect their prognosis for future pregnancy maintenance ([13]).

**Most women with recurrent pregnancy losses tend to experience spontaneous abortion at approximately the same gestational age in sequential pregnancies** ([321]). Unfortunately, the gestational age when pregnancy loss occurs, as determined by last menstrual period, may not be informative, because there is often a 2- to 3-week delay between fetal demise and signs of pregnancy expulsion ([322]). The designation of couples experiencing recurrent abortion into either primary or secondary categories is not helpful in either the diagnosis or management of most women with recurrent abortion. Approximately 10% to 15% of couples cannot be classified into either the primary or secondary category because, although their first pregnancy resulted in a loss, it was followed by a term delivery prior to subsequent losses.

**Table 33.3 Investigative Measures Useful in the Evaluation of Recurrent Early Pregnancy Loss**
It is important to glean any history of subfertility or infertility among couples with recurrent pregnancy loss. This is defined as the inability to conceive after 12 months of unprotected intercourse. By definition, 15% of all couples will meet this criteria; this number increases to 33% among couples with recurrent pregnancy losses. Because many pregnancies are lost before or near the time of missed menses, subfertility among recurrent pregnancy loss patients may in some cases reflect recurrent preclinical losses. Menstrual cycle history may provide information about the possibility of oligo-ovulation or other relevant endocrine abnormalities in recurrent pregnancy losses.
pregnancy loss patients. An assessment of the timing of intercourse relative to ovulation should be reviewed with couples in an effort to detect dyssynchronous fertilization that could contribute to pregnancy loss (323). A personal and family history of thrombotic events or renal abnormalities may provide vital information. A family history of pregnancy losses and obstetric complications should be addressed specifically. Detailed information about drug and environmental exposure should also be obtained.
Physical Examination

A general physical examination should be performed to detect signs of metabolic illness, including PCOS, diabetes, hyperandrogenism, and thyroid or prolactin disorders. During the pelvic examination, signs of infection, DES exposure, and previous trauma should be ascertained. Estrogenization of mucosal tissues, cervical and vaginal anatomy, and the size and shape of the uterus should also be determined.
Laboratory Assessment

Valuable Tests

Laboratory assessment of couples with recurrent pregnancy losses should include the following:

- Chromosome analysis of the products of conception
- Parental peripheral blood karyotyping with banding techniques
- Assessment of the intrauterine cavity with either office hysteroscopy, sonohysterography, three-dimensional transvaginal sonography, or hysterosalpingography, followed by operative hysteroscopy if a potentially correctable anomaly is found
- Thyroid function testing, including serum thyroid-stimulating hormone levels, anticardiolipin, anti-β2 glycoprotein-1, and lupus anticoagulant testing (aPTT or Russell Viper Venom testing)
- Platelet levels

Tests with Unproven Utility

A number of laboratory assessment tools are under investigation for use in patients with a history of recurrent pregnancy loss. At present, results are either too preliminary to warrant unfettered recommendation or studies of their use have been too contradictory to allow final determination of their value. **Tests with unproven or unknown utility include:**

- Evaluation of ovarian reserve using day 3 serum follicle-stimulating hormone or antimüllerian hormone levels. It appears that decreased ovarian reserve may portend a poor outcome in all patients, including those with recurrent pregnancy loss.
- Thrombophilia testing:
  - Factor V Leiden, G20210A prothrombin gene mutation, protein S activity
  - Serum homocysteine levels
  - If there is a family or personal history of venous thromboembolic events, obtain protein C activity and antithrombin activity.
  - Consider altering these screening paradigms based on ethnic background. Factor V Leiden and prothrombin promoter mutations are rare in African and Asian populations. Among Asian populations, protein C and protein S are the most common inherited thrombophilias.
  - Testing for serologic evidence of PCOS using luteinizing hormone or androgen values may be useful.
- Testing for peripheral evidence of TH1/TH2 cytokine dysregulation. Although large studies failed to demonstrate association between peripheral cytokine alterations and pregnancy outcome among patients with recurrent pregnancy loss, smaller studies reported peripheral shifts toward TH1 profiles only in those recurrent pregnancy loss...
patients who subsequently lose their pregnancy (212,213). One study documented a shift toward TH1 profiles at the time of fetal demise in these patients; however, it is particularly difficult to determine cause and effect in this situation (325).

**Preconceptional testing for the prevalence and activity of peripheral NK cells has been reported in small studies to reflect prognosis and to facilitate patient counseling** (326,327). Still, peripheral NK cells may not adequately reflect those at the site of implantation, and this testing remains unproven.

**Testing for antithyroid antibodies among women with recurrent pregnancy loss remains controversial**, but is rapidly gaining support (98–100,103,271–273). Investigators have recently demonstrated an increased prevalence of these antibodies among women with a history of recurrent pregnancy loss, even in the absence of thyroid endocrinologic abnormalities (99,100,102,272).

**Testing for the presence of a variety of autoantibodies (other than lupus anticoagulant and anticardiolipin antibody) has been hotly debated, but without consensus** (245,246,249,262,328,329). Testing for some antiphospholipid antibodies, such as antiphosphatidylserine and anti-β2 glycoprotein-1, are particularly attractive because mechanistic connections between their presence and placental pathology were reported (246,260,261,263,264). Measurement of anti-β2 glycoprotein-1 antibodies was formally added to the criteria defining the antiphospholipid syndrome, and data are accumulating for specific relevance to pregnancy loss (245,246,251,330). Among patients with known autoimmune diseases and recurrent pregnancy loss additional antiphospholipid testing may also be warranted (331).

**Cervical cultures for mycoplasma, ureaplasma, and chlamydia may be considered.**

**Interobserver reproducibility and accuracy are too low to reliably use the Noyes criteria to diagnose a luteal phase defect on timed endometrial biopsy** (332). This tool lacks precision and does not alter clinical management (333). More specific and predictive methodology for diagnosing this disorder is not yet available.

**The following investigations have no place in modern clinical care of patients with recurrent spontaneous pregnancy loss:**

- Evaluations that involve extensive testing for serum or site-specific auto- or alloantibodies (including antinuclear antibodies and antipaternal cytotoxic antibodies) are both expensive and unproven. Their use often verifies the statistical tenet that if the number of tests performed reaches a critical limit, the results of at least one will be positive in every patient.
- Testing for parental HLA profiles is never indicated in outbred populations. Findings that HLA sharing is associated with poor pregnancy outcomes are strictly limited to those specific populations studied, which have very high and sustained levels of marriage within a limited community (279).
- Use of mixed lymphocyte cultures has not proved useful. Use of other immunologic tests is unnecessary also unless these studies are performed, with informed consent, under a specific study protocol in which the costs of these experimental tests are not borne by the
Further work is necessary before suppressor cell or factor determinations, cytokine, oncogene, and growth factor measurements, or embryotoxic factor assessment can be clinically justified.
Postconception Evaluation

Following conception, close monitoring of patients with histories of recurrent pregnancy loss is advised to provide emotional support and to confirm intrauterine pregnancy and its viability. The incidence of ectopic pregnancy and complete molar gestation is increased in women with a history of recurrent spontaneous pregnancy loss. Although somewhat controversial, some data suggest that the risk of pregnancy complications other than spontaneous abortion are not significantly different between women with and without a history of recurrent losses (102,334–338). Two uncontested exceptions to this observation are those women who have antiphospholipid antibodies and those who have an intrauterine infection.

Determining serum levels of $\beta$-hCG may be helpful in monitoring early pregnancy until an ultrasonographic examination can be performed; however, not all investigators have found inadequate $\beta$-hCG levels in pregnancies that ultimately abort (339). Other hormonal determinations are rarely of benefit because levels are often normal until fetal death or abortion occurs (340).

The best method for monitoring in early pregnancy is ultrasonography. If used, serum $\beta$-hCG levels should be serially monitored from the time of a missed menstrual period until the level is approximately 1,200 to 1,500 mIU/mL, at which time an ultrasonographic scan is performed and blood sampling is discontinued. Ultrasonographic assessment may then be performed every 2 weeks until the gestational age at which previous pregnancies were aborted. The prognostic value of serial ultrasonography and a variety of hormonal and biochemical measurements during early pregnancy in women with histories of recurrent losses has been reported (341).

If a pregnancy has been confirmed, but fetal cardiac activity cannot be documented by approximately 6 to 7 weeks of gestation (by sure menstrual or ultrasonographic dating), intervention is recommended to expedite pregnancy termination and to obtain tissue for karyotype analysis. First trimester screening with maternal chemistries and fetal nuchal lucency measurement or chorionic villus sampling are recommended for obstetrical indications. Maternal serum can also be obtained for assessment at 16 to 18 weeks of gestation. Amniocentesis may be recommended to assess the fetal karyotype after the pregnancy has progressed past the time of prior losses.

The importance of obtaining karyotypic analysis from tissues obtained after pregnancy demise in a woman experiencing recurrent losses cannot be overemphasized. Results may suggest karyotypic anomalies in the parents. The documentation of aneuploidy may have important prognostic implications and may direct future interventions. Cost analysis has demonstrated that karyotypic analysis is financially prudent among patients with histories of recurrent pregnancy loss (342). Obtaining karyotypic data from aborted specimens incurs many difficulties in culturing cells from tissues that may have significant inflammation or necrosis and contamination of specimens with maternal cells. Efforts to develop methods that avoid such difficulties include the application of comparative genomic hybridization technology.
to recurrent pregnancy loss (343). This technology was used successfully on archived and paraffin-embedded pregnancy tissues (344). In the future, fetal karyotype assessment may also be performed using DNA isolated from nucleated fetal erythrocytes in maternal blood (345)
Advances in the treatment of patients with recurrent pregnancy loss have been regrettably slow. Despite a rapid expansion in understanding the molecular and subcellular mechanisms involved in implantation and early pregnancy maintenance, extension of these concepts to prevention of recurrent early pregnancy loss has lagged. In addition to these limitations, progress toward treatment of most causes of recurrent pregnancy loss has been hampered by a variety of factors. The condition itself has been inconsistently defined. The results of clinical trials involving recurrent pregnancy loss patients therefore are nearly impossible to compare and evaluate. Trial design is frequently substandard, with lack of rationale, lack of appropriate controls, and poor statistical analysis, limiting the ability to draw rational conclusions from reported results. Finally, epidemiologic data indicate that most patients with a history of recurrent pregnancy loss will, in fact, have a successful pregnancy the next time they conceive (7). For these reasons, with few exceptions, most therapies for recurrent pregnancy loss must be considered experimental. Until further study is completed, treatment protocols involving these therapies should be undertaken only with informed consent and in the setting of a well-designed, double-blind, placebo-controlled clinical trial.

Common therapeutic options available for patients with recurrent pregnancy loss include the use of donor oocytes or sperm, the use of preimplantation genetic diagnosis, the use of antithrombotic interventions, the repair of anatomic anomalies, the correction of any endocrine abnormalities, the treatment of infections, and a variety of immunologic interventions and drug treatments. Psychologic counseling and support should be recommended for all patients.
Recent evidence suggests that, in women with a history of three or more spontaneous pregnancy losses, a subsequent pregnancy loss has a 58% chance of chromosomal abnormality (15). Among women with recurrent pregnancy loss who are age 35 or older, the aneuploidy rate is much higher (8). The majority of chromosomal abnormalities identified in miscarriages are autosomal trisomies and considered to result from maternal nondisjunction. Maternal age appears as a consistent and important risk factor for trisomy in the majority of studies. There are several options for patients who suffer from recurrent pregnancy loss who have an identified miscarriage due to trisomy. The first is to conceive again without any specific change in medical management, as these abnormalities are sporadic and unlikely to recur. Studies examining patients with recurrent pregnancy loss show that women who miscarry chromosomally abnormal conceptions are more likely to achieve a live birth with subsequent pregnancy than those who miscarry chromosomally normal conceptions (13,346). A second involves preimplantation genetic diagnosis (PGD) or preimplantation screening, and a third involves the use of donor gametes.

Because chromosomal abnormalities are the most commonly identified cause of miscarriage, some have argued that the use of PGD is indicated for patients with recurrent pregnancy loss. **PGD involves the removal of a single cell from an in vitro–matured embryo. Genetic testing can be performed on this cell to examine chromosomal composition for the presence of single gene disorders (e.g., cystic fibrosis) or abnormalities in chromosome number and morphology.** Embryos that are diagnosed with genetic abnormalities would be discarded and only those embryos with normal results would be considered appropriate for transfer into the uterus. Use of PGD in patients with known heritable genetic disorders (e.g., cystic fibrosis, X-linked disorders) is presently in widespread use in internationally recognized assisted reproductive technology centers.

The use of PGD has the potential to reduce the incidence of pregnancy loss arising from a genetic etiology. However, definitive studies in this population have not yet been done. The use of PGD requires the patient to go through an IVF cycle to obtain embryos for biopsy, and the impact of the biopsy technique itself on the embryos' viability is not known at this time. Although there are several retrospective studies showing reduced miscarriage rates with this technique, several prospective trials using the outcome of successful pregnancy per started cycle fail to show any benefit (347–357). IVF is invasive and costly and many patients with recurrent pregnancy loss conceive quickly without intervention and have a high likelihood of live birth with their subsequent pregnancy. Therefore, the optimal control group for a study of IVF PGD in the recurrent pregnancy loss population is debated. Should it be natural conceptions or IVF without PGD? Finally, the prognosis for a patient with recurrent pregnancy loss does seem to be linked to the chromosome analysis of prior miscarriages. Recurrent pregnancy loss patients who miscarry chromosomally abnormal embryos, seem to have better prognosis than those who miscarry chromosomally normal conceptions, again arguing for expectant
management for recurrent pregnancy loss patients with a history of aneuploid loss. On the other hand, patients with poorer prognosis are those who miscarry chromosomally normal embryos and therefore would not benefit from PGD. The efficacy of PGD in the treatment of patients with recurrent pregnancy loss continues to be investigated, and the method of embryo biopsy and genetic testing continues to evolve (355,356). As these techniques improve and the understanding of aneuploidy and recurrence improves, there may be a subset of recurrent pregnancy loss patients, such as carriers of parental translocations, who might benefit from this intervention. At this time it cannot be recommended for all patients with a history of recurrent pregnancy loss.

The third approach is to use donor eggs or sperm. This treatment is particularly useful for patients with parental genetic factors and recurrent pregnancy loss, for example, a patient with Robertsonian translocations involving homologous chromosomes. In these patients, their genetic anomaly always results in unbalanced gametes, and the use of donor oocyte or donor sperm is recommended. Use of donor gametes among patients with a history of recurrent pregnancy loss can be useful in other cases where couples are at higher risk for unbalanced offspring because of carrying other forms of chromosomal rearrangements, such as reciprocal translocations or advanced maternal age. In these cases use of donor gametes was demonstrated to be as effective as its use in matched patients without such a history (358). In all cases of balanced translocations or embryonic aneuploidy, genetic counseling is recommended.
Anatomic Anomalies

Hysteroscopic resection represents state-of-the-art therapy for submucous leiomyomas, intrauterine adhesions, and intrauterine septa. This approach appears to limit postoperative sequelae while maintaining efficacy in terms of reproductive outcome (72,76,77,358–362). Use may be safely extended to patients with DES exposure, hypoplastic uteri, and complicated septal anomalies (76,77,363). Attempts to improve on standard hysteroscopic metroplasty, which is typically performed in the operating room using general anesthesia, often with laparoscopic guidance, are under investigation. Ultrasonographically guided transcervical metroplasty is reported to be safe and effective (359). Ambulatory, office-based procedures, including septum resection under fluoroscopic guidance, are attractive options (360).

For patients with a history of loss secondary to cervical incompetence, placement of a cervical cerclage is indicated. This is usually performed early in the second trimester after documentation of fetal viability. Cervical cerclage should be considered as a primary intervention for women with DES-associated uterine anomalies.
Endocrine Abnormalities

Some investigators have proposed the use of ovulation induction for the treatment of recurrent pregnancy loss (361,362). The theory behind its use in these patients rests on hypotheses that ovulation induction is associated with healthier oocytes. Healthier oocytes, in turn, may decrease the incidence of luteal phase insufficiency, which should result in improved pregnancy maintenance. This approach grossly oversimplifies the mechanisms involved in implantation and early pregnancy maintenance. Until appropriately studied, use of empiric ovulation induction for treatment of unexplained recurrent pregnancy loss should be viewed with caution. Evidence from small studies indicates such use is not effective (361). Still, use of ovulation induction in some subsets of patients with recurrent pregnancy loss could be of benefit. For instance, stimulating folliculogenesis with ovulation induction or luteal phase support with progesterone should be considered for women with luteal phase insufficiency. The efficacy of these therapies, however, is not substantiated (363). Ovulation induction might also be beneficial for women with hyperandrogen and LH hypersecretion disorders, especially following pituitary desensitization with gonadotropin-releasing hormone agonist therapy (112). This treatment remains controversial because the only large, prospective, randomized controlled trial to date reports no therapeutic efficacy; none for prepregnancy pituitary suppression nor for luteal phase progesterone supplementation (364).

Links between PCOS, hyperandrogenism, hyperinsulinemia, and recurrent pregnancy loss make use of insulin-sensitizing agents in the treatment of recurrent pregnancy loss associated with PCOS attractive (89–92). Although further study is needed, there are an increasing number of reports that support its use for this application (365,366). Prepregnancy glycemic control may be particularly important for women with overt diabetes mellitus (93,95). Thyroid hormone replacement with Synthroid may be helpful in cases of hypothyroidism. There are data indicating that thyroid hormone therapy may be of some benefit in euthyroid recurrent loss patients with antithyroid antibodies and possibly even in all pregnant women with “euthyroid” TSH levels between 2.5 and 5.0 mIU/L (98–100,272). There does not appear to be a place in the medical management of recurrent pregnancy loss for adding bromocriptine in women who do not have a prolactin disorder.
Infections
Empiric antibiotic treatment has been used for couples with recurrent abortion. Its efficacy is unproven. **Elaborate testing for infectious factors among recurrent pregnancy loss patients and use of therapeutic interventions is not justified unless a patient is immunocompromised or a specific infection has been documented** (113). For cases in which an infectious organism has been identified, appropriate antibiotics should be administered to both partners, followed by posttreatment culture to verify eradication of the infectious agent before attempting conception.
Immunologic Factors

Immune-mediated recurrent pregnancy loss has received more attention than any other single etiologic classification of recurrent pregnancy loss. Nevertheless, the diagnosis and subsequent treatment of the majority of cases remains unclear (102,367–370). Most therapies for proposed immune-related recurrent pregnancy loss must be considered experimental. As stated earlier, it is known that the developing conceptus contains paternally inherited gene products and tissue-specific differentiation antigens, and that there is maternal recognition of these antigens (216–218). Historically, it has been speculated that either inappropriately weak immune responses to these antigens or unusually strong responses could result in early pregnancy loss. As a consequence, both immunostimulating and immunosuppressive therapies have been proposed, but no conclusions about efficacy can be drawn.

Immunostimulating Therapies: Leukocyte Immunization

Stimulation of the maternal immune system using alloantigens on either paternal or pooled donor leukocytes has been promoted for patients with immunologic recurrent pregnancy loss, and a number of reports support possible mechanisms for potential therapeutic value (371–375). Both individual clinical trials and meta-analyses, however, continue to report conflicting results concerning the efficacy of leukocyte alloimmunization in patients with recurrent pregnancy loss (25,364,365,372,376–379). This most certainly reflects the remarkable heterogeneity in study design, patient selection, and therapeutic protocols, as well as the typically small numbers of enrolled subjects in these investigations. One of the largest trials evaluating the efficacy of leukocyte immunization in patients with unexplained recurrent pregnancy loss is a part of the Recurrent Miscarriage (REMIS) study (380). This investigation was large (over 90 patients per treatment arm), prospective, placebo controlled, randomized, and double blinded. It demonstrated no efficacy for paternal leukocyte immunization in couples with unexplained recurrent pregnancy loss. The most recent and best of the meta-analyses definitively rejects use of this therapy in patients with recurrent loss (381). Leukocyte immunization also poses a significant risk to both the mother and her fetus (344,345,382). Several cases of graft-versus-host disease, severe intrauterine growth retardation, and autoimmune and isoimmune complications have been reported (25,378,382–386). In addition, alloimmunization to platelets contained in the paternal leukocyte preparation is associated with cases of potentially fatal fetal thrombocytopenia. The routine use of this therapy for recurrent abortion cannot be clinically justified at this time. The procedure should be performed only as part of an appropriately controlled trial using informed consent. All costs associated with this treatment should be borne by the investigators until its efficacy has been demonstrated.

Other immunostimulating therapies have been proposed and abandoned. Intravenous preparations consisting of syncytiotrophoblast microvillus plasma membrane vesicles have been used to mimic the fetal cell contact with maternal blood that normally occurs.
in pregnancy (387). The efficacy of this therapy has not been established (381,387,388). The use of third-party seminal plasma suppositories has also been attempted, based on the misconception that TLX was part of an idiotype–anti-idiotype control system (389,390). Third-party seminal plasma suppositories for recurrent abortion have no scientifically credible rationale and should not be used.

**Immunosuppressive Therapies**

Immunosuppressive and other immunoregulating therapies have been advocated for cases in which abortion was believed to result from antiphospholipid antibodies or inappropriate cellular immunity toward the implanting fetus. Again, study design problems, including small numbers of recruited patients, lack of prestratification by maternal age and number of prior losses before randomization, and other methodologic and statistical inaccuracies preclude definitive statements regarding therapeutic efficacy for most of the proposed immunosuppressive approaches.

**Intravenous Immunoglobulin**

Intravenous immunoglobulins (IVIgs) are composed of pooled samples of immunoglobulins harvested from a large number of blood donors. Studies on the use of IVIg therapy in the treatment of recurrent pregnancy loss are based on the theory that some recurrent pregnancy loss patients have an overzealous immune reactivity to their implanting fetus. IVIgs do have immunosuppressive effects, but the mechanisms underlying this immune modulation are only partially understood. These mechanisms may include decreased autoantibody production and increased autoantibody clearance, T-cell and Fc-receptor regulation, complement inactivation, enhanced T-cell suppressor function, decreased T-cell adhesion to the extracellular matrix, and downregulation of TH1 cytokine synthesis (391–394). Based on a large number of relatively small studies using a variety of treatment protocols, there remains no conclusive evidence to suggest that use of IVIg in the treatment of patients with unexplained (and presumed immunologic) recurrent pregnancy loss has any benefit (383,395–399). This includes a recent trial using IVIg in women with secondary recurrent pregnancy loss that was ended early because interim analyses revealed no effect (395). The Cochrane review of immune therapy for recurrent pregnancy loss also addressed IVIg therapy and reported that its use did not alter pregnancy outcomes in patients with otherwise unexplained recurrent pregnancy loss (381,388). Improved posttreatment pregnancy rates may be seen, however, when IVIg is used in those specific patients with autoimmune-mediated pregnancy loss associated with APS (400,401). Therapy with IVIgs for recurrent pregnancy loss is expensive, invasive, and time-consuming, requiring multiple intravenous infusions over the course of pregnancy (402). Side effects of IVIg therapy include nausea, headache, myalgias, and hypotension. More serious adverse effects include anaphylaxis (particularly in patients with IgA deficiency) (403).
**Progesterone**

As mentioned earlier, progesterone also has known immunosuppressive effects (220–223,227,228). A number of studies using in vitro cellular systems relevant to the maternal–fetal interface have now demonstrated that progesterone either inhibits TH1 immunity or causes a shift from TH1- to TH2-type responses (208,227,228,404). Although the mechanism of action remains unclear, a recent Cochrane review concluded that progesterone supplementation was effective in the treatment of recurrent, but not isolated, spontaneous pregnancy loss (405,406). The review makes no recommendations on dosage, timing of initiation, nor route of progesterone administration. Progesterone has been administered both intramuscularly and intravaginally for the treatment of recurrent pregnancy loss. It is thought that vaginal administration may increase local, intrauterine concentrations of progesterone better than systemic administration. Vaginal formulations may therefore provide a better method of attaining local immunosuppressive levels of progesterone while averting any adverse systemic side effects.

**Intralipid Infusion**

The relative paucity of inflammatory diseases among the Greenland Inuit population, who consume a diet high in fish oils, led investigators to study the immune modulatory effects of lipid emulsions in total parenteral nutrition preparations for preoperative patients and for burn and trauma victims (406–409). The wide range of demonstrated effects, including lipid preparations that reduced natural killer cell activity, reduced monocytes proinflammatory cytokine production and increased susceptibility to infection, led investigators to hypothesize, as early as 1994, that lipid infusions might promote an immune environment that would favor pregnancy maintenance (410). Since that time, a small number of publications have addressed the effects of lipid infusions (Intralipid) in women with a history of pregnancy loss (411,412). These investigations have demonstrated a decrease in peripheral natural killer cell activity in women treated with one to three infusions of Intralipid. This effect lasted from 4 to 9 weeks after the last infusion (411). The authors did not address NK cell cytokine secretion patterns nor did they assay decidual NK cell function. Despite this paucity of data, Intralipid infusions are being administered to recurrent pregnancy loss patients with increasing frequency. The existing data do not support this practice. At this time, Intralipid infusions in recurrent pregnancy loss patients should only be administered under an institutional review board–approved protocol and in a study setting. They should not generate clinical income.

**TNF-α Inhibition**

Interest in the potent proinflammatory cytokine, TNF-α, as a mediator of pregnancy loss came out of the description of the TH1 and TH2 paradigm (209). Over the past 10 years, there have been several publications that link maternal serum TNF-α levels and activating TNF-α gene promoter polymorphisms to recurrent pregnancy loss (413–415). The
development of antagonists of TNF-α in the form of blocking antibodies (adalimumab, infliximab) and inhibitory recombinant proteins (etanercept) has allowed for successful treatment of several autoimmune disorders, including rheumatoid arthritis, psoriasis, and Crohn’s disease. Their use, however, has not been associated with universally positive outcomes and may worsen some disorders, including multiple sclerosis (416). These products are associated with rare but worrisome side effects, including liver failure, aplastic anemia, interstitial lung disease, and anaphylaxis (417). Although there exists only a single, small, retrospective, observational, nonrandomly assigned case series that involved treatment of recurrent pregnancy loss patients with inhibitors of TNF-α, these positive preliminary results have led a growing number of clinics to offer this therapy to patients, often at a significant cost (418). The safety of these compounds in pregnancy has not been appropriately studied, and preliminary reports associating exposure to TNF-α inhibitors during early pregnancy to fetal VACTERL syndrome is concerning (419). As with Intralipid therapy, use of TNF-α inhibition for the treatment of recurrent pregnancy loss should only be administered under an institutional review board–approved protocol in a study setting and should not generate clinical income.

Other immunoregulating therapies theoretically useful in treating recurrent pregnancy loss include the use of cyclosporine, pentoxifylline, and nifedipine, although maternal and fetal risks with these agents preclude their clinical use. Plasmaphoresis has also been used to treat women with recurrent abortion and antiphospholipid antibodies (420). Generalized immunosuppression with corticosteroids, such as prednisone, has been advocated during pregnancy for women with recurrent losses and chronic intervillusitis and those with recurrent pregnancy loss and APS (421). Although corticosteroids have shown some treatment promise in these patients, maternal and fetal side effects and the availability of alternative therapies have limited their use (421,422). That said, in response to successful use of prednisolone in a woman with 10 prior losses, Quenby et al. have demonstrated that such treatment decreases the number of uterine NK cells in the peri-implantation decidua among women with a history of recurrent loss and have plans for a trial of therapy using live birth as a secondary outcome (423–425). The efficacy and side effects of prednisone plus low-dose aspirin was examined in a recent, large, randomized, placebo-controlled trial treating patients with autoantibodies and recurrent pregnancy losses. Pregnancy outcomes for treated and control patients were similar; however, the incidence of maternal diabetes and hypertension and the risk of premature delivery were all increased among those treated with prednisone and aspirin (426).

Antithrombotic Therapy

Therapy for patients with recurrent pregnancy losses associated with either APS or other thrombophilic disorders has now shifted toward the use of antithrombotic medications. Unlike immunosuppressive treatments, this approach appears to address the effect (hypercoagulability), but not the underlying cause (e.g.,
genetic, APS) of recurrent pregnancy loss. However, there are reports that heparin, one typical anticoagulant, may exert direct immunomodulatory effects by binding to antiphospholipid antibodies and may decrease movement of inflammatory cells to sites of alloantigen exposure (427,428). The combined use of low-dose aspirin (75 to 80 mg per day) and subcutaneous unfractionated heparin (5,000 to 10,000 units twice daily) during pregnancy has been best studied among women with APS and appears to be efficacious (429–433). A typical regimen for women with antiphospholipid antibody syndrome would include use of aspirin (80 mg every day) beginning with any attempts to conceive. After pregnancy has been confirmed, 10,000 IU unfractionated sodium heparin is administered subcutaneously twice daily, throughout gestation. An aPTT should be obtained weekly and dosages of heparin should be adjusted until anticoagulation is achieved. Patients using this therapy should be treated in conjunction with a perinatologist because of their increased risks for preterm labor, premature rupture of the membranes, intrauterine growth restriction, intrauterine fetal demise, and pre-eclampsia. Other potential risks include gastric bleeding, osteopenia, and abruptio placentae.

Attempts have recently been made to extend the finding that antithrombotic therapy is efficacious when used to treat patients with APS and recurrent pregnancy loss in a number of directions. These directions include the use of low-molecular weight heparins (LMWH), the use of antithrombotic therapy in non-APS patients with thrombophilia and recurrent pregnancy loss, and even its use among recurrent pregnancy loss patients without thrombophilia (unexplained recurrent losses).

New formulations of heparin, termed low-molecular weight heparins, have been demonstrated to be superior to unfractionated heparin in the treatment of many clotting disorders (434–436). LMWH has the advantage of an increased antithrombotic ratio when compared with unfractionated heparin. This results in improved treatment of inappropriate clotting but fewer bleeding side effects. In addition, LMWH has been associated with a decreased incidence of thrombocytopenia and osteoporosis when compared with its unfractionated counterpart. Finally, LMWH has a long half-life and requires less frequent dosing and monitoring, thereby improving patient compliance. LMWH appear to be safe for use in pregnancy, and LMWH has shown promise when combined with low-dose aspirin in the treatment of recurrent pregnancy loss associated with APS (430,435,437). Only a few studies have compared the use of unfractionated heparin and aspirin to LMWH and aspirin in the treatment of women with APS and adverse pregnancy outcomes (433,438). The therapies had similar effects in one study (438). A meta-analysis suggested that unfractionated heparin was superior to LMWH, however, there was significant heterogenicity between studies (433). Efficacy has been suggested for LMWH treatment for patients with recurrent pregnancy loss associated with other thrombophilias, including activated protein C resistance associated with factor V Leiden, mutations in the promoter region of the prothrombin gene, and decreases in protein C and protein S activities (63,439–441). The use of LMWH for this indication appears to have an excellent safety profile for mother and fetus (437,442,443).
The prophylactic use of daily-low dose aspirin has become common practice within the lay public based on its perceived cardiovascular effects combined with its low incidence of side effects. Its sole use in the treatment of recurrent pregnancy loss has likewise gained momentum, and many patients with histories of recurrent loss will either be self-prescribing this therapy or will inquire about its usefulness. At present, there are no good data supporting its use either in patients with heritable thrombophilias or in the general recurrent pregnancy loss population. Although studies are small, the use of low-dose aspirin alone has not been shown to be effective in the treatment of recurrent pregnancy loss associated with APS (431, 444, 445). When used in these patients, it should be in combination with unfractionated or LMWH. Large randomized prospective trials examining the empiric use of aspirin alone or in combination with prophylactic doses of heparin have shown no benefit of these therapies in unexplained recurrent pregnancy loss (445). In addition, the use of aspirin in early pregnancy has been called into question with reports of an increased incidence of isolated spontaneous pregnancy loss among women who used this medication (316, 317). However, these reports are poorly designed and do not adequately address the level of aspirin exposure (81 mg vs. 325 mg).

Although reviews have touted the overall safety of aspirin in pregnancy, outside of use in combination with heparin for patients with recurrent pregnancy loss and APS, this medication should be used only with justification in the well-informed patient during early pregnancy (446).

More directed antithrombotic therapies have also been described for the treatment of recurrent pregnancy loss among patients with thrombophilias. For instance, the use of protein C concentrates has been reported to be associated with favorable pregnancy outcome in a patient with a history of thrombosis, recurrent fetal losses, and protein C deficiency (447).

As mentioned previously, vitamins B₆, B₁₂, and folate are important in homocysteine metabolism, and hyperhomocysteinemia is linked to recurrent pregnancy loss (21, 23, 38, 66, 68, 72). Women with recurrent pregnancy loss and isolated fasting hyperhomocysteinemia should be offered supplemental folic acid (0.4 to 1.0 mg per day), vitamin B₆ (6 mg per day), and possibly vitamin B₁₂ (0.025 mg per day) (448–451). Fasting homocysteine levels should be retested after treatment. If levels are normalized or remain only marginally elevated, no further therapy is necessary. Homocysteine levels will predictably decrease during pregnancy.

Treatment of women with recurrent pregnancy loss and an identified inherited or acquired thrombophilia should be based on accompanying history. Currently, there are no prospective controlled trials examining the benefit of anticoagulation for the prevention of miscarriage in the absence of APS, and, therefore, anticoagulation recommendations for patients with inherited thrombophilias are based on individualized risk of venous thromboembolic events in pregnancy (28).

If a venous thromboembolic event occurs during the index pregnancy, posthospitalization management requires therapeutic anticoagulation.
UFH: 10,000 to 15,000 U subcutaneous every 8 to 12 hours (monitor to keep aPTT 1.5 to 2.5 times normal) OR
LMWH: enoxaparin 40 to 80 mg subcutaneous twice a day or dalteparin 5,000 to 10,000 U subcutaneous twice a day). Consider monitoring trough factor Xa levels in the third trimester.

If there is a personal history of venous thromboembolic events (particularly in a previous pregnancy or with hormonal contraceptive use) or a strong thrombophilic family history, treat with therapeutic anticoagulation. Thrombotic risk is greatest during the postpartum period. Anticoagulation should be reinitiated after delivery in doses reflecting predelivery treatment regimens. Postpartum anticoagulation should be continued for 6 to 12 weeks postpartum (435). Women may continue injectable therapy or transition to oral anticoagulants (e.g., coumarin). Use of heparin or of coumarin derivatives does not prohibit breastfeeding.
Psychological Support

There is no doubt that experiencing both isolated and recurrent losses can be emotionally devastating. The risk of major depression is increased greater than twofold among women with spontaneous pregnancy loss; in most women it arises in the first weeks following delivery (452). A caring and empathetic attitude is prerequisite to all healing. The acknowledgment of the pain and suffering couples have experienced as a result of recurrent abortion can be a cathartic catalyst enabling them to incorporate their experience of loss into their lives rather than their lives into their experience of loss (112). **Referrals to support groups and counselors should be offered.** Self-help measures, such as meditation, yoga, exercise, and biofeedback may also be useful.
Prognosis

The prognosis for successful pregnancy depends both on the potential underlying cause of pregnancy loss and (epidemiologically) on the number of prior losses (Table 33.4). As previously discussed, epidemiologic surveys indicate that the chance of a viable birth even after four prior losses may be as high as 60%. Depending on the study, the prognosis for successful pregnancy in couples with a cytogenetic etiology for reproductive loss varies from 20% to 80% (453–455). Women with corrected anatomical anomalies may expect a successful pregnancy in 60% to 90% of cases (74,453,456–459). A success rate higher than 90% has been reported for women with corrected endocrinologic abnormalities (454). Between 70% to 90% of pregnancies reported among women receiving therapy for antiphospholipid antibodies have been viable (460,461).

Table 33.4 Prognosis for a Viable Birth

Following:
- One spontaneous loss: 76%
- Two spontaneous losses: 70%
- Three spontaneous losses: 65%
- Four spontaneous losses: 60%

With:
- Genetic factors: 20%–80%
- Anatomic factors: 60%–90%
- Endocrine factors: >90%
- Infectious factors: 70%–90%
- Antiphospholipid antibodies: 70%–90%
- TH1 cellular immunity: 70%–87%
- Unknown factors: 40%–90%

Following detection of fetal cardiac activity:
- Unexplained recurrent pregnancy loss: 77%–97%
- Antiphospholipid antibody syndrome and recurrent pregnancy loss: Much lower

Many forms of pre- or postconceptional tests have been proposed to help predict pregnancy outcome (201,219,327,462,463) ; none have been fully substantiated in large, prospective trials. The documentation of fetal cardiac activity on ultrasound may offer prognostic value; however, it appears that its predictions may be greatly affected by any underlying diagnosis. In one study, the live birth rate following documentation of fetal cardiac activity between 5 to 6 weeks from the last menstrual period was approximately 77% in women with two or more unexplained spontaneous abortions (464). It may be important to note that the majority of the patients in this study had evidence of inappropriate antitrophoblast cellular
immunity. Others have shown that 86% of patients with antiphospholipid antibodies and recurrent pregnancy loss had fetal cardiac activity detected prior to subsequent demise (465). A prospective, longitudinal, observational study of 325 patients with unexplained recurrent pregnancy losses demonstrated that only 3% of 55 miscarriages occurred following the detection of fetal cardiac activity using transvaginal ultrasonography (466).

Vasomotor symptoms affect up to 75% of perimenopausal women. Symptoms last for 1 to 2 years after menopause in most women but may continue for 10 years or longer in others.

Topical vaginal application of low doses of estrogen is an effective and safe treatment of vaginal dryness, dyspareunia, and some urinary symptoms. Counseling women to alter modifiable risk factors is important for the prevention and treatment of osteoporosis. Many women have diets deficient in calcium and vitamin D and will benefit from dietary changes and supplementation. Women should receive 1,000 to 1,500 mg of calcium and 400 to 800 IU of vitamin D daily.

Contraindications to hormone therapy use include known or suspected breast or endometrial cancer, undiagnosed abnormal genital bleeding, cardiovascular disease (including coronary heart disease, cerebrovascular disease, and thromboembolic disorders), and active liver or gallbladder disease. Relative contraindications include high-risk states for the above disorders.

Menopause, the permanent cessation of menstruation, occurs at a mean age of 51 years. Despite a great increase in the life expectancy of women, the age at menopause remains remarkably constant. A woman in the United States today will live approximately 30 years, or greater than a third of her life, beyond the menopause. The age at menopause appears to be genetically determined and is unaffected by race, socioeconomic status, age at menarche, or number of prior ovulations. Factors that are toxic to the ovary often result in an earlier age of menopause; women who smoke experience an earlier menopause, as do many women exposed to chemotherapy or pelvic radiation (1). Women who had surgery on their ovaries or had a hysterectomy, despite retention of their ovaries, may experience early menopause (2). Premature ovarian insufficiency, defined as menopause before
the age of 40 years, occurs in approximately 1% of women. It may be idiopathic or associated with a toxic exposure, chromosomal abnormality, or an autoimmune disorder.

Although menopause is associated with changes in the hypothalamic and pituitary hormones that regulate the menstrual cycle, menopause is not a central event, but rather primary ovarian failure. At the level of the ovary, there is a depletion of ovarian follicles, most likely secondary to apoptosis or programmed cell death. The ovary, therefore, is no longer able to respond to the pituitary hormones, follicle-stimulating hormone (FSH), and luteinizing hormone (LH), and ovarian estrogen and progesterone production ceases. The ovarian–hypothalamic–pituitary axis remains intact during the menopausal transition; thus, FSH levels rise in response to ovarian failure and the absence of negative feedback from the ovary. Atresia of the follicular apparatus, in particular the granulosa cells, leads to decreased production of estrogen and inhibin, resulting in elevated FSH levels, a cardinal sign of menopause. Antimüllerian hormone (AMH) is produced by small ovarian follicles, so levels decrease with declining ovarian reserve (3). Although still considered experimental, AMH may one day be used as a reliable marker of the menopause transition.

Androgen production from the ovary continues beyond the menopausal transition because of sparing of the stromal compartment. Androgen concentrations are lower in menopausal women than in women of reproductive age. This finding appears to be associated with aging and decreased functioning of the ovary and adrenal glands over time rather than with menopause per se. Menopausal women continue to have low levels of circulating estrogens, principally from peripheral aromatization of ovarian and adrenal androgens. Adipose tissue is a major site of aromatization, so obesity affects many of the sequelae of menopause.

Several staging systems were developed to describe the many changes that encompass the transition from reproductive life to postmenopause. The late reproductive years are characterized by regular menses associated with elevated FSH levels (4). Menopausal transition is characterized by elevated FSH levels associated with variable cycle lengths and missed menses, whereas the postmenopausal period is marked by amenorrhea. The menopausal transition begins with variability in menstrual cycle length accompanied by rising FSH levels and ends with the final menstrual period.

Menopause is defined retrospectively as the time of the final menstrual period followed by 12 months of amenorrhea. Postmenopause describes the period following the final menses (4).

The pathophysiologic consequences of menopause may be best understood by considering that the ovary is a women’s only source of oocytes, her primary source of estrogen and progesterone, and a major source of androgens. Menopause results in infertility secondary to oocyte depletion. Ovarian cessation of progesterone production
appears to have no clinical consequences except for the increased risk of endometrial proliferation, hyperplasia, and cancer associated with continued endogenous estrogen production or administration of unopposed estrogen therapy in menopausal women. The possible effects of declining androgen concentrations that occur with aging are an area of controversy and active investigation.

The major consequences of menopause are related primarily to estrogen deficiency. It is very difficult to distinguish the consequences of estrogen deficiency from those of aging, as aging and menopause are inextricably linked. Studying the effects of estrogen deficiency and replacement in young women with ovarian failure or of drugs that suppress estrogen synthesis (such as gonadotropin-releasing hormone antagonists) helps to distinguish between the effects of aging and estrogen deficiency. These models are imperfect, though, and differ from natural menopause in many ways.

Principal health concerns of menopausal women include vasomotor symptoms, urogenital atrophy, osteoporosis, cardiovascular disease, cancer, cognitive decline, and sexual problems. Options for caring for menopausal women have increased greatly since hormone therapy was first introduced in the 1960s. With respect to hormone use, there are many choices of hormone type, dose, and method of administration. In addition to hormones, estrogen agonist-antagonists, centrally acting agents, and bisphosphonates are available to treat menopausal health concerns. Women are requesting more information on complementary and alternative therapies, which are being studied more carefully. The many options now available make caring for the postmenopausal woman more challenging and more rewarding.
Health Concerns After Menopause

Vasomotor Symptoms

Vasomotor symptoms affect up to 75% of perimenopausal women. Symptoms last for 1 to 2 years after menopause in most women, but may continue for up to 10 years or longer in others. Hot flashes are the primary reason women seek care at menopause. Hot flashes disturb women at work, interrupt daily activities and disrupt sleep (5). Many women report difficulty concentrating and emotional lability during the menopausal transition. **Treatment of vasomotor symptoms should improve these cognitive and mood symptoms if they are secondary to sleep disruption and its resulting daytime fatigue.** The incidence of thyroid disease increases as women age; therefore, thyroid function tests should be performed if vasomotor symptoms are atypical or resistant to therapy.

The physiologic mechanisms underlying hot flashes are incompletely understood. A central event, probably initiated in the hypothalamus, drives an increased core body temperature, metabolic rate, and skin temperature; this reaction results in peripheral vasodilation and sweating in some women. The central event may be triggered by noradrenergic, serotonergic, and/or dopaminergic activation. Although an LH surge often occurs at the time of a hot flash, it is not causative, because vasomotor symptoms occur in women who had their pituitary glands removed. In symptomatic postmenopausal women, hot flashes likely are triggered by small elevations in core body temperature acting within a narrow thermoneutral zone (6). Exactly how estrogen and alternative therapies play a role in modulating these events is unknown. Vasomotor symptoms are a consequence of estrogen withdrawal, not simply estrogen deficiency. For example, a young woman with primary ovarian insufficiency resulting from Turner syndrome will have a very high FSH level and low estrogen levels, but she will not experience hot flashes until she is treated with estrogens and then therapy is withdrawn.

**Lifestyle interventions may safely decrease vasomotor symptoms.** Being in a cool environment is associated with fewer subjective and objective hot flashes, so women experiencing symptoms should be advised to keep the room temperature low and wear light, layered clothing (7). **Overweight women and those who smoke have more severe vasomotor symptoms than women of normal weight and nonsmokers.** These findings provide additional reasons to encourage women to lose weight and stop smoking (8,9).

Many menopausal women are interested in trying complementary and alternative (CAM) therapies for relief of hot flashes. These are diverse medical and health care products and practices generally not considered part of conventional medicine. Vasomotor symptoms are particularly sensitive to placebo treatments, and numerous nutritional supplements and other interventions claim to relieve hot flashes but are rarely studied in controlled trials (10). Phytoestrogens are plant-derived substances that may act as estrogen agonists-antagonists, with their effects modulated through interactions with the estrogen
receptor. Although they decrease hot flash severity and frequency, symptom improvement is similar to that seen with placebo treatment (11). Black cohosh is another popular alternative treatment, with efficacy likely similar to that of placebo (12). Although often recommended, vitamin E (800 IU per day) only minimally reduced hot flashes in a placebo-controlled, randomized, crossover trial (13).

Acupuncture reduced vasomotor symptoms in several studies, although a traditional Chinese medicine approach may be no more effective than shallow or “sham” needling techniques (14). Exercise and paced respiration demonstrated an improvement in hot flashes in several uncontrolled studies, with additional health benefits, including stress reduction. Women may choose to use alternative and complementary therapies for relief of symptoms, but they should be aware that the safety and efficacy of these approaches often are unproven.

**Systemic estrogen therapy** is the most effective treatment for vasomotor symptoms and the only therapy currently approved by the U.S. Food and Drug Administration (FDA) for this indication (see Table 34.1 for available hormone therapy formulations). Although standard doses are usually effective, younger women and those with recent oophorectomy may require higher doses. Healthy, nonsmoking women in the perimenopausal transition who are experiencing bothersome hot flashes but still menstruating may benefit from oral contraceptives. The supraphysiologic doses of estrogens and progestins in oral contraceptives effectively treat vasomotor symptoms and provide cycle control. Low-dose estrogen therapy also effectively treats hot flashes for many women. Low-dose oral esterified and conjugated estrogens (CE) (0.3 mg daily), oral estradiol (0.5 mg daily), and transdermal estradiol (0.025 and 0.014 mg weekly) often are effective and associated with minimal side effects and endometrial stimulation (15–17). Progestin therapy must be given concurrently if a woman has not had a hysterectomy, although with low-dose estrogen therapy, intermittent progestin treatment may be an option.

Given the known risks, described in detail later in this chapter, hormone therapy should be used at the lowest effective dose for the shortest amount of time that meets treatment goals. The majority of healthy women with very bothersome hot flashes at the time of the menopausal transition will benefit from short-term therapy and be able to wean off hormones after several years of use.

Because vasomotor symptoms appear to be the result of estrogen withdrawal, rather than simply low estrogen levels, if cessation of estrogen therapy is desired, the dose should be reduced slowly over time. Abruptly stopping treatment may result in a return of disruptive vasomotor symptoms. This recommendation is based on clinical experience, as no controlled trials have been performed to examine the optimal way to cease hormone therapy use. One possible approach to stopping therapy is
to reduce the dose and dosing interval slowly (e.g., every 2 or 3 months) and let the patient’s symptoms guide the pace at which she discontinues therapy.

When a woman chooses not to take estrogen or when it is contraindicated, other options are available (Table 34.2) (18). Progestin therapy alone is an option for some women. Medroxy-progesterone acetate (MPA; Provera) (20 mg per day) and megestrol acetate (Megace) (20 mg per day) effectively treat vasomotor symptoms (19,20). Several drugs that alter central neurotransmitter pathways are effective. Agents that decrease central noradrenergic tone, such as clonidine (Catapres), decrease hot flashes, although the effect size is not great. Potential side effects include orthostatic hypotension and drowsiness.

aNot U.S. Food and Drug Administration–approved for treatment of vasomotor symptoms.

**Selective serotonin or serotonin norepinephrine reuptake inhibitors**
SSRIs/SNRIs are effective and are the mainstay of nonhormonal treatment of hot flashes, although none are FDA approved for this purpose. In a double-blind, randomized, placebo-controlled trial of paroxetine CR (Paxil) (12.5 and 25 mg per day), menopausal women with hot flashes experienced a significant reduction in both hot flash frequency and severity (21). Actual hot flash frequency decreased by 3.3 hot flashes per day on paroxetine versus 1.8 on placebo, and the improvement in vasomotor symptoms was independent of any significant change in mood or anxiety symptoms. The most common side effects were headache, nausea, and insomnia. Paroxetine is a potent inhibitor of the cytochrome P450 system (CYP2D6) required to convert tamoxifen to its active form. It should not be used in women with breast cancer who are receiving tamoxifen, as concurrent use may result in a higher rate of breast cancer recurrence. Venlafaxine (Effexor) (75 mg per day), an SNRI, significantly reduced hot flashes in a controlled trial, though the active treatment group experienced significantly more side effects, including dry mouth, nausea, and anorexia (22). Most studies of SSRI or SNRI use for vasomotor symptoms are only short term and not all show an improvement in symptoms. In a double-blind, parallel-group trial of 9 months' duration, there was no significant improvement in hot flashes with either fluoxetine (Prozac) or citalopram (Celexa) (10 to 30 mg per day) compared to placebo (23).

**Gabapentin (Neurontin)** is a γ-aminobutyric acid analogue approved for the treatment of seizures that reduced hot flash frequency and severity significantly more than placebo in several randomized, double-blind trials (24). Hot flash scores decreased 54% in the women treated with gabapentin (900 mg per day) compared with a 31% reduction in placebo-treated women. Side effects include disorientation, dizziness, and drowsiness. Women who are principally bothered by night sweats and disrupted sleep may benefit from sleeping medication. In a double-blind, placebo-controlled study of peri- and postmenopausal women, the prescription insomnia treatment, eszopiclone, significantly improved sleep and menopause-related symptoms, with a positive impact on next-day functioning, mood, and quality of life (25). The antihistamine diphenhydramine hydrochloride is an inexpensive, over-the-counter sleep aid.
Urogenital Atrophy

Urogenital atrophy results in vaginal dryness and pruritus, dyspareunia, dysuria, and urinary urgency. These common problems in menopausal women respond well to therapy (26). **Systemic estrogen therapy is a very effective treatment for vaginal dryness, dyspareunia, and associated symptoms.** Low doses of estrogen applied vaginally are preferred to systemic estrogen therapy when vasomotor symptoms are not present, given minimal systemic absorption and increased safety. Low doses of estrogen cream (Premarin, Estrace) (0.5 g) are effective when used only once or twice a week (27). An estradiol vaginal tablet (Vagifem) (10 μg) inserted twice weekly may be less messy and easier to use than estrogen cream. An estrogen-containing vaginal ring (Estring) (7.5 μg per day) is another convenient formulation, which is placed in the vagina every 3 months and slowly releases a low dose of estradiol (28). Studies of the low-dose estrogen vaginal ring and tablet confirm a small increase in serum estradiol and estrone levels, but these levels remain within the normal range for postmenopausal women (29).

Studies of the vaginal tablets and ring of up to 1 years' duration confirmed endometrial safety, but long-term studies on the effects of low-dose vaginal estrogen therapy on the endometrium are not available. Women using vaginal estrogen therapy should be reminded to report any vaginal bleeding, and a thorough evaluation should be performed. Typically, concurrent progestin therapy is not prescribed with low-dose vaginal estrogen preparations. Long-acting vaginal moisturizers, available without a prescription, are an effective nonhormonal alternative for treating symptoms of urogenital atrophy when used two to three times weekly (e.g., Replens, KY-Long Acting). Nonhormonal vaginal lubricants (e.g., Astroglide, KY-Silk) increase comfort with intercourse.

**Vaginal estrogen therapy appears to reduce urinary symptoms, such as frequency and urgency, and reduces the likelihood of recurrent urinary tract infections in postmenopausal women** (30). The effect of estrogen therapy on urinary incontinence is unclear. Whereas the results of some studies suggest improvement in incontinence with estrogen therapy, others show a worsening of symptoms (31).
Osteoporosis

Low bone mass and osteoporosis affect an estimated 30 million US women, or approximately 55% of women older than age 50 years (32). Because therapy is most likely to benefit those at highest risk, it is important to review a woman’s risk factors for osteoporosis when making treatment decisions. **Bone mineral density screening should be considered for high-risk women** (Table 34.3). Nonmodifiable risk factors include age, family history, Asian or Caucasian race, history of a prior fracture, small body frame, early menopause, and prior oophorectomy. Modifiable risk factors include smoking, decreased intake of calcium and vitamin D, and a sedentary lifestyle. Medical conditions associated with an increased risk of osteoporosis include anovulation during the reproductive years (e.g., secondary to excess exercise or an eating disorder), chronic renal disease, hyperparathyroidism, hyperthyroidism, and diseases requiring systemic corticosteroid use.

**Table 34.3 Risk Factors for Osteoporosis**

Nonmodifiable

- Age
- Race (white, Asian)
- Small body frame
- Early menopause
- Prior fracture
- Family history of osteoporosis

Modifiable

- Inadequate intake of calcium and vitamin D
- Smoking
- Low body weight
- Excess alcohol use
- Sedentary lifestyle

Associated Medical Conditions

- Hyperthyroidism
- Hyperparathyroidism
- Chronic renal disease
- Conditions requiring systemic corticosteroid use

**Assessment**

Bone mineral density (BMD) measurements may be used to determine fracture risk, diagnose osteoporosis, and identify women who would benefit from
therapeutic interventions. Dual x-ray absorptiometry (DXA) of the hip and spine is the primary technique for BMD assessment. BMD is expressed as a T score, which is the number of standard deviations from the mean for a young, healthy woman. A T score above −1 is considered normal, a score between −1 and −2.5 indicates low bone mass, and a score below −2.5 denotes osteoporosis. Although there is a strong association between BMD and fracture risk, a woman’s age, risk for falls, and overall health status significantly influence fracture risk. Evaluation of BMD by DXA is recommended for all women aged 65 and older, regardless of risk factors, and for younger postmenopausal women with one or more risk factors, other than being white and menopausal (33).

Modifiable Risk

Women should be counseled to alter modifiable risk factors as an important step in the prevention and treatment of osteoporosis. Women with diets deficient in calcium and vitamin D will benefit from dietary modification and supplementation. Daily intake of calcium 1,000 to 1,500 mg and vitamin D 400 to 800 IU is recommended. This may be achieved through a combination of diet and vitamin and mineral supplementation. Treatment with calcium and vitamin D may reduce fracture risk, especially in older women, according to some but not all studies (34–36). Reducing the risk of osteoporosis is another of the many health benefits of regular exercise and smoking cessation. Treatment is indicated for all women with osteoporosis and for those at high fracture risk. FRAX, an online fracture risk assessment tool, provides the 10-year probability of a major osteoporotic fracture for an individual woman (37,38).

Treatment

Drugs used in the prevention and treatment of osteoporosis are principally antiresorptive agents that reduce bone loss and anabolic drugs that stimulate new bone formation (Table 34.4). Hormone therapy effectively prevents and treats osteoporosis. In observational studies, estrogen therapy started soon after menopause and continued long term reduces osteoporosis-related fractures by approximately 50% (39). The Women’s Health Initiative (WHI) trial confirmed a significant (34%) reduction in hip fractures in healthy women randomized to hormone therapy (conjugated estrogen 0.625 mg per day) after a mean follow-up of 5.6 years (40). Combined with calcium and vitamin D, even very low-dose estrogen therapy (conjugated estrogen 0.3 mg per day; transdermal estradiol 0.014 mg per day) produces significant increases in bone mineral density compared with placebo (41).

**Risedronate (Actonel)** (35 mg/week or 150 mg/month orally)

**Ibandronate (Boniva)** (150 mg/month orally or 3 mg/every 3 months intravenous)

**Zoledronic Acid (Zometa)** (5 mg/year intravenous)

Additional potential benefits: none
Potential risks: esophageal ulcers, osteonecrosis of jaw (rare), atypical femoral fractures (rare) Zoledronic acid: hypocalcemia, atrial fibrillation, renal impairment
Side effects: gastrointestinal distress, arthralgias/myalgias

**Hormone Therapy**

**Estrogen or Estrogen/Progestin Therapy**

Additional potential benefits: treatment of vasomotor symptoms and urogenital atrophy
Potential risks: breast cancer, gallbladder disease, venous thromboembolic events, coronary heart disease, stroke
Side effects: vaginal bleeding, breast tenderness

**Estrogen Agonists-Antagonists**

**Raloxifene (Evista)** (60 mg/day orally)

Additional potential benefits: reduced risk of breast cancer
Potential risks: venous thromboembolic events
Side effects: vasomotor symptoms, leg cramps

**Other**

**Calcitonin (Miacalcin)** (200 IU/day intranasally or 100 IU/day subcutaneously or intramuscularly)

Additional potential benefits: none
Potential risks: none
Side effects: rhinitis, back pain

**Forteo (Teriparatide)** (20 μg/day subcutaneously)

Additional potential benefits: none
Potential risks: osteosarcoma (after long-term use in rodents), hypercalcemia
Side effects: musculoskeletal pain

**Prolia (Denosumab)** (60 mg subcutaneously every 6 months)

Additional potential benefits: none
Potential risks: rash, serious infection, hypocalcemia
Side effects: musculoskeletal pain
Bisphosphonates, including alendronate (Fosamax, 35 or 70 mg orally weekly), risedronate (Actonel, 35 mg weekly or 150 mg orally monthly), ibandronate (Boniva, 150 mg orally monthly or 3 mg every 3 months intravenous), and zoledronic acid (Zometa, 5 mg intravenous yearly) specifically inhibit bone resorption and are very effective for both the prevention and treatment of osteoporosis (42–44). Patients should take oral bisphosphonates on an empty stomach with a large glass of water and remain upright for at least 30 minutes. The major side effect is gastrointestinal distress; esophageal ulceration, osteonecrosis of the jaw, and atypical femoral fractures are very rare occurrences.

The estrogen agonist-antagonist raloxifene (Evista, 60 mg per day orally) prevents vertebral fractures in women with low bone mass and osteoporosis, though does not appear to reduce the risk of nonvertebral fractures (45). Raloxifene exercises estrogen-like actions on bone and lipids without stimulating the breast or endometrium. Calcitonin nasal spray (Miacalcin, 200 IU per day intranasal) is another approved treatment for established osteoporosis. Unlike most treatments for osteoporosis that inhibit bone resorption, parathyroid hormone (human recombinant PTH 1–34) (teriparatide, Forteo, 20 μg per day subcutaneously) stimulates new bone formation, resulting in significant reductions in vertebral and nonvertebral fractures (46). Recently approved for the treatment of postmenopausal osteoporosis, denosumab (Prolia) 60 mg, a monoclonal antibody to the receptor activator of nuclear factor-κB ligand, decreases the risk of vertebral and hip fractures in postmenopausal osteoporotic women when given subcutaneously twice yearly for 36 months' duration (47).
Cardiovascular disease (CVD) is the leading cause of death for women, accounting for approximately 45% of mortality. Nonmodifiable risk factors include family history and age. Modifiable risk factors include a sedentary lifestyle, obesity, and smoking. Medical conditions associated with an increased risk of heart disease include diabetes, hypertension, and hyperlipidemia. Advising women to alter modifiable risk factors for CVD and adequately treating diabetes, hypertension, and hyperlipidemia are important parts of the comprehensive care of midlife women.

As epidemiologic studies identify an approximately 50% decrease in coronary heart disease (CHD) in woman who use hormone therapy, prevention of heart disease was considered a potential benefit of postmenopausal hormones (48). This observed reduction in CHD was considered secondary to beneficial effects of hormone therapy on the vascular wall and lipid levels (49). Observational studies are prone to bias, and women who used hormone therapy were generally healthier and at lower risk for CHD than nonusers (50).

The WHI randomized controlled trial of combination hormone therapy versus placebo showed that hormone therapy did not prevent heart disease in healthy women, but instead, it increased the risk of cardiovascular events in older women (51). The WHI was a 15-year study sponsored by the National Institutes of Health that examined ways to prevent heart disease, osteoporosis, and breast and colorectal cancer in women. There were several different studies in WHI, involving more than 160,000 healthy postmenopausal women. The WHI randomized controlled trial enrolled approximately 16,000 women nationwide between the ages of 50 and 79 years. The average age of women in the study was 63 years. The major goal of the WHI clinical trial was to determine whether combined estrogen and progestin hormone therapy prevented heart disease and to evaluate associated benefits and risks. After an average of 5 years of follow-up, risks (hazard ratio) were increased for CHD (1.3), breast cancer (1.3), stroke (1.4), and pulmonary embolism (PE) (2.1), and decreased for hip fracture (0.7) and colorectal cancer (0.6) (51). The absolute excess risk per 10,000 woman-years attributable to hormone therapy was small, with seven more CHD events, eight breast cancers, eight strokes, and eight pulmonary embolisms, with six fewer colorectal cancers and five fewer hip fractures.

Approximately 11,000 women without a uterus participated in a separate WHI study and were randomized either to estrogen alone or placebo. After an average follow-up of 7 years, there was no increased risk of heart disease or breast cancer in estrogen users. Outcomes were similar to those seen in the estrogen plus progestin arm of WHI with respect to venous thromboembolism, stroke, and osteoporotic fractures; there was no effect on colorectal cancer (52) (see Table 34.5 for a summary of WHI findings).

Studies confirmed that the increased risk of CHD in WHI occurs principally in older women and those who are a number of years beyond menopause (Table
In a secondary analysis of data from the combined WHI trials, no increased risk of CHD was seen in women between the ages 50 to 59 or in those within 10 years of menopause (53). Although stroke was increased with hormone therapy, regardless of age or years since menopause, the absolute excess risk of stroke in the younger women was minimal. These data do not support a

role for hormone therapy in the prevention of heart disease, but they do provide reassurance regarding the safety of hormone therapy use for bothersome hot flashes and night sweats in otherwise healthy women at the time of the menopausal transition.

The WHI trials examined treatment only with conjugated equine estrogens and medroxyprogesterone acetate. The effects of other oral estrogen agents, transdermal estradiol, therapy with other progestins, or cyclic hormone therapy may be different. In observational studies, transdermal estrogen therapy is not associated with an increased risk of venous thromboembolic disease (54). The average age of women participating in these trials was more than 15 years beyond the age at which women typically initiate hormone therapy for the treatment of vasomotor symptoms. It is possible that early initiation of hormone therapy may result in a more favorable risk–benefit profile.

The effects of the estrogen agonist-antagonist raloxifene on CHD was studied in a multicenter, randomized trial of approximately 10,000 older postmenopausal women with heart disease or multiple risk factors. Compared with placebo, raloxifene had no significant effect on death from any cause, coronary events, or total stroke, though risk of fatal stroke and venous thromboembolic disease was increased (55). The risks of clinical vertebral fractures and invasive breast cancer were significantly reduced.

$^b$Global index is a composite of coronary heart disease, stroke, pulmonary embolism, breast cancer, colorectal cancer, endometrial cancer, hip fracture, and mortality.

Breast Cancer

Breast cancer is a major health concern for menopausal women, as it is the most common cancer in women and the second leading cause of cancer death (56). The lifetime risk of invasive breast cancer for US women is 12%; therefore, any therapies that increase or reduce this risk will have a major impact on women’s health. Risk factors for breast cancer include age, family history, early menarche, late menopause, and prior breast disease, including epithelial atypia and cancer. Risk is reduced in women who had bilateral oophorectomy or a term pregnancy before the age of 30. Many of these risk factors are consistent with the hypothesis that prolonged estrogen exposure increases breast cancer risk.

Long-term use of hormone therapy, generally defined as greater than 5 years, is associated with an increased risk of breast cancer (relative risk [RR] = 1.3) in observational studies (57). There is no increased risk of breast cancer in past users of hormone therapy. The results of several studies suggest that the risk of breast cancer associated with the use of estrogen alone may be lower, with a higher risk in users of estrogen plus progestin (58). The WHI randomized controlled trial demonstrated a significant (26%) increase in the risk of invasive breast cancer after approximately 5 years of use of hormone therapy (51). In women with a prior hysterectomy, there was no increased risk of breast cancer after an average of 7 years of use of estrogen alone (52).

Hormone therapy should not be prescribed to women with a history of breast cancer and should be used by women at high risk only after a very careful assessment of potential benefits and risks. A randomized trial of hormone therapy use in women with a history of breast cancer and bothersome hot flashes was stopped after only 2 years, as more new breast cancers were diagnosed in woman randomized to hormone therapy (59).

The estrogen agonist-antagonist tamoxifen (Nolvadex, 20 mg per day orally) is used in the treatment of estrogen-receptor positive breast cancer. Both tamoxifen and raloxifene reduce the risk of breast cancer in high-risk women by approximately 50% and are approved for this indication (60). The risk of venous thromboembolism is increased approximately threefold with the use of tamoxifen and raloxifene, similar to the increase seen with hormone therapy. Tamoxifen acts as an estrogen agonist in the endometrium, increasing the risk of endometrial polyps, hyperplasia, and cancer, whereas no endometrial stimulation is seen with raloxifene. Performing a screening mammography examination annually for women older than age 50 years reduces breast cancer mortality. Monthly breast self-examination is advised.
Alzheimer’s Disease

Alzheimer’s disease is the most common form of dementia. Women are at greater risk for developing the disease than men, and the number of affected individuals in the United States is estimated to be more than 5 million with an annual cost of 183 billion dollars. Although several small studies suggest that hormone therapy may decrease the risk of Alzheimer’s disease, a randomized controlled study in women with mild to moderate Alzheimer’s disease showed that 1 year of estrogen therapy neither slowed disease progression nor improved cognition (61). The WHI Memory Study (WHIMS) was a randomized placebo-controlled study of women aged 65 years or older enrolled in WHI, which assessed the effect of hormone therapy on cognitive function. In contrast to observational studies, women in WHIMS randomized to hormone therapy experienced a significant twofold increased risk of dementia, most commonly Alzheimer’s disease (62). Hormone therapy use was associated with an adverse effect on cognition, as women randomized to hormone therapy scored significantly lower on the Modified Mini-Mental State Examination compared with placebo-treated women (63). Given the increased incidence of stroke identified in hormone therapy users in the WHI trial, it is possible that small, undetected cerebrovascular events were more likely to occur in the hormone therapy group, increasing the risk of dementia.
Hormone Therapy Use

For a healthy woman with bothersome hot flashes, hormone therapy remains a very reasonable option, especially if she is within 10 years of menopause or less than age 60. **Hormone therapy should be used at the lowest effective dose for the shortest duration consistent with treatment goals** (64–66). **The need for continued hormone therapy use should be assessed at least annually.**

The use of unopposed estrogen is associated with an increased risk of endometrial hyperplasia and cancer. Therefore, **combination estrogen-progestin therapy is recommended for all women with a uterus**. Treatment may be provided in a sequential manner, with estrogen daily and progestin for 12 to 14 days of each month, or in a continuous-combined fashion with estrogen and a lower dose of progestin daily. Sequential regimens result in regular, predictable vaginal bleeding. The majority of women using continuous-combined regimens will experience amenorrhea by the end of 1 year of therapy, but the bleeding that does occur is irregular and unpredictable. Low-dose combination hormone therapy products (e.g., Prempro 0.45/1.5 and 0.3/1.5 mg per day) generally result in a lower incidence of breakthrough bleeding and breast tenderness (67).

Women using low doses of oral or transdermal estrogens may elect intermittent progestin use (e.g., 14 days every 3 to 4 months) (68), although these are not approved regimens. **A progestin-containing intrauterine device approved for contraception in premenopausal women provides endometrial protection in estrogen-treated menopausal women, although it is not approved for this indication** (69). Increased endometrial surveillance is advised with these alternative regimens.

**Transdermal administration of estradiol with a patch, spray, or gel may be preferred by some women.** Avoiding the “first pass hepatic effect” of oral estrogens on lipids, binding globulins and clotting factors may have benefits for women on thyroid replacement or those with low libido (70). In contrast to oral administration, transdermal estradiol does not appear to increase the risk of venous thromboembolic events or gallbladder disease, though it remains contraindicated in women at high risk for venous thromboembolic disease or those with active liver or gallbladder disease.

Popularized by the media, many women are interested in using “bioidentical hormones” for treatment of menopausal symptoms. Bioidentical generally refers to hormones structurally identical to “natural” hormones made by the ovary, including estradiol and progesterone. FDA-approved oral and transdermal estradiol products are available in a wide range of doses, as is an oral form of micronized progesterone (Prometrium, 100 to 200 mg per day). Progesterone should be taken at bedtime, as it may cause drowsiness.

**There is potentially significant increased risk and no known benefit to the use of custom-compounded bioidentical hormone therapy formulations, preparations that are “custom” mixed and packaged by a compounding pharmacist for an individual patient** (see Table 34.1 for approved hormone therapy formulations).
Contraindications to hormone therapy use include known or suspected breast or endometrial cancer, undiagnosed abnormal genital bleeding, cardiovascular disease (including coronary heart disease, cerebrovascular disease, and thromboembolic disorders), and active liver or gallbladder disease. Relative contraindications include high-risk states for the above disorders. These situations require a thoughtful assessment of potential risks and benefits and documentation of informed patient consent before treatment.
Sexual Dysfunction

Sexual problems are highly prevalent, reported in approximately 40% of US women, with 12% reporting a sexual problem associated with personal distress (71). Although sexual problems generally increase with aging, distressing sexual problems peak in midlife women (aged 45 to 64) and are lowest in women 65 years or older. The etiology of female sexual dysfunction is often multifactorial, including depression or anxiety, relationship conflict, stress, fatigue, prior abuse, medications, or physical problems that make sexual activity uncomfortable, such as endometriosis or atrophic vaginitis. The impact of the menopausal transition on sexual function was examined in a prospective, longitudinal cohort study of approximately 3,000 women who were pre- or perimenopausal at baseline and followed for 6 years. Pain during sexual intercourse increased and sexual desire decreased over the menopausal transition, but other factors were unaffected, including sexual arousal, frequency, and pleasure (72). In contrast to menopausal factors, which were unrelated to most aspects of sexual functioning, age, social, health, and psychological factors were strongly linked.
Treatment Options

Hormone Therapy

Estrogen therapy is very effective in treating vaginal dryness and dyspareunia; however, a significant effect of estrogen therapy on sexual interest, arousal, and orgasmic response, independent from its role in treating menopausal symptoms, is not supported by evidence. A woman with distressing low libido concurrent with the onset of bothersome night sweats, sleep disruption, and fatigue likely will experience increased sexual interest with effective treatment of her menopausal symptoms, but this is probably secondary to improved well-being, rather than a direct effect of estrogen therapy on libido. A double-blind, randomized trial of combined oral and vaginal estrogen therapy in 285 sexually active postmenopausal women demonstrated decreased dyspareunia and significant improvements in pleasure of orgasm and sexual interest in women treated with estrogen therapy compared to placebo (73). As this trial used a combination of systemic and vaginal estrogens, it is not possible to determine the relative impact of systemic versus local effects.

In contrast to estrogen therapy, androgen therapy is consistently shown to improve sexual function in selected populations of postmenopausal women (74–76). Potential risks of androgen therapy include hirsutism, acne, irreversible deepening of the voice, and adverse changes in liver function and lipids. As most androgens are aromatized to estrogens, there is potential for an increased risk of cardiovascular events or breast cancer. A transdermal testosterone patch is approved in Europe for the treatment of hypoactive sexual desire disorder in surgically postmenopausal women using concomitant estrogen therapy. An advisory panel of the FDA did not recommend approval in the United States pending additional data on long-term safety.

Alternatives to Hormone Therapy

Although vaginal atrophy and dyspareunia respond very well to estrogen therapy, most other sexual problems may be effectively treated without hormones. Relationship quality and conflict, stress, and fatigue predict sexual satisfaction, so couples often benefit from counseling, lifestyle changes, and prescribed “date nights.” Women and their partners should be referred to sex therapists who provide education, materials, counseling, and instruction in specific exercises (77). In one study, 65% of 365 couples undergoing sex therapy for a range of sexual dysfunctions described their treatment as successful (78). Underlying depression and anxiety should be treated, and antidepressant medication may need adjustment. Bupropion may be an alternative to SSRIs, and one small, double-blind study reported increased sexual pleasure, arousal, and orgasm in nondepressed women with distressing low desire treated with bupropion (79). Sildenafil citrate may benefit women who develop problems with arousal and orgasmic response on SSRIs but generally is no more effective than placebo for most
Despite the fact that sexual problems are common, the majority of women with distressing sexual problems do not seek formal care, but when they do, it is typically the woman, rather than the physician, who initiates the conversation (82,83). Clinicians should routinely ask their menopausal patients whether vaginal dryness, dyspareunia, or another bothersome sexual problem is present, as many effective interventions are available.
Summary
There are many options available to address the health and quality of life concerns of menopausal women. The primary indication for hormone therapy is the alleviation of hot flashes and associated symptoms. Women must be informed of the potential risks and benefits of all therapeutic options. Care should be individualized based on a woman’s medical history, needs, and preferences.
References

SECTION VIII GYNECOLOGIC ONCOLOGY
Most risk factors for the development of endometrial carcinoma are related to prolonged, unopposed estrogen stimulation.

Office endometrial aspiration biopsy is the accepted first step in evaluating a woman with abnormal uterine bleeding or suspected endometrial pathology. Serous and clear cell endometrial carcinomas make up less than 10% of endometrial cancers, yet account for more than one-half of all endometrial cancer deaths.

Most patients with endometrial cancer should undergo surgical staging, including hysterectomy, bilateral salpingo-oophorectomy, pelvic and para-aortic lymphadenectomy, and peritoneal cytology. Lymphadenectomy may be omitted in patients with negligible risk of lymphatic spread.

The most important adverse prognostic variables in endometrial cancer are advancing patient age, nonendometrioid or grade 3 histology, deep myometrial invasion, lymphovascular space invasion, large tumor size, cervical extension, lymph node metastasis, and intraperitoneal spread.

Postoperative adjuvant radiotherapy in selected patients with endometrial cancer decreases the risk of local vaginal/pelvic recurrence and improves disease-free survival.

Overall 5-year survival rate in endometrial cancer is approximately 75%.

Uterine sarcomas are, in general, the most malignant group of uterine tumors and differ from endometrial cancers with regard to risk factors, diagnosis, clinical behavior, pattern of spread, and management.

Endometrial carcinoma is the most common malignancy of the female genital tract, accounting for almost one-half of all gynecologic cancers in the United States. In 2011, an estimated 46,470 new cases and 8,120 cancer-related deaths are
Endometrial carcinoma is the fourth most common cancer, ranking behind breast, lung, and colorectal cancers, and the eighth leading cause of death from malignancy in women. Overall, about 2% to 3% of women develop endometrial cancer during their lifetimes (1). Certain factors are increasing awareness of and emphasis on diagnosis and treatment of endometrial cancer. These factors include the declining incidence of cervical cancer-related deaths in the United States, prolonged life expectancy, postmenopausal use of hormone therapy, and earlier diagnosis. The availability of easily applied diagnostic tools and a clearer understanding of premalignant lesions of the endometrium led to an increase in the number of women diagnosed with endometrial cancer. Although endometrial carcinoma usually presents as early-stage disease and often is managed without radical surgery or radiotherapy, deaths from endometrial carcinoma now exceed those from cervical carcinoma in the United States. **Endometrial cancer is a disease that occurs primarily in postmenopausal women and is increasingly virulent with advancing age. The definite role of estrogen in the development of most endometrial cancers is established. Any factor that increases exposure to unopposed estrogen increases the risk for endometrial cancer.**

The histopathology, spread patterns, and clinicopathologic factors that affect the prognosis of endometrial cancers have become better defined. Management of endometrial cancer evolved from a program of preoperative intrauterine or external pelvic radiation followed by hysterectomy based on clinical staging, to an individualized approach using hysterectomy as primary therapy and employing additional postoperative treatment depending on surgical and pathologic findings. Further analysis and investigation are needed to determine whether this initial operative approach to treatment and staging, followed by targeted postoperative therapy, will translate into improved survival rates and lower morbidity.

Epidemiology and Risk Factors

There appear to be two pathogenetic types of endometrial cancer (2). Type I, accounting for about 75% to 85% of cases, occurs in younger, perimenopausal women with a history of exposure to unopposed estrogen, either endogenous or exogenous. In these women, tumors begin as hyperplastic endometrium and progress to carcinoma. These “estrogen-dependent” tumors tend to be better differentiated and have a more favorable prognosis than tumors that are not associated with hyperestrogenism.

Type II endometrial carcinoma occurs in women without estrogenic stimulation of the endometrium. These spontaneously occurring cancers are not associated pathologically with endometrial hyperplasia, but may arise in a background of atrophic endometrium. They are less differentiated and associated with a poorer prognosis than estrogen-dependent tumors. These “estrogen-independent” tumors tend to occur in older, postmenopausal, thin women and are present disproportionately in African American and Asian women. Over the past decade, molecular genetic studies showed that these two tumor types evolve via distinct pathogenetic pathways (3) (see Type I and II Endometrial Carcinoma: Molecular Aberrations, below).

Several risk factors for the development of endometrial cancer are identified (4–9) (Table 35.1). Most of these risk factors are related to prolonged, unopposed estrogen stimulation of the endometrium. Nulliparous women have two to three times the risk of parous women. Infertility and a history of irregular menses as a result of anovulatory cycles (prolonged exposure to estrogen without sufficient progesterone) increase risk. Natural menopause occurring after age 52 years increases the risk for endometrial cancer 2.4-fold compared with women who experienced menopause before 49 years of age, probably as a result of prolonged exposure of the uterus to progesterone-deficient menstrual cycles. The risk of endometrial cancer is increased 3 times in women who are 21 to 50 pounds overweight and 10 times in those more than 50 pounds overweight (resulting from excess estrone as a result of peripheral conversion of adrenallyderived androstenedione by aromatization in fat). The obesity epidemic in Western countries, together with growing rates of insulin resistance and “metabolic syndrome,” can be expected to increase the incidence of endometrial cancer in coming years.

Other factors leading to long-term estrogen exposure, such as polycystic ovary syndrome and functioning ovarian tumors, also are associated with an increased risk for endometrial cancer. Menopausal estrogen therapy without progestins increases the risk of endometrial cancer four to eight times. This risk increases with higher doses and with more prolonged use and can be reduced to essentially baseline levels by the addition of progestin (8). The use of the antiestrogen tamoxifen for treatment of breast cancer is associated with a two- to threefold increased risk for the development of endometrial cancer, although this finding is confounded by the apparent greater risk of endometrial cancer in women who have breast cancer, with or without treatment with tamoxifen (9,10). Diabetes mellitus increases a women’s risk for endometrial cancer by 1.3 to 2.8 times. Women with
Lynch II syndrome (previously referred to as hereditary nonpolyposis colorectal cancer syndrome, or HNPCC), a cancer susceptibility syndrome with germline mutations in mismatch repair genes MLH1, MSH2, and MSH6, have a 40% to 60% lifetime risk for endometrial and colon cancer (11). Other medical conditions, such as hypertension and hypothyroidism, are associated with endometrial cancer, but a causal relationship is not confirmed.

Endometrial Hyperplasia

Endometrial hyperplasia represents a spectrum of morphologic and biologic alterations of the endometrial glands and stroma, ranging from an exaggerated physiologic state to carcinoma in situ. Clinically significant hyperplasias usually evolve within a background of proliferative endometrium as a result of protracted estrogen stimulation in the absence of progestin influence. Endometrial hyperplasias are important clinically because they may cause abnormal bleeding, be associated with estrogen-producing ovarian tumors, result from hormonal therapy, and precede or occur simultaneously with endometrial cancer.

The classification scheme endorsed by the International Society of Gynecological Pathologists is based on architectural and cytologic features and long-term studies that reflect the natural history of the lesions (12) (Table 35.2). Architecturally, hyperplasias are either simple or complex; the major differing features are complexity and crowding of the glandular elements. Simple hyperplasia is characterized by dilated or cystic glands with round to slightly irregular shapes, an increased glandular-to-stromal ratio without glandular crowding, and no cytologic atypia. Complex hyperplasia has architecturally complex (budding and infolding) crowded glands, with less intervening stroma without atypia. Atypical hyperplasia refers to cytologic atypia and can be categorized as simple or complex, depending on the corresponding glandular architecture. Criteria for cytologic atypia include large nuclei of variable size and shape that have lost polarity, increased nuclear-to-cytoplasmic ratios, prominent nucleoli, and irregularly clumped chromatin with parachromatin clearing (Fig. 35.1).

Figure 35.1 Atypical hyperplasia (complex hyperplasia with severe nuclear atypia) of endometrium. A: The proliferative endometrial glands reveal considerable crowding and papillary infoldings. The endometrial stroma, although markedly diminished, can still be recognized between the glands. B: Higher magnification demonstrates disorderly nuclear arrangement and nuclear enlargement and irregularity. Some contain small nucleoli. (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)
The risk of endometrial hyperplasia progressing to carcinoma is related to the presence and severity of cytologic atypia. Kurman et al. retrospectively studied endometrial curettings from 170 patients with untreated endometrial hyperplasia followed a mean of 13.4 years (13). They found that progression to carcinoma occurred in 1% of patients with simple hyperplasia, 3% of patients with complex hyperplasia, 8% of patients with atypical simple hyperplasia, and
29% of patients with atypical complex hyperplasia. Most of the hyperplasias seemed to remain stable (18%) or regress (74%). The premalignant potential of hyperplasia is influenced by age, underlying ovarian disease, endocrinopathy, obesity, and exogenous hormone exposure (14,15).

As many as 25% to 43% of patients with atypical hyperplasia detected in an endometrial biopsy or curettage specimen will have an associated, usually well-differentiated, endometrial carcinoma detected during hysterectomy (16). Marked cytologic atypia, a high mitotic rate, and marked cellular stratification are features of atypical endometrial hyperplasia most often associated with the finding of an undiagnosed carcinoma at hysterectomy.
Younger patients with endometrial cancer tend to have disorders such as polycystic ovarian syndrome, chronic anovulation, and infertility, indicative of exposure to intrinsic estrogen excess (17). Lesions in this age group are usually well-differentiated and of endometrioid subtype with the potential to regress with progestational therapy (18). Although standard treatment for all endometrial cancer is hysterectomy and staging, nonsurgical treatment with hormonal therapy may be an option for appropriately selected women desiring to preserve fertility. Surrogate staging techniques, such as magnetic resonance imaging (MRI), may be employed to evaluate the depth of myometrial invasion or identify extrauterine disease (19,20). The sensitivity of MRI to evaluate these factors is limited and has the potential for underdiagnosis (21).

High regression rates for both endometrial cancer and atypical hyperplasia following treatment with progestin therapy are extensively documented (18,22–28). However, relatively small cohorts of patients and reports of hormone failure suggest caution when counseling patients for conservative management (27,29). In a 2004 meta-analysis, Ramirez et al. reported a comprehensive review of hormonal treatment of grade 1 endometrial cancer, including 27 articles with a combined total of 81 patients. A variety of progestational agents were utilized with an overall response rate of 76% (62/81) and the median time to regression was 12 weeks (30). The recurrence rate was 24% among responders; nearly all recurrences occurred within 1 year of diagnosis. Only 1 month of progestational treatment was required to achieve a response in the 76% of patients without recurrence. Twenty patients achieved pregnancy following treatment. It is important to note that 24% (19/81) of the original cohort never responded to treatment, and only 68% had any documented follow-up endometrial sampling. Progestational therapy can successfully treat disease while preserving fertility for patients with atypical hyperplasia and well-differentiated presumed stage I endometrial cancer. Appropriate patient selection and exclusion criteria remain undefined. Patients must be counseled that failure to identify recurrence or extension of disease during progestational treatment may lead to a delay in definitive surgery and ultimately a compromised prognosis (27).

Continuous progestin therapy with megestrol acetate (40–160 mg per day) is probably the most reliable treatment for reversing complex or atypical hyperplasia. No clear consensus exists for an optimal follow-up interval. Therapy should be continued for at least 2 to 3 months, and endometrial biopsy should be performed 3 to 4 weeks after completion of therapy to assess response. Periodic endometrial biopsy or transvaginal ultrasonography is advisable in patients being monitored after progestin therapy for atypical hyperplasia because of the presence of undiagnosed cancer in 25% of cases, the 29% progression rate to cancer, and the high recurrence rate after treatment with progestins. In this setting the use of progesterone should be considered a temporary, rather than long-term, treatment. For women with atypical complex hyperplasia who no longer desire fertility, hysterectomy is recommended.
Screening for endometrial cancer should not be undertaken because of the lack of an appropriate, cost-effective, and acceptable test that reduces mortality (31–33). Routine Papanicolaou (Pap) testing is inadequate, and endometrial cytologic assessment is too insensitive and nonspecific to be useful in screening for endometrial cancer, even in a high-risk population. A progesterone challenge test reveals whether the endometrium is primed by estrogen, but it does not identify abnormal endometrial pathology. Transvaginal ultrasonographic examination of the uterus and endometrial biopsy are too expensive to be employed as screening tests.

Although many risk factors for endometrial cancer have been identified, screening of high-risk individuals using current technologies could, at best, detect only one-half of all cases of endometrial cancer. Furthermore, no controlled trials were carried out to evaluate the effectiveness of screening for endometrial cancer. Screening for endometrial cancer or its precursors may be justified for certain high-risk women, such as those receiving postmenopausal estrogen therapy without progestins and members of families with hereditary nonpolyposis colorectal cancer (34). Women taking tamoxifen receive no benefit from routine screening with transvaginal ultrasonography or endometrial biopsy (35,36).

Most patients who have endometrial cancer present with abnormal perimenopausal or postmenopausal uterine bleeding early in the development of the disease, when the tumor is still confined to the uterus. Application of an appropriate and accurate diagnostic test in this situation usually results in early diagnosis, timely treatment, and a high cure rate. It is important to recognize that the workup of abnormal uterine bleeding should include endometrial biopsy even in premenopausal patients as 5% are in women under the age of 40.
Surveillance and Prevention in Patients at High Risk

Most endometrial carcinomas are sporadic, but about 10% of cases have a hereditary basis (37–41). Two genetic models were described in the development of familial endometrial cancer: HNPCC or Lynch II syndrome and a predisposition for endometrial cancer alone; both are inherited in an autosomal dominant fashion (42). The majority of studies focused on the increased incidence of endometrial cancer associated with Lynch II syndrome, a highly penetrant disorder (80% to 85%) (43). HNPCC or Lynch II syndrome is caused by an inherited mutation in one of the following mismatch repair genes: hMSH2, hMLH1, PMS1, PMS2, or hMSH6 (44–47). The disorder is characterized by early age (average age younger than 45 years) at onset of neoplastic lesions in a variety of tissues, including the colon, uterus, stomach, ureters, ovaries, and skin (43,48,49). The lifetime risk of endometrial cancer in women with Lynch II syndrome is 32% to 60% and the lifetime risk of ovarian cancer is 10% to 12% (50,51). Interestingly, colorectal cancer is less prevalent in women with HNPCC or Lynch II syndrome than in men, whose risk approaches 100%. In a study of 1,763 patients from 50 HNPCC or Lynch II syndrome families in the Finnish Cancer Registry, the cumulative incidence of colorectal cancer in women was 54% by age 70, while the cumulative incidence of endometrial cancer was 60% (11). Although these data appear to support the use of endometrial cancer surveillance strategies for women with Lynch syndrome, a specific algorithm is not defined (50,52). No effective screening method exists for patients at increased risk for ovarian cancer.

In 2006, a European workshop of 21 experts in the treatment of hereditary gastrointestinal cancers from nine countries (the Mallorca group) recommended the following endometrial cancer surveillance strategy for patients with HNPCC or Lynch II syndrome: annual pelvic examination, transvaginal ultrasound, and endometrial biopsy beginning at 30 to 35 years of age (53). These recommendations are by expert opinion only, and it is unknown whether these interventions are cost-effective or will impact mortality from endometrial or ovarian cancer in patients with Lynch II syndrome. An attractive alternative to early detection is prophylactic surgery after completion of childbearing (54,55). In 2006 a multi-institutional, matched case-control study found that prophylactic hysterectomy with bilateral salpingo-oophorectomy is an effective primary prevention strategy in women with Lynch II syndrome (51). No woman with hysterectomy and bilateral salpingo-oophorectomy developed endometrial, ovarian, or primary peritoneal carcinoma during the period of follow-up. In contrast, endometrial cancer developed in 33% and ovarian cancer in 5% of women who did not undergo prophylactic surgery (51).

There are rare reports of pedigrees in which family members are affected by endometrial cancer alone, and genetic studies have not found a germline mutation associated with site-specific endometrial cancer (42,56,57). A population-based study of endometrial cancer and familial risk in younger women (Cancer and Steroid Hormone, or CASH, Study Group) reported that a history of endometrial cancer in a first-degree relative increased the risk of endometrial cancer by nearly threefold (odds ratio of 2.8; 95% confidence
interval [CI], 1.9–4.2) (58). A significant association was found with colorectal cancers, with an observed odds ratio of 1.9 (95% CI, 1.1–3.3). The presence of Lynch II syndrome families within the cohort may explain the latter association, but a family history of endometrial cancer was an independent risk factor for endometrial cancer, after adjusting for age, obesity, and number of relatives (58).

Endometrial cancer and breast cancer share some of the same reproductive and hormonal risk factors such as nulliparity and exposure to unopposed estrogen (4,8,59–63). However, the familial association between breast and endometrial cancer is still uncertain and studies report conflicting results (63–67). For example, in the past it was thought that patients with BRCA mutations were at elevated risk for endometrial cancer, in addition to breast and ovarian cancer. A study suggests that this increase in risk is seen only in those patients with a personal history of breast cancer who are taking tamoxifen (68).
Endometrial Cancer

Clinical Features

Symptoms
Endometrial carcinoma most often occurs in women in the sixth and seventh decades of life, at an average age of 60 years; 75% of cases occur in women older than 50 years of age. **About 90% of women with endometrial carcinoma have vaginal bleeding or discharge as their only presenting symptom.** Most women recognize the importance of this symptom and seek medical consultation within 3 months. Some women experience pelvic pressure or discomfort indicative of uterine enlargement or extrauterine disease spread. Bleeding may not have occurred because of cervical stenosis, especially in older patients, and may be associated with hematometra or pyometra, causing a purulent vaginal discharge. This finding is often associated with a poor prognosis (69). **Less than 5% of women diagnosed with endometrial cancer are asymptomatic.** In the absence of symptoms, endometrial cancer usually is detected as the result of investigation of abnormal Pap test results, discovery of cancer in a uterus removed for some other reason, or evaluation of an abnormal finding on a pelvic ultrasonography examination or computed tomography (CT) scan obtained for an unrelated reason. Women who are found to have malignant cells on Pap test are more likely to have a more advanced stage of disease (70).

Abnormal perimenopausal and postmenopausal bleeding should always be taken seriously and be properly investigated, no matter how minimal or nonpersistent. Causes may be nongenital, genital extrauterine, or uterine (71). Nongenital tract sites should be considered based on the history or examination, including testing for blood in the urine and stool.

Invasive tumors of the cervix, vagina, and vulva are usually evident on examination, and any tumors discovered should be biopsied. Traumatic bleeding from an atrophic vagina may account for up to 15% of all causes of postmenopausal vaginal bleeding. This diagnosis can be considered if inspection reveals a thin, friable vaginal wall, but the possibility of a uterine source of bleeding must first be eliminated.
Possible uterine causes of perimenopausal or postmenopausal bleeding include endometrial atrophy, endometrial polyps, estrogen therapy, hyperplasia, and cancer or sarcoma (72–75) (Table 35.3). Uterine leiomyomas should never be accepted as a cause of postmenopausal bleeding. **Endometrial atrophy is the most common endometrial finding in women with postmenopausal bleeding, accounting for 60% to 80% of such bleeding.** Women with endometrial atrophy usually were menopausal for about 10 years. **Endometrial biopsy often yields insufficient tissue or only blood and mucus, and usually bleeding ceases after biopsy.** Endometrial polyps account for 2% to 12% of postmenopausal bleeding. Polyps are often difficult to identify with office endometrial biopsy or curettage. Hysteroscopy, transvaginal ultrasonography, or both may be useful adjuncts in identifying endometrial polyps. Unrecognized and untreated polyps may be a source of continued or recurrent bleeding, leading eventually to unnecessary hysterectomy.

Estrogen therapy is an established risk factor for endometrial hyperplasia and cancer. **The risk for endometrial cancer is fourto eighttimes greater in postmenopausal women receiving unopposed estrogen therapy, and the risk increases with time and higher estrogen doses.** This risk can be decreased by the addition of a progestin to the estrogen, either cyclically or continuously. Endometrial biopsy should be performed as indicated to assess unscheduled bleeding or annually in women not taking a progestin. **Endometrial hyperplasia occurs in 5% to 10% of patients with postmenopausal uterine bleeding.** The sources of excess estrogen should be considered, including obesity, exogenous estrogen, or an estrogen-secreting ovarian tumor. **Only about 10% of patients with postmenopausal bleeding have endometrial cancer.**

Premenopausal women with endometrial cancer invariably have abnormal uterine bleeding, which is often characterized as menometrorrhagia or oligomenorrhea, or cyclical bleeding that continues past the usual age of menopause. The diagnosis of endometrial cancer must be considered in premenopausal women if abnormal bleeding is persistent or recurrent or if obesity or chronic anovulation is present.

**Signs**

Physical examination seldom reveals any evidence of endometrial carcinoma, although **obesity and hypertension are commonly associated constitutional factors.** Special attention should be given to the more common sites of metastasis. Peripheral lymph nodes and breasts should be assessed carefully. Abdominal examination is usually unremarkable, except in advanced cases in which ascites or hepatic or omental metastases may be palpable. On gynecologic examination, the vaginal introitus and suburethral area, and the entire vagina and cervix, should be carefully inspected and palpated. Bimanual rectovaginal examination should be performed specifically to evaluate the uterus for size and mobility, the adnexa for masses, the parametria for induration, and the cul-de-sac for nodularity.
Diagnosis

Office endometrial aspiration biopsy is the accepted first step in evaluating a patient with abnormal uterine bleeding or suspected endometrial pathology (76). The diagnostic accuracy of office-based endometrial biopsy is 90% to 98% when compared with subsequent findings at dilation and curettage (D&C) or hysterectomy (77–79).

The narrow plastic cannulas are relatively inexpensive, often can be used without a tenaculum, cause less uterine cramping (resulting in increased patient acceptance), and are successful in obtaining adequate tissue samples in more than 95% of cases. If cervical stenosis is encountered, a paracervical block can be performed, and the cervix can be dilated. Premedication with an antiprostaglandin agent can reduce uterine cramping. Complications following endometrial biopsy are exceedingly rare; uterine perforation occurs in only 1 to 2 cases per 1,000. Endocervical curettage may be performed at the time of endometrial biopsy if cervical pathology is suspected. A Pap test is an unreliable diagnostic test because only 30% to 50% of patients with endometrial cancer have abnormal Pap test results (80).

Hysteroscopy and D&C should be reserved for situations in which cervical stenosis or patient tolerance does not permit adequate evaluation by aspiration biopsy, bleeding recurs after a negative endometrial biopsy, or the specimen obtained is inadequate to explain the abnormal bleeding. Hysteroscopy is more accurate in identifying polyps and submucous myomas than endometrial biopsy or D&C alone (81–83).

Transvaginal ultrasonography may be a useful adjunct to endometrial biopsy for evaluating abnormal uterine bleeding and selecting patients for additional testing (84–87). Transvaginal ultrasonography, with or without endometrial fluid instillation (sonohysterography), may be helpful in distinguishing between patients with minimal endometrial tissue whose bleeding is related to perimenopausal anovulation or postmenopausal atrophy and patients with significant amounts of endometrial tissue or polyps who are in need of further evaluation. The finding of an endometrial thickness greater than 4 mm, a polypoid endometrial mass, or a collection of fluid within the uterus requires further evaluation. Although most studies agree that an endometrial thickness of 5 mm or less in a postmenopausal woman is consistent with atrophy, more data are needed before ultrasonography findings can be considered to eliminate the need for endometrial biopsy in a patient with symptoms (88).
Pathology

The histologic classification of carcinoma arising in the endometrium is shown in Table 35.4 (12,89).

Endometrioid Adenocarcinoma

The endometrioid type of adenocarcinoma accounts for about 80% of endometrial carcinomas. These tumors are composed of glands that resemble normal endometrial glands; they have columnar cells with basally oriented nuclei, little or no intracytoplasmic mucin, and smooth intraluminal surfaces (Fig. 35.2). As tumors become less differentiated, they contain more solid areas, less glandular formation, and more cytologic atypia. The well-differentiated lesions may be difficult to separate from atypical hyperplasia.

Criteria that indicate the presence of invasion and are used to diagnose carcinoma are desmoplastic stroma, back-to-back glands without intervening stoma, extensive papillary pattern, and squamous epithelial differentiation. These changes, with the exception of the infiltrating pattern with desmoplastic reaction, require an area of involvement equal to or exceeding one-half of a low-power microscopic field (LPF) (>1 LPF; 4.2 mm in diameter) (90,91).

The differentiation of a carcinoma, expressed as its grade, is determined by architectural growth pattern and nuclear features (Table 35.5). In the International Federation of Gynecology and Obstetrics (FIGO) grading system proposed in 1989, tumors are grouped into three grades: grade 1, 5% or less of the tumor shows a solid growth pattern; grade 2, 6% to 50% of the tumor shows a solid growth pattern; and grade 3, more than 50% of the tumor shows a solid growth pattern. The presence of notable nuclear atypia that is inappropriate for the architectural grade increases the tumor grade by one.
Adenocarcinomas with squamous differentiation are graded according to the nuclear grade of the glandular component. This FIGO system is applicable to all endometrioid carcinomas, including its variants, and to mucinous carcinomas. In serous and clear cell carcinomas, nuclear grading takes precedence; however, most investigators believe that these two carcinomas should always be considered high-grade lesions, making grading unnecessary.

**About 15% to 25% of endometrioid carcinomas have areas of squamous differentiation** (Fig. 35.3). In the past, tumors with benign-appearing squamous areas were called adenoacanthomas, and tumors with malignant-looking squamous elements were called adenosquamous carcinomas. It is recommended that the term endometrial carcinoma with squamous differentiation be used to replace these two designations because the degree of differentiation of the squamous component parallels that of the glandular component, and the behavior of the tumor is largely dependent on the grade of the glandular component (92,93).

**Figure 35.2 Well-differentiated adenocarcinoma of endometrium.** The glands and complex papillae are in direct contact with no intervening endometrial stroma, the so-called back-to-back pattern. (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)

G2 6%–50% nonsquamous or nonmorular growth pattern
G3 >50% nonsquamous or nonmorular growth pattern

Notes on pathologic grading:
Notable nuclear atypia, inappropriate for the architectural grade, raises a grade 1 (G1) or grade 2 (G2) tumor by one grade.

In serous adenocarcinoma, clear cell adenocarcinoma, and squamous cell carcinoma,
nuclear grading takes precedence.
Adenocarcinomas with squamous differentiation are graded according to the nuclear grade of the glandular component.

Figure 35.3 Adenocarcinoma with squamous differentiation of endometrium. This lesion is also classified as adenoacanthoma. Squamous cells with eosinophilic cytoplasm and distinct cell borders form solid clusters in the lumina of neoplastic glands. (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)

Avilloglandular configuration is present in about 2% of endometrioid carcinomas (94,95). In these tumors, the cells are arranged along fibrovascular stalks, giving a papillary appearance but maintaining the characteristics of endometrioid cells.
The villoglandular variants of endometrioid carcinomas are always well-differentiated lesions that behave like the regular endometrioid carcinomas, and they should be distinguished from serous carcinomas. **Secretory carcinoma is a rare variant of endometrioid carcinoma that accounts for about 1% of cases** ([96,97]). It occurs mostly in women in their early postmenopausal years. The tumors are composed of well-differentiated glands with intracytoplasmic vacuoles similar to early secretory endometrium. These tumors behave as regular well-differentiated endometrioid carcinomas and have an excellent prognosis. Secretory carcinoma may be an endometrioid carcinoma that exhibits progestational changes, but a history of progestational therapy is rarely elicited. Secretory carcinoma must be differentiated from clear cell carcinoma because both tumors have predominately clear cells. These two tumors can be distinguished by their structure: secretory carcinomas have uniform glandular architecture, uniform cytology, and low nuclear grade, whereas clear cell carcinomas have more than one architectural pattern and a high nuclear grade.

**Mucinous Carcinoma**

About 5% of endometrial carcinomas have a predominant mucinous pattern in which more than one-half of the tumor is composed of cells with intracytoplasmic mucin ([98,99]). Most of these tumors have a well-differentiated glandular architecture; their behavior is similar to that of common endometrioid carcinomas, and the prognosis is good. It is important to recognize mucinous carcinoma of the endometrium as an entity and to differentiate it from endocervical adenocarcinoma. Features that favor a primary endometrial carcinoma are the merging of the tumor with areas of normal endometrial tissue, presence of foamy endometrial stromal cells, presence of squamous metaplasia, or presence of areas of typical endometrioid carcinoma. Positive perinuclear immunohistochemical staining with vimentin suggests an endometrial origin ([100]).

**Serous Carcinoma**

About 3% to 4% of endometrial carcinomas resemble serous carcinoma of the ovary and fallopian tube ([101–104]). Most often, these tumors are composed of fibrovascular stalks lined by highly atypical cells with tufted stratification (Fig. 35.4). Psammoma bodies frequently are observed.

**Figure 35.4 Serous carcinoma of endometrium.** Branching papillae are supported by delicate fibrovascular cores and lined with columnar cells with moderate nuclear atypism, multiple nucleoli, and mitotic figures. (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)
Serous carcinomas, also referred to as uterine papillary serous carcinomas, are considered high-risk lesions. The first description in 1982, noted that this entity usually occurred in elderly, hypoestrogenic women who presented with advanced-stage disease and accounted for up to one-half of deaths from endometrial carcinoma (101). Since then, several reports documented the aggressive nature and poor prognosis of serous carcinomas.

They are commonly admixed with other histologic patterns, but mixed tumors behave as aggressively as pure serous carcinomas. Even patients with a very small proportion of serous features (5%) remain at high risk of recurrence (105). Serous carcinomas are often associated with lymph–vascular space and deep myometrial invasion. The presence of lymph node metastases, positive peritoneal cytology, and intraperitoneal tumor does not necessarily correlate with increasing myometrial invasion (104). Even when these tumors appear to be confined to the endometrium or endometrial polyps without myometrial or vascular invasion, they behave more aggressively than endometrioid carcinomas and have a propensity to spread intra-abdominally, simulating the behavior of ovarian carcinoma. In one series, 37% of patients with serous carcinomas of the endometrium confined to a polyp demonstrated extrauterine disease when subjected to exploration and surgical staging (106).

A multi-institutional review of 206 patients with surgical stage I and II serous carcinomas demonstrated recurrence in 21% (105). Substage and treatment with platinum-based chemotherapy were associated with improved overall survival. Survival of surgically
staged patients without myometrial invasion or extrauterine disease is between 89% and 100%, suggesting that observation may be appropriate in select patients, particularly in elderly patients with comorbidities (107). However, stage I patients, particularly those with myometrial invasion, remain at high risk of both peritoneal and vaginal recurrence. Therefore, platinum-based chemotherapy and vaginal brachytherapy should be considered in these patients (107–109).

Surgical treatment of advanced disease is no different from the endometrioid subtype, consisting of complete extirpation of visible disease (108). In one investigation from the Mayo Clinic, cytoreduction to microscopic residual was associated with a median overall survival of 51 versus 12 months for those patients with any residual (110). Postoperative treatment of advanced disease in the United States consists of chemotherapy and pelvic radiation, with or without para-aortic radiation. The Gynecologic Oncology Group study GOG184 included serous carcinomas and randomized patients to carboplatin and paclitaxel versus cisplatin, doxorubicin (Adriamycin), and paclitaxel together with tumor volume-directed radiation (111). The former regimen demonstrated similar outcomes with less toxicity. Limited data suggest that delivering radiation “sandwiched” with chemotherapy improves progression-free and overall 3-year survival rates (112). Ongoing studies are evaluating the role of chemotherapy alone for these tumors, especially because of the high rate of peritoneal dissemination and recurrences. It remains unknown whether radiation improves survival in addition to chemotherapy alone. For elderly patients with multiple comorbidities who cannot tolerate multimodal therapy, chemotherapy alone.

**Clear Cell Carcinoma**

**Clear cell carcinoma accounts for less than 5% of all endometrial carcinomas** (96,113,114). Clear cell carcinoma usually has a mixed histologic pattern, including papillary, tubulocystic, glandular, and solid types. The cells have highly atypical nuclei and abundant clear or eosinophilic cytoplasm. Often, the cells have a hobnail configuration arranged in papillae with hyalinized stalks (Fig. 35.5).

**Figure 35.5 Clear cell adenocarcinoma of the endometrium.** Back-to-back glands lined by polygonal to columnar cells with distinct cell membrane, abundant granular to clear cytoplasm, and variably sized nuclei (including binucleated and multinucleated forms) with prominent nucleoli (magnification X400). (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)
Clear cell carcinoma characteristically occurs in older women and like serous carcinoma is considered a poor prognosticator. Traditionally clear cell carcinoma was associated with very poor outcomes with overall survival rates varying from 33% to 64%. A multi-institutional review of 99 patients with uterine clear cell carcinoma documented only 1 recurrence (vaginal) in the 22 patients without extrauterine disease subjected to thorough surgical staging (115). Considering all 49 patients with stage I or II disease (regardless of the extent of staging), only 1 hematologic failure was noted. These data argue against the use of systemic therapy in patients with clear cell carcinoma limited to the pelvis, while the 10% vaginal cuff failure suggests that vaginal brachytherapy alone may be sufficient treatment. In contrast, others argued for systemic treatment of patients with stage I disease (116).

Complete surgical staging is important because 52% of patients with clinical stage I clear cell carcinoma have metastatic disease. Patients who undergo a complete cytoreduction appear to have improved progression-free and overall survivals compared to women left with residual disease following surgery (115). Postoperative therapy for patients with advanced disease is platinum-based (116).

**Squamous Carcinoma**

**Squamous carcinoma of the endometrium is rare.** Some tumors are pure, but most have a few glands. To establish primary origin within the endometrium, there must be no connection with or spread from cervical squamous epithelium. Squamous carcinoma often
is associated with cervical stenosis, chronic inflammation, and pyometra at the time of diagnosis. This tumor has a poor prognosis, with an estimated 36% survival rate in patients with clinical stage I disease (117).

Simultaneous Tumors of the Endometrium and Ovary

Synchronous endometrial and ovarian cancers are the most frequent simultaneously occurring genital malignancies, with a reported incidence of 1.4% to 3.8% (118–122). Most commonly, both the ovarian and endometrial tumor are well-differentiated endometrioid adenocarcinomas of low stage, resulting in an excellent prognosis. Patients often are premenopausal and present with abnormal uterine bleeding. The ovarian cancer usually is discovered as an incidental finding and is diagnosed at an earlier stage because of the symptomatic endometrial tumor, leading to a more favorable outcome. Up to 29% of patients with endometrioid ovarian adenocarcinomas have associated endometrial cancer. If more poorly differentiated, nonendometrioid histologic subtypes are present or if the uterine and ovarian tumors are histologically dissimilar, the prognosis is less favorable. Immunohistochemical studies, flow cytometry, and assessment of molecular DNA patterns to detect loss of heterozygosity may be helpful in distinguishing between metastatic and independent tumors, but the differential diagnosis can usually be determined by conventional clinical and pathologic criteria.
Pretreatment Evaluation

After establishing the diagnosis of endometrial carcinoma, the next step is to evaluate the patient thoroughly to determine the best and safest approach to management of the disease. A complete history and physical examination are of utmost importance. Patients with endometrial carcinoma are often elderly and obese with a variety of medical problems, such as diabetes mellitus and hypertension, which complicate surgical management. Any abnormal symptoms, such as bladder or intestinal symptoms, should be evaluated.

On physical examination, attention should be directed to enlarged or suspicious lymph nodes, including the inguinal area, abdominal masses, and possible areas of cancer spread within the pelvis. Evidence of distant metastasis or locally advanced disease in the pelvis, such as gross cervical involvement or parametrial spread, may alter the treatment approach.

Chest radiography should be performed to exclude pulmonary metastasis and to evaluate the cardiorespiratory status of the patient. Other routine preoperative studies should include electrocardiography, complete blood and platelet counts, serum chemistries (including renal and liver function tests), and blood type and screen. Other preoperative or staging studies are neither required nor necessary for most patients with endometrial cancer. Studies such as cystoscopy, colonoscopy, intravenous pyelography, and barium enema are not indicated unless dictated by patient symptoms, physical findings, or other laboratory tests (123). CT scanning of the abdomen and pelvis may be considered in patients with type II uterine cancer to determine if minimally invasive surgery is appropriate. Stage IV disease is usually clinically evident based on patient symptomatology and clinical examination. Ultrasonography and MRI can be used to assess myometrial invasion preoperatively with a fairly high degree of accuracy (124). This information may be of use in planning the surgical procedure with regard to whether lymph node sampling should be undertaken.

Serum CA125, an antigenic determinant that is elevated in 80% of patients with advanced epithelial ovarian cancers, is elevated in most patients with advanced or metastatic endometrial cancer (125). In one study, 23 of 81 patients with apparently localized disease preoperatively had elevated CA125 levels. At surgery, 20 (87%) of these 23 patients with an elevated CA125 were found to have extrauterine disease, whereas only 1 of 58 patients with a normal CA125 had disease spread outside the uterus (126). Another study found that 78% of endometrial cancer patients with lymph node metastases had an elevated preoperative CA125 level (127). Preoperative measurement of serum CA125 may help determine the extent of surgical staging and, if elevated, may be useful as a tumor marker in assessing response to subsequent therapy (128,129).
Clinical Staging

Clinical staging, according to the 1971 FIGO system, should be performed only in patients who are deemed not to be surgical candidates because of their poor medical condition or the degree of disease spread (130). The current FIGO staging is surgical, as discussed below, which has supplanted the old clinical system. With improvements in preoperative and postoperative care, anesthesia administration, and surgical techniques, almost all patients are medically suitable for operative therapy. One study reported an operability rate of 87% in a series of 595 consecutive patients with clinical early-stage endometrial cancer (131). A small percentage of patients will not be candidates for surgical staging because of gross cervical involvement, parametrial spread, invasion of the bladder or rectum, or distant metastasis.
Surgical Staging

Widely accepted management of endometrial cancer consists of hysterectomy, removal of remaining adnexal structures, and appropriate surgical staging in patients considered at risk for extrauterine disease (132–134). Surgical staging was recommended for patients with endometrial cancer since 1988 (134). In spite of this general recommendation, the incorporation of a systematic pelvic and para-aortic lymphadenectomy in all patients is not universally accepted (135–137). This recommendation became more controversial after the publication of two large prospective randomized trials that failed to demonstrate improved outcomes for patients who underwent pelvic lymphadenectomy (138,139). These two studies show differences in their design: in the ASTEC trial all women with clinical stage I were included without exclusion criteria, whereas the Italian study excluded women with stage IA and IB grade 1 tumors, and nonendometrioid malignancies. In the Italian study, systematic nodal dissection was performed, as opposed to pelvic node sampling in the ASTEC trial (median number of lymph nodes harvested 30 vs. 12, respectively). The studies share characteristics that could lead to misinterpretation of their results. The percentage of nodal positivity is low in both studies (13% and 9%), suggesting that regardless of differences in exclusion criteria, low-risk cases were included in both studies, thus diluting possible (if any) therapeutic benefit of lymphadenectomy. Another important limitation is that nodal dissection was limited to the pelvis without any recommendation for para-aortic lymphadenectomy. It was demonstrated previously that radiotherapy limited to the pelvis does not improve survival (136). It is not surprising that pelvic lymphadenectomy alone has no therapeutic impact, considering that 67% of patients with nodal involvement have para-aortic lymph node metastases and 16% of patients with documented lymphatic dissemination have isolated para-aortic metastases (140). Neither study used the information derived from lymphadenectomy to target postoperative treatment (i.e., to spare patients with negative nodes from radiotherapy or to target postoperative treatment to the metastatic areas), thus eliminating one of the potential benefits of this surgical procedure.

IIIC2 - Positive para-aortic lymph nodes with or without positive pelvic lymph nodes

Stage IV* - Tumor invades bladder and/or bowel mucosa, and/or distant metastases

IVA* - Tumor invasion of bladder and/or bowel mucosa

IVB - Distant metastases, including intra-abdominal metastases and/or inguinal lymph nodes

*Either G₁, G₂, or G₃.

**Endocervical glandular involvement only should be considered as Stage I and no longer as Stage II.

#Positive cytology has to be reported separately without changing the stage.

Systematic pelvic and para-aortic lymphadenectomy remains one of the most important steps to assess the presence of extrauterine disease and to guide targeted postoperative treatment. GOG33 demonstrated that patients with absent or superficial myometrial invasion have a low probability of lymphatic metastases (141). Furthermore, Mariani et al. demonstrated that no patient with endometrioid grade 1 or 2 disease and superficial myometrial invasion harbored a lymphatic metastasis when the tumor diameter was 2 cm or less (137). The importance of tumor size as a predictor for lymphatic spread was reported by Schink et al. (142). It is possible to identify a group of patients in whom lymphadenectomy is likely to increase the risk of surgical complications without producing any concrete benefits. Tumor diameter, along with myometrial invasion and histologic grade and subtype, can be utilized to determine whether or not lymphadenectomy is appropriate.

An observational study reported a significant survival benefit of para-aortic lymphadenectomy in patients at intermediate or high risk of recurrence (based on presence of histologic grade 3 or deep myometrial invasion, or lymphovascular invasion, or evidence of spread outside of the uterine corpus), compared to patients who had hysterectomy with pelvic lymphadenectomy but without para-aortic dissection. This benefit was not observed in patients with low-risk endometrial cancer (143). In addition, the Postoperative Radiation Therapy in Endometrial Carcinoma (PORTEC) studies identified patients with stage IC, grade 3 endometrial carcinoma as being at high risk of early distant spread and death when treated with hysterectomy only (no staging), followed by pelvic external-beam radiation therapy. These patients had a 31% risk of distant recurrence (136). From the literature, it seems that the patients who have the potential to benefit from surgical staging are those with risk factors such as histologic grade 3, deep myometrial invasion, or lymphovascular invasion.

In summary, surgical staging should (i) identify patients with disseminated disease who are at high risk of recurrence; (ii) target postoperative treatment; (iii) reduce the number of patients potentially requiring postoperative treatment when the provided information is
used appropriately (avoiding the risk of morbidity without reasonable benefit); and (iv) possibly eradicate lymphatic disease. In spite of these potential benefits in high-risk patients, prospective randomized data demonstrating a survival advantage or reduction in overall morbidity resulting from a potential reduction of adjuvant treatment still are not available.

The FIGO published the updated surgical staging system for endometrial cancer (Table 35.6) (144). In comparison with recommendations from 1988, the new system introduces the following changes: (i) former stages IA and IB are combined; (ii) former stage IIA was eliminated so that only the presence of cervical stroma involvement is considered stage II disease; (iii) alone, peritoneal cytologic findings positive for endometrial cancer are no longer a criterion for disease upstaging (although FIGO still recommends the collection of peritoneal washing, recognizing the predictive value of positive cytologic findings when combined with other poor-prognosis factors); and (iv) stage IIIC was divided into IIIC1 and IIIC2 in accordance with the absence or presence of positive paraaortic nodes. The presence of parametrial disease is now formally recognized as stage IIIB disease.
Prognostic Variables

Although disease stage is the most significant variable affecting survival, a number of other individual prognostic factors for disease recurrence or survival are known, including tumor grade, histopathology, depth of myometrial invasion, patient age, and surgical–pathologic evidence of extrauterine disease spread (Tables 35.7 and 35.8). Other factors, such as tumor size, peritoneal cytology, hormone receptor status, flow cytometric analysis, and oncogene perturbations, are implicated as having prognostic importance.

Age
In general, younger women with endometrial cancer have a better prognosis than older women. Two reports observed no deaths related to disease in patients with endometrial cancer diagnosed before 50 years of age (145,146). Another series demonstrated a 60.9% 5-year survival rate for patients older than 70 years of age, compared with 92.1% survival rate for patients younger than 50 years of age (147). Decreased survival was associated with an increased risk for extraperitoneal spread (38% vs. 21%) and deep myometrial invasion (57% vs. 24%) for these two groups. The GOG reported 5-year survival rates of 96.3% for patients 50 years of age or younger, 87.3% for patients 51 to 60 years, 78% for patients 61 to 70 years, 70.7% for patients 71 to 80 years, and 53.6% for patients older than 80 years (148).

Increased risk for recurrence in older patients was related to a higher incidence of grade 3 tumors or unfavorable histologic subtypes; however, age appears to be an independent prognostic variable. Increasing patient age appears to be independently associated with disease recurrence in endometrial cancer. In one study, the mean age at diagnosis of patients who had recurrence or died of disease was 68.6 years, compared with 60.3 years for patients without recurrence. For every 1-year increase in age, the estimated rate of recurrence increased 7%. None of the patients younger than 50 years of age developed recurrent cancer, compared with 12% of patients aged 50 to 75 years and 33% of patients older than 75 years (149).

Histologic Type
Nonendometrioid histologic subtypes account for about 10% of endometrial cancers and carry an increased risk for recurrence and distant spread (150,151). In a retrospective review of 388 patients treated at the Mayo Clinic for endometrial cancer, 52 (13%) had an uncommon histologic subtype, including 20 adenosquamous, 14 serous, 11 clear cell, and 7 undifferentiated carcinomas. In contrast
to the 92% survival rate among patients with endometrioid tumors, the overall survival for patients with one of these more aggressive subtypes was only 33%. At the time of surgical staging, 62% of the patients with an unfavorable histologic subtype had extrauterine spread of disease (150).

**Histologic Grade**

**Histologic grade of the endometrial tumor is strongly associated with prognosis** (132,141,149,152–156). In one study, recurrences developed in 7.7% of grade 1 tumors, 10.5% of grade 2 tumors, and 36.1% of grade 3 tumors. Patients with grade 3 tumors were in excess of five times more likely to have a recurrence than were patients with grades 1 and 2 tumors. The 5-year disease-free survival rates for patients with grades 1 and 2 tumors were 92% and 86%, respectively, compared with 64% for patients with grade 3 tumors (149). Another study reported similar results, noting recurrences in 9% of patients with grades 1 and 2 tumors compared with 39% of patients with grade 3 lesions (153). Increasing tumor anaplasia is associated with deep myometrial invasion, cervical extension, lymph node metastasis, and both local recurrence and distant metastasis.

**Tumor Size**

**Tumor size is a significant prognostic factor for lymph node metastasis and survival in patients with endometrial cancer** (142,157). One report determined tumor size in 142 patients with clinical stage I endometrial cancer and found lymph node metastasis in 4% of patients with tumors 2 cm or smaller, in 15% of patients with tumors larger than 2 cm, and in 35% of patients with tumors involving the entire uterine cavity (156). Tumor size better defined an intermediate-risk group for lymph nodes metastasis (i.e., patients with grade 2 tumors with less than 50% myometrial invasion). Overall, these patients had a 10% risk for lymph node metastasis, but there was no nodal metastasis associated with tumors 2 cm or smaller, compared with 18% when tumors were larger than 2 cm. Five-year survival rates were 98% for patients with tumors 2 cm or smaller, 84% for patients with tumors larger than 2 cm, and 64% for patients with tumors involving the whole uterine cavity (137,157).

**Hormone Receptor Status**

**Estrogen receptor and progesterone receptor levels are prognostic indicators for endometrial cancer independent of grade in several studies** (158–164). Patients whose tumors are positive for one or both receptors have longer survival times than patients whose carcinomas lack the corresponding receptors. Even patients with metastasis have an improved prognosis with receptor-positive tumors (161). Progesterone receptor levels appear to be stronger predictors of survival than estrogen receptor levels, and the higher the absolute level of the receptors, the better the prognosis.

**DNA Ploidy and Proliferative Index**
About two-thirds of endometrial adenocarcinomas have a diploid DNA content as determined by flow cytometric analysis (162,165–174). The proportion of nondiploid tumors increases with stage, lack of tumor differentiation, and depth of myometrial invasion. In several studies, DNA content was related to clinical course of the disease, with death rates reported to be higher in women whose tumors contained aneuploid populations of cells. The proliferative index is related to prognosis.

**Myometrial Invasion**

**Because access to the lymphatic system increases as cancer invades into the outer one-half of the myometrium, increasing depth of invasion is associated with increasing likelihood of extrauterine spread and recurrence** (153,155,175). The association of depth of myometrial invasion with extrauterine disease and lymph node metastases was reported (175). Of patients without demonstrable myometrial invasion, only 1% had pelvic lymph node metastasis, compared with patients with outer one-third myometrial invasion who had 25% pelvic and 17% aortic lymph node metastases. Deep myometrial invasion (>50% for all stages; ≥66% for stage I) is the strongest predictor of hematogenous recurrence (176). Survival decreases with increasing depth of myometrial invasion. In general, patients with noninvasive or superficially invasive tumors have an 80% to 90% 5-year survival rate, whereas those with deeply invasive tumors have a 60% survival rate. The most sensitive indicator of the effect of myometrial invasion on survival is distance from the tumor–myometrial junction to the uterine serosa. Patients with tumors that are less than 5 mm from the serosal surface are at much higher risk for recurrence and death than those with tumors greater than 5 mm from the serosal surface (177,178).

**Lymph–Vascular Space Invasion**

Lymph–vascular space invasion (LVSI) appears to be an independent risk factor for recurrence and death from all types of endometrial cancer (178–181). The overall incidence of LVSI in early endometrial cancer is about 15%, although it increases with increasing tumor grade and depth of myometrial invasion. One study reported LVSI in 2% of grade 1 tumors and 5% of superficially invasive tumors, compared with 42% of grade 3 tumors and 70% of deeply invasive tumors (180). LVSI was demonstrated to be a strong predictor of lymphatic dissemination and lymphatic recurrence (182). Another study reported deaths in 26.7% of patients with clinical stage I disease who had LVSI, compared with 9.1% of those without LVSI (183). Likewise, an 83% 5-year survival rate was reported for patients without demonstrable LVSI, compared with a 64.5% survival rate for those in whom LVSI was present (181). Using multivariate analysis, only depth of myometrial invasion, DNA ploidy, and vascular invasion–associated changes correlated significantly with survival of patients with stage I endometrial adenocarcinomas in another report (165).

**Isthmus and Cervix Extension**
The location of the tumor within the uterus is important. Involvement of the uterine isthmus, cervix, or both is associated with an increased risk for extrauterine disease, lymph node metastasis, and recurrence. Cervical stromal invasion was a strong predictor of lymphatic dissemination and lymphatic recurrence, especially for pelvic lymph nodes (182). One study reported that if the fundus of the uterus alone was involved with tumor, there was a 13% recurrence rate, whereas if the lower uterine segment or cervix was involved with occult tumor, there was a 44% recurrence rate (151). A subsequent GOG study found that tumor involvement of the isthmus or cervix without evidence of extrauterine disease was associated with a 16% recurrence rate and a relative risk of 1.6 (132). Patients with cervical involvement tended to have higher-grade, larger, and more deeply invasive tumors, undoubtedly contributing to the increased risk for recurrence.

**Peritoneal Cytology**

Several reports noted increased recurrence rates and decreased survival rates and, on this basis, recommended treatment for positive cytology (184–186). Most of the studies included patients with other evidence of extrauterine disease spread and were performed without appropriate multivariate analysis and with patients who were incompletely staged. The GOG study critically analyzed 1,180 clinical stages I and II endometrial cancer patients in whom appropriate surgical and pathologic staging was performed (132). Considering only the 697 patients for whom peritoneal cytology status and adequate follow-up were available, 25 (29%) of 86 patients with positive cytology developed recurrence, compared with 64 (10.5%) of 611 patients with negative cytology. They noted that 17 of the 25 recurrences in the positive cytology group were outside the peritoneal cavity.

In contrast to these reports, an equal number of studies found no significant relationship between malignant peritoneal cytology and an increased incidence of disease recurrence in the absence of other risk factors such as extrauterine disease (186–189). Patients with positive peritoneal cytology as the only site of extrauterine disease (i.e., no adnexal or uterine serosal invasion) and without poor prognosticators (i.e., myometrial invasion more than 50%, nonendometrioid histologic subtype, grade 3, lymphovascular space invasion, cervical invasion) have a very favorable outcome with an absence of extra-abdominal recurrences (190). These patients have an associated 5-year survival of 98% to 100% even when not treated with adjuvant therapy (148,191,192). On the other hand, patients with positive cytology in addition to poor prognostic factors demonstrate a high rate (47%) of distant extra-abdominal failure and may potentially benefit from systemic chemotherapy. **Positive peritoneal cytology seems to have an adverse effect on survival only if the endometrial cancer has spread to the adnexa, peritoneum, or lymph nodes, not if the disease is otherwise confined to the uterus (188,189,191).** These considerations led to the omission of cytology as a factor impacting stage in the FIGO 2009 staging criteria.

The following conclusions may be reached regarding the prognostic...
Implications of positive peritoneal cytology:

Positive peritoneal cytology is associated with other known poor prognostic factors.

Positive peritoneal cytology in the absence of other evidence of extrauterine disease or poor prognostic factors has no significant effect on recurrence and survival.

Positive peritoneal cytology, when associated with other poor prognostic factors or extrauterine disease, increases the likelihood for distant as well as intra-abdominal disease recurrence and has a significant adverse effect on survival.

Use of several different therapeutic modalities has not resulted in any proven benefit to patients with endometrial cancer and positive peritoneal cytology.

Stage IIIA: Adnexal or Uterine Serosal Involvement

Most patients with stage IIIA disease have other poor prognostic factors that place them at high risk for recurrence. One series described treatment of all patients with serosal or adnexal invasion (or both) with whole-abdomen radiotherapy. Failures were observed outside the abdomen in 100% of patients with full thickness myometrial invasion or uterine serosal invasion, and in 20% to 25% of cases in the presence of isolated adnexal invasion (132,193). These patients may benefit from postoperative systemic chemotherapy.

Lymph Node Metastasis

Lymph node metastasis is the most important prognostic factor in clinical early-stage endometrial cancer. Of patients with clinical stage I disease, about 10% will have pelvic and 6% will have para-aortic lymph node metastases. Patients with lymph node metastases have almost a sixfold higher likelihood of developing recurrent cancer than patients without lymph node metastases. One study reported a recurrence rate of 48% with positive lymph nodes, including 45% with positive pelvic nodes and 64% with positive aortic nodes, compared with 8% with negative nodes. The 5-year disease-free survival rate for patients with lymph node metastases was 54%, compared with 90% for patients without lymph node metastases (148). The GOG found that the presence or absence of para-aortic lymph node metastases was of paramount importance in determining prognosis. Of 48 para-aortic node–positive patients, 28 (58%) developed progressive or recurrent cancer, and only 36% of these patients were alive at 5 years, compared with 85% of patients without para-aortic node involvement (194). One series examined patients with lymph nodes metastases in addition to other extrauterine sites of disease (vagina, uterine serosa, positive peritoneal cytology, adnexal invasion). The recurrence rates were 67% (41% extranodal) for those with lymphatic dissemination versus. 32% (5% extranodal) for those with other sites of extrauterine disease spread (190).
Intraperitoneal Metastases

Extrauterine metastasis, excluding peritoneal cytology and lymph node metastasis, occurs in about 4% to 6% of patients with clinical stage I endometrial cancer. Gross intraperitoneal spread is highly correlated with lymph node metastases; one study noted that 51% of patients with intraperitoneal tumor had positive lymph nodes, whereas only 7% of patients without gross peritoneal spread had positive nodes (141). Extrauterine spread other than lymph node metastasis is significantly associated with tumor recurrence. Another study found that 50% of patients with extrauterine disease developed recurrence, compared with 11% of patients without extrauterine disease, making recurrence almost five times more likely in patients with extrauterine disease spread. The 5-year disease-free survival rate for patients with nonlymphatic extrauterine disease was 50%, compared with 88% in other patients (148). Predictors of peritoneal relapse include stage IV disease or stage II or III disease with two or more of the following risk factors: cervical invasion, positive peritoneal cytology, positive lymph nodes, and nonendometrioid histology (195).

Types I and II Endometrial Carcinoma: Molecular Aberrations

Based on their etiological and pathological features, sporadic endometrial cancer is classified into two subtypes (2,134). Type I (endometrioid histology) represents the majority of lesions (approximately 80%), which are mostly low grade, estrogen receptor positive, associated with hyperestrogenism, and arise from atypical complex hyperplasia (196,197). Hyperestrogenism may be attributed to obesity with peripheral conversion of androgens to estrogens, anovulation, or exposure to excessive exogenous estrogen (134,198–202). Obesity, polycystic ovarian syndrome, tamoxifen use, and unopposed estrogen use are all associated with increased risk of endometrial cancer. Other associated findings include late onset of menopause, nulliparity, diabetes mellitus, and hypertension. The molecular basis for the progression from hyperplasia to invasive endometrial carcinoma as a result of hyperestrogenism remains unknown because the involvement of only a minority of factors is reproducible (203). In contrast, type II endometrial cancer (serous, clear cell carcinoma) appears to be unrelated to high estrogen levels and often develops in nonobese women. Type II cancers arise from its precursor, endometrial intraepithelial carcinoma (EIC) adjacent to an atrophic endometrium background in relatively older women (204). Distinct molecular changes are associated with these two subtypes. Common genetic changes in endometrioid endometrial cancer include mutations in PTEN (205–212), or β-catenin genes (213–215). In contrast, type II cancers frequently demonstrate alterations in HER2/neu, p53, p16, e-cadherin, and loss of heterozygosity (LOH) (216–218). These distinct molecular alterations underscore prognostic differences. Type I endometrial cancer is limited to the uterus in 70% of cases with a 5-year survival greater than 85%. Type II endometrial cancer displays a more aggressive clinical course and a poor prognosis; even in tumors with little or no myometrial invasion, more than one in three patients will have extensive extrauterine spread with complete surgical staging, resulting in an overall survival of 20%
Inactivation of the PTEN tumor-suppressor gene is one of the earliest aberrations observed in endometrial cancer precursors and is the most common genetic defect in type I cancers, observed in up to 83% of tumors (206). Tumors with PTEN mutations tend to be well differentiated and minimally invasive (220–222). Approximately 20% of sporadic endometrioid cancers demonstrate a molecular phenotype referred to as microsatellite instability (MSI) (223–225). Microsatellites are short segments of repetitive DNA bases scattered throughout the genome. MSI describes the accumulation of sequence changes in these DNA segments that occur because of the inactivation of intranuclear proteins that comprise the mismatch repair system (226). Inactivation of MLH1, a component of the mismatch repair system, is a common event in type I endometrial cancer. This alteration occurs through hypermethylation of CpG islands in the gene promoter, a process known as epigenetic silencing (227). This is in contrast to colon cancer, in which MSI and inactivation of the mismatch repair genes occurs through mutations in mismatch repair genes, including hMSH2, hMLH1, PMS1, PMS2, or hMSH6 (44–46). MSI and abnormal methylation of MLH1 are early events in endometrial carcinogenesis and are described in precancerous lesions (196,224). Mutations in codons 12 or 13 of the K-ras oncogene are reported in 10% to 20% of endometrial adenocarcinomas (228). The presence of mutations of K-ras appears to be an independent unfavorable prognostic factor (229,230).

Chromosomal instability with extensive genomic derangements is commonly found in type II endometrial cancers (231). The most frequent genetic alteration is TP53 mutation, present in about 90% of serous carcinomas (205,227,232,233). In contrast to endometrioid carcinoma, MSI is rare (<5%), as are K-ras and PTEN mutations (210,234,235). Other genetic alterations that occur more frequently in serous compared to endometrioid carcinomas are inactivation of p16 (45%) and overexpression and gene amplification of HER2/neu oncogene (45% and 70%, respectively) (232,236,237). HER-2/neu overexpression is related to diminished, progression-free survival (238–240). E-cadherin, an oncogene responsible for cell-to-cell adhesion that seems to play a critical role in initiation and progression of endometrial neoplasia, is absent or reduced in 62% to 87% of cases. Loss of E-cadherin is often associated with advanced stage and LOH in both serous and clear cell carcinomas (214,241,242).
Surgical Treatment

An algorithm for the management of patients with clinical stage I and II endometrial cancer is presented in Figure 35.6. The most common current protocol for surgical management of endometrial cancer includes peritoneal cytology, hysterectomy and bilateral salpingo-oophorectomy, and surgical staging. In patients with nonendometrioid cancer, omentectomy along with appendectomy and peritoneal biopsies may be performed. The need to perform lymphadenectomy is based on the type of endometrial cancer, the grade of the tumor, the tumor size and extent of myometrial invasion determined during the surgery, and the presence of extrauterine disease. Bilateral pelvic and para-aortic lymphadenectomy is performed if the patient has any of the following factors: evidence of extrauterine disease, tumor that is FIGO grade 3, nonendometrioid-type endometrial cancer, or evidence of tumor invasion more than 50% of the thickness of the myometrium. In the absence of these risk factors only bilateral pelvic lymphadenectomy is performed, if the tumor size is greater than 2 cm; para-aortic lymphadenectomy would be performed only if pelvic lymph nodes were positive (Fig. 35.7). Lymphadenectomy is omitted altogether for patients without the above risk factors, absence of cervical involvement, and tumor size less than 2 cm. The decision to administer postoperative radiation, chemotherapy, or both is predicated on the final results of pathological examination of the surgical specimen and cytology, according to previously described criteria (243).

Figure 35.6 Surgical management of patients with stage I–II endometrial carcinoma.

Figure 35.7 Radical pelvic sidewall resection. Photo taken of a patient with a left pelvic sidewall recurrence following resection of psoas muscle and bony ilium. Structures from lower to upper aspect of the photo (medial to lateral) include ureter, internal and external iliac artery, common iliac vein, lumbosacral trunk, obturator nerve (sacrificed), and femoral nerve. The cut edge of the psoas muscle is seen at left. (Provided by Sean C. Dowdy, MD, Mayo Clinic.)
Hysterectomy with bilateral salpingo-oophorectomy represents the first step in the treatment of endometrial cancer. The most debated issue in endometrial cancer management concerns the utility of lymph node dissection. This topic is extensively discussed in the “Surgical Staging” section of this chapter.

**Vaginal Hysterectomy**

Vaginal hysterectomy may be considered for selected patients who are extremely obese and have a poor medical status or for patients with extensive uterovaginal prolapse. Vaginal hysterectomy with bilateral salpingo-oophorectomy may be considered adequate treatment for patients with low risk tumors (endometrioid, grade 1 or 2, <50% myometrial invasion, and tumor diameter <2 cm; Fig. 35.7. Vaginal hysterectomy is particularly suitable for patients who are at low risk for extrauterine spread of disease (i.e., those with clinical stage I, well-differentiated tumors). In one report, a 94% survival rate was found in 56 patients with clinical stage I endometrial carcinoma treated by vaginal hysterectomy, with or without postoperative radiotherapy (mostly brachytherapy). Three-fourths of these patients had grade 1 lesions (244). Others reported similar good results (245–247). Vaginal hysterectomy is preferable to radiation therapy alone, but should be reserved for specific patients.

**Laparoscopic Management**

Advances in endoscopic technologies and power sources allowed application of a laparoscopic approach to the management of endometrial cancer. Since 1992, there were multiple reports documenting the feasibility of laparoscopically-assisted vaginal hysterectomy with bilateral salpingo-oophorectomy and laparoscopic lymphadenectomy for staging and treatment of patients with endometrial cancer (248–256). These early studies demonstrated no differences in lymph node
counts, estimated blood loss, and recurrence or survival rates with laparoscopy versus laparotomy, whereas decreased perioperative morbidity, longer operating times, shorter hospital stays, and earlier return to work were associated with laparoscopy.

Although the literature has isolated case reports of port site metastases, there are few data documenting the incidence. Martinez et al. analyzed 1,216 patients with endometrial and cervical cancer and showed that the port site metastasis rate was less than 0.5%; no port site metastases occurred after excluding patients with peritoneal disease (257).

A large prospective study by GOG randomized patients to laparoscopy versus laparotomy for the primary treatment of patients with endometrial cancer (258). Over 2,500 patients were enrolled, 1,696 to laparoscopy and 920 to laparotomy. Consistent with early reports, patients randomized to laparoscopy had shorter hospital stay (52% more than 2 days vs. 94% in the laparotomy group), less blood loss, and fewer postoperative complications (14% vs. 21%). The rate of intra-operative complications was similar, and the operative time was longer in the laparoscopy cohort. There was no difference in lymph node counts, and stage distribution was identical between groups. A follow-up quality-of-life investigation of the same cohorts revealed improved Functional Assessment of Cancer Therapy–General (FACT-G) scores, better physical functioning, better body image, less pain and its interference with quality of life, and an earlier resumption of normal activities and return to work over the 6-week recovery period in the laparoscopic group (259). Although the differences were modest and negligible by 6 months, the analysis was performed as per intention to treat. Of concern is the 24% rate of conversions in the laparoscopic cohort; only 4% were converted because of advanced disease. Furthermore, the conversion rate increased dramatically with body mass index (BMI). This is problematic recognizing that the vast majority of patients with endometrial cancer are obese. The conversion rate for patients with a BMI of 40 was 57%. This implies a limitation of the surgical technique in obese patients.

The use of extraperitoneal laparoscopic staging for para-aortic lymphadenectomy was reported in a prospective investigation of 293 patients with endometrial cancer (260). The extraperitoneal approach greatly improved exposure by circumventing handling of the small bowel and was successful in over 90% of unselected patients up to a BMI of 51. There was no difference in lymph node counts, all dissections were performed to the level of the renal veins, and significant improvements in blood loss, postoperative complications, and length of stay were noted compared to the laparotomy group. The ability to gain access to the renal veins is important, given that 60% of patients with nodal involvement above the inferior mesenteric artery have negative ipsilateral inframesenteric para-aortic nodes (140). Thus, 38% to 46% of patients with para-aortic metastases will be missed if the dissection is limited to the region below the inframesenteric artery. Although infrarenal lymphadenectomy has yet to be proven necessary, the extraperitoneal approach offers the most reliable method to consistently perform a thorough dissection.

Robotic-assisted surgery gained popularity for endometrial cancer treatment (see Chapter...
Improved instrumentation and visualization allow minimally invasive surgery to be performed by surgeons with less laparoscopic experience, and in patients, particularly obese patients, who otherwise might not be candidates for minimally invasive surgery. In one report limited to obese patients with endometrial carcinoma, the robotic approach offered reduced operating times, less blood loss, higher lymph node yields, and shorter hospital stays compared to laparoscopy (261). The extent of para-aortic dissection was not described in this report, and infrarenal para-aortic lymphadenectomy remains challenging, even with robotic assistance.

When not limited to obese patients, robotic-assisted surgery appears to offer the same benefits as laparoscopy in regards to postoperative morbidity and convalescence compared to laparotomy, but with shorter operative times (262). Although oncologic outcomes have yet to be proven in patients with endometrial cancer, robotic surgery is simply an advanced laparoscopic tool, and it can be expected to find equal outcomes. Given the great costs associated with robotic instruments and the absence of differential reimbursement, it is still undetermined which group of patients will benefit most from this approach from a clinical and financial perspective.

Radical Hysterectomy

Radical hysterectomy, with removal of the parametria and upper vagina, and bilateral pelvic lymphadenectomy, does not improve survival of patients with clinical stage I disease compared with extrafascial hysterectomy and bilateral salpingo-oophorectomy alone (263–266). Radical hysterectomy increases both intraoperative and postoperative morbidity and should not be performed for treatment of apparent early endometrial cancer. In the presence of demonstrable invasion of the cervix, a modified extrafascial hysterectomy may be performed. This may improve outcomes and decrease the risk of local recurrences, especially if postoperative local radiation is not planned in younger patients (267).

Radiation Therapy as Primary Treatment

Primary surgery followed by individualized radiation therapy is the most widely accepted treatment for early-stage endometrial cancers. However, about 5% to 15% of endometrial cancer patients have severe medical conditions that render them unsuitable for surgery (131). These patients tend to be elderly and obese with multiple chronic or acute medical illnesses, such as hypertension, cardiac disease, diabetes mellitus, and pulmonary, renal, and neurologic diseases.

Several series show that radiotherapy is effective treatment for patients with inoperable endometrial cancer (268–277) (Table 35.9). One reported on the treatment of 120 patients with clinical stage I and 17 patients with clinical stage II endometrial cancer with radiation alone, 85% of whom received only intracavitary radiation. Because of the high incidence of death caused by intercurrent illness in this group of patients, the 5- and 10-year overall survival rates were only 55% and 28%,
respectively, compared with disease-specific survival rates of 87% and 85%, respectively. There was no difference in disease-specific survival rates between patients with stage I and II disease. Intrauterine cancer recurred in 14% of patients, and extrauterine pelvic disease recurred in 3%. The authors treated 15 patients with stage III and IV disease, usually with a combination of external-beam and intracavitary radiation therapy, yielding a 5-year disease-specific survival rate of 49%. Five patients (3%) had serious late complications of radiation therapy (277).

*For all stages combined.

Although it is generally agreed that intracavitary radiation is necessary to achieve adequate local control, the indications for external-beam radiation therapy in the primary treatment of endometrial cancer are less well defined. Patients with cervical involvement and known or suspected extraterine pelvic spread undoubtedly would benefit from external-beam radiation therapy. Theoretically, external-beam radiation could sterilize microscopic nodal disease and possibly increase the radiation dose to deep myometrial or subserosal uterine disease, which may receive an insufficient dose from intracavitary radiation alone. A correlation between tumor grade and recurrence was noted in several reports. One found that the 5-year progression-free survival rate for medically inoperable patients with clinical stage I disease treated with radiotherapy alone was 94% for grade 1, 92% for grade 2, and 78% for grade 3 tumors (274). Therefore, patients with grade 3 tumors and a known propensity for deep myometrial invasion and lymph node metastasis may benefit from external-beam therapy.

The decision to treat a patient who has endometrial cancer with radiation alone must involve a careful analysis of the relative risks and benefits of surgery. Although radiation
alone can produce excellent survival and local control, it should be considered for definitive treatment only if the operative risk is estimated to exceed the 10% to 15% risk for uterine recurrence that is expected with radiation treatment alone.
Patterns of Metastatic Dissemination: Implications for Postoperative and Disease-Based Adjuvant Treatment

Endometrial cancer is commonly diagnosed early in its natural history with approximately 80% of patients presenting with stage I disease. Nevertheless, approximately one of every three women who die of endometrial cancer was considered to have early locoregional disease at primary diagnosis. The majority of treatment failures and the accompanying compromised longevity probably result from the failure to recognize sites of occult extraterine dissemination at primary diagnosis. Traditional postoperative therapy (modality-based) for high-risk endometrial cancer is external-beam radiotherapy that is frequently supplemented with vaginal brachytherapy (278). This approach improves local control but not survival in early stage disease (135,155,279).

Understanding the different pathways of metastatic dissemination of endometrial cancer and their predictive factors allows the development of an individualized model for target-based therapeutic approaches to the predicted site(s) of failure. The natural history of epithelial corpus cancer includes four potential routes of metastasis: (i) contiguous extension (mainly to the vagina), (ii) hematogenous dissemination, (iii) lymphatic embolization, and (iv) exfoliation with intraperitoneal spread. On the basis of regression analysis, independent pathologic risk factors predictive of the four routes of metastatic spread were identified:

**Contiguous extension:** histologic grade 3 and lymphovascular space invasion are proven predictors of vaginal relapse in stage I endometrial cancer (280).

**Hematogenous:** deep myometrial invasion is the strongest predictor of hematogenous recurrence (>50% for all stages and ≥66% for stage I) (176,281).

**Lymphatic:** lymphatic failure is more likely to occur when cervical stroma involvement or positive lymph nodes are present (182).

**Peritoneal:** predictors of peritoneal relapse are: (i) stage IV disease or (ii) stage II or III disease with two or more of the following risk factors: cervical invasion, peritoneal cytologic results positive for endometrial cancer, positive lymph nodes, and nonendometrioid histologic findings (195).

Patients with the risk factors summarized in Table 35.10 account for 35% of the overall population with endometrial cancer, but 89% of the observed hematogenous, lymphatic, and peritoneal relapses. Importantly, 46% of the patients considered at risk subsequently experienced a recurrence in one or more of the three sites, compared with only 2% of patients not judged to be at risk based on these criteria (p <0.001). The identification of subgroups of patients at risk for the different patterns of recurrence would allow postoperative treatment targeted to the predicted areas of tumor dissemination. The recurrence sites predicted by risk factors would presuppose different adjuvant treatment strategies. Patients at risk for hematogenous or peritoneal recurrence would potentially benefit from systemic cytotoxic treatment, while patients at risk for lymphatic or vaginal recurrence would potentially benefit from radiation treatment directed at areas at risk.

Modalities of Postoperative Treatment

Observation

Patients with grades 1 and 2 lesions without myometrial invasion or any of the above risk factors (Table 35.10) have an excellent prognosis and require no postoperative therapy. In a GOG study, there were no recurrences and a 100% disease-free 5-year survival rate in the 91 patients in this category, 72 of whom received no additional treatment after hysterectomy (132). Other investigators reported equally favorable results with only surgical therapy in similar patients (282,283).

Vaginal Vault Radiation

Vaginal brachytherapy is an attractive alternative to external radiation therapy (ERT). High-dose rate (HDR) brachytherapy is well tolerated with low rates of severe or chronic complications. Vaginal control rates with the more convenient, better-tolerated HDR brachytherapy are comparable to control rates with the lengthier low-dose rate (LDR) brachytherapy. Pearcey and Petereit established the HDR dosing of 21 Gy to 5-mm depth in three fractions as the standard brachytherapy dose, providing local control rates of 98% to 100% (284). Additional retrospective data demonstrate 98% to 100% vaginal control rates with HDR in high risk early-stage endometrial cancer (285,286). Retrospective data suggest that the vaginal relapse rate after brachytherapy averages 4% to 5% (Table 35.11) and this is similar to the 5-year vaginal failure rate of 3.5% reported among the highest-risk patients who received ERT in PORTEC-1 (135,282,285,287–291).

ERT, external radiation therapy.
*Includes 18 distant (78% of all recurrences), 3 vaginal (13%), 1 isolated pelvic sidewall (4.3%), 1 unknown site (4.3%).

PORTEC-2 randomized patients with apparent uterine-confined endometrial cancer at high risk for recurrence (>60 years of age with grade 1 or 2, stage IB and grade 3, stage IA; or any age, any grade IIA with <50% myometrial invasion), to pelvic ERT (46 Gy, in
23 fractions) versus vaginal brachytherapy (21 Gy in three HDR fractions or 30 Gy LDR, to a depth of 0.5 cm). At 3 years, there was no difference in vaginal failure rates (0.9% for vaginal brachytherapy, 2% for pelvic ERT; \( p = .97 \)). There was a higher rate of nonvaginal pelvic relapse in the brachytherapy group (3.6%) compared to the ERT group (0.7%; \( p = .03 \)), however, the absolute difference was small and there was no difference in overall survival (292). The difference between nonvaginal pelvic recurrences may be a reflection of unrecognized lymph node metastases at the time of initial surgery treated with ERT.

One concern regarding PORTEC-2 is that there was not a surgery-only control in the study. However, the highest risk endometrial cancer subgroup in PORTEC-1 (patients >60 years of age with grade 3 or deeply invasive grade 1 or 2, all stage I) was similar to the cohort included in PORTEC-2 and the locoregional recurrence rate in patients who did not receive adjuvant ERT in PORTEC-1 was 18% (135).

**Grade 3 histology and lymphovascular space invasion are proven predictors of vaginal relapse in stage I endometrial cancer.** Patients with these risk factors are the most likely group to benefit from vaginal vault brachytherapy (280).

Although vaginal recurrences can be successfully treated and controlled in up to 81% of cases, the addition of vaginal brachytherapy to the initial surgical intervention can significantly reduce the risk of such recurrences (293).

### External Pelvic Radiation

Radiation therapy traditionally was suggested to patients who were deemed to have intermediate or high risk of recurrence, according to grade and depth of myometrial invasion. Several retrospective studies and large, randomized trials did not show an overall survival benefit for intermediate- and high-risk patients with stage I endometrial cancer (or occult IIA endometrial cancer according to the 1988 FIGO staging) who received adjuvant pelvic radiotherapy.

The PORTEC trial tested the role of postoperative pelvic radiation therapy for presumed stage I endometrial cancer in 714 patients. Eligibility criteria were stage IB, grades 1 to 2, and stage IA, grades 2 to 3; patients with stage IA, grade 3, were only 10% of the study population, and lymph node biopsies and peritoneal cytology were not required. Local-regional recurrences developed in 14% of the surgery group, compared with 4% of the postoperative pelvic radiation group. Overall, the 5-year survival rate was no different between the two groups (85% vs. 81%, respectively) (135). These results were confirmed by GOG99, a prospective, randomized investigation of surgery alone (including lymphadenectomy to the level of the inferior mesentry artery in some patients) versus surgery plus adjuvant pelvic radiation in intermediate-risk endometrial cancer (stages IA to IIb occult). Of 392 patients accrued to the study, more than 80% were actually low-risk patients (90.6% stage I, 81.6% grades 1 to 2, 82% <50% myometrial invasion). Disease recurrence was reduced by 58% (\( p = 0.007 \)) with the use of postoperative pelvic radiation. After 2 years, the cumulative recurrence rate was 12% in the group with no postoperative treatment compared with 3% in the group that received pelvic radiation. The pelvic failure rate was 8.9% in the surgery-alone group compared with 1.6% in the...
Overall survival rates were not significantly improved in patients receiving postoperative pelvic radiation compared with those treated only with surgery (92% vs. 86%, respectively) (279). Recently, the intergroup ASTEC/EN.5 trial provided further confirmation that external-beam radiation therapy in patients at intermediate to high risk of recurrence has no significant effect on overall survival (294).

Postoperative whole-pelvis external-beam radiation usually involves the delivery of 4,500 to 5,040 cGy in 180 cGy daily fractions over 5 to 6 weeks to a field encompassing the upper one-half of the vagina inferiorly, the lower border of the L4 vertebral body superiorly, and 1 cm lateral to the margins of the bony pelvis. The dose of radiation at the surface of the vaginal apex usually is boosted to 6,000 to 7,000 cGy by a variety of techniques. The most frequently reported side effects are gastrointestinal, usually abdominal cramps and diarrhea, although more serious complications such as bleeding, proctitis, bowel obstruction, and fistula can occur and may require surgical correction. The urinary system may be affected in the form of hematuria, cystitis, or fistula. The overall complication rate ranges from 25% to 40%; and the rate of serious complications requiring surgical intervention is about 1.5% to 3%.

External-beam pelvic radiation does not appear to impact survival in patients with high-risk stage I endometrial cancer. Patients with extrauterine pelvic disease, including adnexal spread, parametrial involvement, and pelvic lymph node metastases, in the absence of extrapelvic disease, are likely to benefit from postoperative pelvic radiation.

Extended-Field Radiation

Patients with histologically proven para-aortic node metastases and no other evidence of disease spread outside the pelvis should be treated with extended-field radiation. The entire pelvis, common iliac lymph nodes, and para-aortic lymph nodes are included within the radiation field. The para-aortic radiation dose is limited to 4,500 to 5,000 cGy. Extended-field radiotherapy appears to improve survival in patients with endometrial cancer who have positive para-aortic lymph nodes (132,295–298). Five-year survival rates of 47% and 43% were reported for patients with surgically confirmed isolated para-aortic lymph node metastases and for those with para-aortic and pelvic lymph node metastases, respectively, using postoperative extended-field radiation. In one report, only one case of severe enteric morbidity occurred in 48 patients, a complication rate of 2% (295). In a GOG study, 37 of 48 patients with positive para-aortic nodes received postoperative para-aortic radiation, 36% of whom remained tumor free at 5 years (132). A comparison of patients with positive para-aortic nodes treated with megestrol acetate alone versus megestrol acetate and extended-field radiation showed that the survival rate in the patients receiving extended-field radiation was significantly better: 53% versus 12.5%, respectively (296). In another study of 18 patients with positive para-aortic nodes, 5-year
survival rates were 67% for microscopic nodal disease and 17% for gross nodal disease (297).

**Whole-Abdomen Radiation**

Whole-abdomen radiation therapy is usually reserved for patients with stages III and IV endometrial cancer. It may be considered for patients who have serous or carcinosarcomas, which have a propensity for upper-abdominal recurrence (299–304). The recommended dose to the whole abdomen is 3,000 cGy in 20 daily fractions of 150 cGy, with kidney shielding at 1,500 to 2,000 cGy, along with an additional 1,500 cGy to the para-aortic lymph nodes and 2,000 cGy to the pelvis. Gastrointestinal side effects, including nausea, vomiting, and diarrhea, sometimes make it necessary to interrupt therapy, but it is rare for patients to discontinue treatment because of these symptoms. Hematologic toxicity can be expected to occur during whole-abdomen radiation, but it is usually mild. The incidence of late complications, mainly chronic diarrhea and small bowel obstruction, is low (5% to 10%).

In a series of 27 patients treated with surgical stage III endometrial cancer with whole-abdomen radiation, patients with spread to the adnexa, positive peritoneal cytology, or both had a 5-year, relapse-free survival of 90%, whereas all patients with macroscopic disease beyond the adnexa had recurrence (298). Similar results were reported by others (300,301). Some advocated the use of adjuvant whole-abdomen radiotherapy for patients with high-risk stages I and II endometrial carcinoma, including those with deep myometrial invasion, high-grade tumors, and serous histology, because of the high proportion of recurrences in the upper abdomen. A 5-year recurrence-free survival rate of 85% was reported (302,303). With whole-abdomen radiation in patients at increased risk for intra-abdominal metastatic disease, such as those with nonnodal extrauterine disease and serous histology, an actuarial 5-year relapse-free survival rate of 70% was reported, with no significant toxicity (304). Similarly, others noted a 3-year disease-free survival rate of 79% in patients with stages III and IV endometrial adenocarcinoma treated with whole-abdomen radiation (305). Other reports of using adjuvant postoperative whole-abdomen radiation in early-stage uterine serous carcinoma suggest a reduction in recurrence rates (304–306). Most recurrences are in the upper abdomen in all of these patients, despite use of this type of radiotherapy. After the publication of GOG122, demonstrating the superiority of chemotherapy over whole-abdominal radiotherapy in advanced endometrial cancer, the utilization of whole-abdominal radiotherapy is not common (see section on “Chemotherapy”) (307).

**Progestins**

Because most endometrial cancers have both estrogen and progesterone receptors and progestins were used successfully to treat metastatic endometrial cancer, postoperative adjuvant progestin therapy attempted to reduce the risk of recurrence. This therapy is attractive because it provides systemic treatment and has few side effects. Unfortunately, several large randomized, placebo-controlled studies failed to identify a
benefit for adjuvant progestin therapy (308–313).

Chemotherapy

Adjuvant cytotoxic chemotherapy was studied in a few trials. The GOG treated 181 patients who had poor prognostic factors with postoperative radiation and then randomly assigned patients to receive no further therapy or doxorubicin chemotherapy. After 5 years of observation, there was no difference in recurrence rates between the two groups (314).

In cases of advanced disease, chemotherapy is now standard treatment. The GOG122 trial compared whole-abdominal radiotherapy versus systemic chemotherapy (eightcycles of doxorubicin and cisplatin) in 388 patients with stage III or IV disease who underwent maximal surgical resection of disease to less than 2 cm. Its results showed a significant advantage of chemotherapy on 5-year survival (307). Patients who received chemotherapy had a 13% improvement in 2-year progression-free survival (50% vs. 46%) and an 11% improvement in overall 2-year survival (70% vs. 59%) compared with patients treated with whole-abdomen radiation. Although this study was the first to suggest an improvement in outcome for use of adjuvant chemotherapy compared with radiation, toxicity was more prevalent with chemotherapy; patients with gross residual disease were assigned to the radiation arm, almost guaranteeing failure; and overall, 55% of patients experienced a recurrence or progression during the study period (315).

GOG184 randomized 552 patients with advanced disease to sixcycles of cisplatin and doxorubicin with or without paclitaxel following surgical debulking and radiotherapy. Side effects were more pronounced with the three-drug regimen, and recurrence-free survival at 36 months was no different between arms (62% vs. 64% for the three-drug regimen). The investigation was closed to patients with stage IV disease during the trial, but subgroup analysis suggested a 50% reduction in recurrence or death in the 57 patients with gross residual disease who received cisplatin, doxorubicin, and paclitaxel (111).

Other GOG studies and the PORTEC-3 trial are investigating the combination of chemotherapy and radiotherapy in advanced or high-risk endometrial cancer. Results of these trials await maturation. GOG258 is comparing chemoradiation followed by chemotherapy versus chemotherapy alone in advanced endometrial cancer. PORTEC-3 is investigating overall survival and failure-free survival of patients with high-risk and advanced stage endometrial carcinoma treated after surgery with chemoradiation followed by chemotherapy versus pelvic radiation alone.

Regarding the use of chemotherapy in high-risk populations with early stage endometrial cancer, the European Organisation for Research and Treatment of Cancer, along with the Nordic Society of Gynecologic Oncology, presented the results of a collaborative trial comparing external radiotherapy versus chemoradiotherapy in patients with stages I or II or IIIC1 (positive pelvic nodes only) and one of the following characteristics: grade 3 or myometrial invasion greater than 50%, DNA aneuploidy, or clearcell or serous histologic type. Performance of a systematic lymphadenectomy was optional. A total of 375 patients
were enrolled over a 10-year period and the study was closed early because of slow recruitment. The hazard ratio for progression-free survival was 0.58 (95% CI, 0.34–0.99) in favor of chemoradiation after a median follow-up of 3.5 years (316).

The Japanese GOG randomized patients to pelvic radiotherapy versus platinum-based chemotherapy in patients with stage IB to IIIC endometrial cancer and myometrial invasion greater than 50%. Assessment of para-aortic nodal status was performed in only 29% of cases. The investigators found no differences between the two experimental arms in terms of progression-free survival and overall survival. A subgroup analysis of 120 patients with either (i) stage IB tumor and age greater than 70 years or grade 3 endometrioid adenocarcinoma or (ii) stage II or IIIA tumor (positive cytologic findings) showed that chemotherapy was associated with significantly improved disease-free and overall survival rates (317). The benefits achieved with combined chemoradiation, identification of the best chemotherapeutic regimen, and the identification of subgroups of patients who may benefit from these treatments deserves further investigation.

Clinical Stage II

Endometrial cancer involving the cervix either contiguously or by lymphatic spread has a poorer prognosis than disease confined to the corpus (267,278,318–334). Preoperative assessment of cervical involvement is difficult. Endocervical curettage has relatively high false-positive (50% to 80%) and false-negative rates. Histologic proof of cancer infiltration of the cervix or presence of obvious tumor on the cervix is the only reliable means of diagnosing cervical involvement, although ultrasonography, hysteroscopy, or MRI may show cervical invasion.

The relatively small number of true stage II cases in reported series and the lack of randomized, prospective studies preclude formulation of a definitive treatment plan. Three areas must be addressed in any treatment plan:

For optimal results, the uterus should be removed in all patients. Because the incidence of pelvic lymph node metastases is about 36% in stage II endometrial cancer, any treatment protocol should include treatment of these lymph nodes.

Because the incidence of disease spread outside the pelvis to the para-aortic lymph nodes, adnexal structures, and upper abdomen is higher than in stage I disease, attention should be directed to evaluating and treating extrapelvic disease.

Two approaches usually were used in the treatment of clinical stage II disease:

Radical hysterectomy, bilateral salpingo-oophorectomy, and pelvic and para-aortic lymphadenectomy

Combined radiation and surgery (external pelvic radiation and intracavitary radium or cesium followed in 6 weeks by total abdominal hysterectomy and
An initial radical surgical approach to treatment of clinical stage II endometrial cancer has the advantage of collecting accurate surgical–pathologic information. Conversely, many patients with endometrial cancer are elderly and obese and have medical problems that make this approach unsuitable. Reported results are no better than those with combined radiation and less radical surgical therapy (267). The use of radical hysterectomy may be limited to patients with anatomic problems that prevent optimum dosimetry or other conditions that conflict with the use of radiation therapy.

The most common, traditional approach to the management of clinical stage II endometrial cancer is to use external and intracavitary radiation followed by extrafascial hysterectomy. This combined approach resulted in 5-year survival rates of 60% to 80%, with severe gastrointestinal or urologic complications occurring in about 10% of patients (319–327). Patients who have medically inoperable disease are usually treated with external-beam radiation and one or two intracavitary insertions. Compared with combined radiation and surgery, the results with radiation alone are diminished, but about 50% of patients are long-term survivors (279) (Table 35.9).

Another method of management of clinical stage II endometrial cancer that is gaining favor is an initial surgical approach followed by radiation. This method is based on the difficulty in establishing the preoperative diagnosis of cervical involvement in the absence of a gross cervical tumor, the evidence that radiation is equally effective when given after hysterectomy, and the high incidence of extrapelvic disease when the cervix is involved. Exploratory laparotomy with an extrafascial or modified radical hysterectomy, bilateral salpingo-oophorectomy, peritoneal washings for cytology, and resection of grossly enlarged lymph nodes are performed. These procedures are followed by appropriate pelvic or extended-field external and intravaginal radiation, depending on the results of surgical staging. Excellent results were reported using this treatment scheme (329–331).

Clinical Stages III and IV

Clinical stage III disease accounts for about 7% to 10% of all endometrial carcinomas (335–340). Patients usually have clinical evidence of disease spread to the parametria, pelvic sidewall, or adnexal structures; less frequently, there is spread to the vagina or pelvic peritoneum. Treatment for stage III endometrial carcinoma must be individualized, but initial operative evaluation and treatment should be considered because of the high risk for occult lymph node metastases and intraperitoneal spread when disease is known to extend outside of the uterus into the pelvis. In the presence of an adnexal mass, the initial impetus for surgery is to determine the nature of the mass. Surgery is performed to determine the extent of disease and to remove the bulk of the disease if possible. This procedure should include peritoneal washings for cytologic examination, para-aortic and pelvic lymphadenectomy,
biopsy or excision of any suspicious areas within the peritoneal cavity, and omentectomy and peritoneal biopsies. Except in patients with bulky parametrial disease, total abdominal hysterectomy and bilateral salpingo-oophorectomy should be performed. **The goal of surgery is eradication of all macroscopic disease because this finding is of major prognostic importance in the management of patients with clinical stage III disease.** Postoperative therapy can be tailored to the extent of disease.

Results of therapy depend on the extent and nature of disease. A 5-year survival rate of 54% was reported for all patients with stage III disease; however, the survival was 80% when only adnexal metastases were present, compared with 15% when other extraperitoneal pelvic structures were involved (335). Patients with surgical–pathologic stage III disease have a much better survival rate (40%) than those with clinical stage III disease (16%) (326). Patients who are treated with combined surgery and radiation fare better than patients who receive radiation therapy alone (340).

Stage IV endometrial adenocarcinoma, in which tumor invades the bladder or rectum or extends outside the pelvis, makes up about 3% of cases (340–344). **Treatment of stage IV disease is patient dependent but usually involves a combination of surgery, radiation therapy, and systemic hormonal therapy or chemotherapy.** One objective of surgery and radiation therapy is to achieve local disease control in the pelvis to provide palliative relief of bleeding, discharge, and complications involving the bladder and rectum. In one report, control of pelvic disease was achieved in 28% of 72 patients with stage IV disease treated with radiation alone or in combination with surgery, progestins, or both (342). Several reports noted a positive impact of cytoreductive surgery on survival, the median survival being about threetimes greater with optimal cytoreduction (18 to 34 months vs. 8 to 11 months, respectively) (342–344). Pelvic exenteration may be considered in the very rare patient in whom disease is limited to the bladder, rectum, or both (345,346).
Recurrent Disease

About one-fourth of patients treated for early endometrial cancer develop recurrent disease. More than one-half of the recurrences develop within 2 years, and about three-fourths occurs within 3 years of initial treatment. The distribution of recurrences is dependent in large part on the type of primary therapy: surgery alone versus surgery plus local or regional radiotherapy. In a GOG study of 390 patients with surgical stage I disease, vaginal and pelvic recurrences were noted to comprise 53% of all recurrences in the group treated with surgery alone, whereas only 30% of recurrences were vaginal or pelvic in the group treated with combined surgery and radiotherapy (132). Therefore, after combined surgery and radiotherapy (vaginal or external beam), 70% or more of patients with treatment failures have distant metastases, and most of these patients do not have evidence of local or pelvic recurrence. The most common sites of extrapelvic metastases are the lung, abdomen, lymph nodes (aortic, supraclavicular, inguinal), liver, brain, and bone. Patients with isolated vaginal recurrences fare better than those with pelvic recurrences, who in turn have a better chance of cure than those with distant metastases. Patients who initially have well-differentiated tumors or who develop recurrent cancer more than 3 years after the primary therapy also tend to have an improved prognosis.

In a 1984 report on 379 patients with recurrent endometrial cancer seen at the Norwegian Radium Hospital from 1960 to 1976, site of recurrence was local or regional in 190 patients (50%), distant in 108 patients (28%), and local and distant in 81 patients (21%) (347). The median time of recurrence was 14 months for patients with local recurrences and 19 months for patients with distant metastases. Of all recurrences, 34% were detected within 1 year, and 76% were detected within 3 years of primary treatment. At the time of diagnosis of recurrence, 32% of patients had no symptoms. Vaginal bleeding was the most common symptom associated with local recurrence, and pelvic pain was most often present with pelvic recurrence. Hemoptysis was the initial symptom in 32% of patients with lung metastases, but 45% of cases of lung metastases were asymptomatic and picked up on routine chest x-ray. Only 9% of patients with metastases at other sites did not have symptoms; most had pain (37%) or other symptoms such as anorexia, nausea and vomiting, or ascites related to intra-abdominal carcinomatosis, neurologic symptoms such as seizures from brain metastases, or jaundice caused by liver metastases. Overall, only 29 (7.7%) of the 379 patients were alive without evidence of disease from 3 to 19 years. This included 22 patients (12%) with local or pelvic recurrence, 5 patients (5%) with distant metastases, and 2 patients (2%) with both local and distant recurrences. The best results were obtained in the 42 patients with vaginal vault recurrences who were treated with radiotherapy, resulting in a 24% survival rate. None of the 78 patients with pelvic soft tissue recurrence survived. Three patients (7%) with only lung metastases treated with progestins, two patients with lymph node metastases treated with combined radiotherapy and progestins, and two patients with local recurrence and lung metastases treated with radiotherapy, surgery, and progestins survived.
Surgery

A small subset of patients with isolated recurrent endometrial cancer may benefit from surgical intervention. A search for distant recurrences prior to treatment is obligatory as such patients are best treated with chemotherapy. In one small series, upper-abdominal disease was found at laparotomy in three (37.5%) of eight patients with presumed localized pelvic recurrence. Presence of subclinical extrapelvic metastases was associated with larger pelvic tumor size (>2 cm) and elevated serum CA125 levels \( (348) \). As discussed in the next section, isolated vaginal recurrence in patients who have not received prior pelvic radiation is best treated with external radiation plus some type of brachytherapy.

Treatment of patients with pelvic recurrence (generally located on the pelvic sidewall secondary to lymphatic failure) is more complex. Although the study by Aalders et al. reviewed above showed no survivors in patients with pelvic recurrences, there is evidence that a multimodality approach consisting of radiotherapy followed by radical surgical resection and intraoperative radiotherapy (IORT) will cure some patients \( (347) \). A retrospective investigation at Mayo Clinic of 25 heavily pretreated patients with recurrent endometrial cancer demonstrated a survival of 71% in patients with complete surgical resection \( (349) \). Over 50% of these patients underwent radiation as primary therapy and one-half of those treated with radiation also received chemotherapy or an attempt at surgical resection at the time of recurrence. Radical procedures performed at the time of IORT included resection of the pelvic sidewall en bloc with the obturator nerve, external iliac vein, psoas, iliacus, or obturator internus muscles, ureter, or boney ileum \( (Fig. 35.7) \). Seven patients required exenteration in combination with resection of the pelvic sidewall. Two patients with isolated para-aortic recurrences were alive and disease-free at 54 and 71 months. Although survival in this cohort was impressive, the complication rate was similarly impressive at 64%. The most common complication was neuropathy; other complications included functional ureteral obstruction and four patients developed fistulas. Until more active agents are developed, radical multimodality treatment remains the only viable alternative for patients with pelvic recurrences. Memorial Sloan-Kettering Cancer Center reported on 36 patients with isolated central pelvic recurrence who underwent pelvic exenteration for recurrent endometrial carcinoma. Seventy-five percent died of their cancer within 1 year of operation, and 14% were alive after 5 years \( (349) \).

Radiation Therapy

Radiotherapy is the best treatment option for patients with isolated local or regional recurrences who are unable or unwilling to undergo radical pelvic resection \( (350–356) \). The best local control and subsequent cure are usually achieved by a combination of ERT followed by a brachytherapy boost to deliver a total tumor dose of at least 6,000 cGy. Women with low-volume disease limited to the pelvis have the best outcome. For patients with isolated vaginal recurrence treated with radiation, reported 5-year survival rates range from 24% to 45%. The reclamation rate was 81% in one multi-institutional series that was limited to stage I patients with isolated vaginal failures \( (357) \). Conversely,
for those patients who undergo radiation for the pelvic extension of their disease, lower survival rates (0% to 26%) are reported. Factors associated with improved survival and control of pelvic disease in patients with locally recurrent endometrial cancer include initial endometrial cancer grade 1, younger age at recurrence, recurrent tumor size 2 cm or less, time from initial treatment to recurrence of more than 1 year, vaginal versus pelvic disease, and use of vaginal brachytherapy.

Hormonal Therapy

The use of progestational agents for treatment of metastatic endometrial cancer was first described in 1961 when researchers observed an objective response rate of 29% in 21 patients (358). In a report from 1974, a beneficial response was observed in 35% of 308 patients (359). Subsequent reports noted somewhat less optimistic response rates, probably as a result of more strictly applied criteria for objective responses (359–362) (Table 35.12). Reports from Roswell Park Cancer Center and the Mayo Clinic observed objective response rates of 16% and 11%, respectively, with an additional 15% to 40% of patients exhibiting stable disease for at least 3 months (358,363). In 1986, the GOG reported on the use of oral medroxyprogesterone acetate for treatment of patients with advanced or recurrent endometrial cancer (361). Of 219 patients with measurable disease, 8% had a complete response, 6% had a partial response, 52% had stable disease, and 34% developed progressive disease within 1 month. The mean survival time for the entire group was 10.4 months. In a follow-up study comparing two different doses of oral medroxyprogesterone acetate, similar response rates were achieved (26% for 200 mg per day and 18% for 1,000 mg per day) (362). The type, dosage, and route of administration of the progestin seemed to have no effect on response in these studies.

The response of metastatic endometrial carcinoma to progestin therapy is related to several clinical and pathologic factors. Higher response rates are observed in well-differentiated tumors. A 20.5% response in low-grade tumors and only 1.4% response in high-grade tumors are noted (360). Likewise, the probability of an objective response to progestin therapy is about 70% for tumors that are estrogen- and progesterone-
receptor positive, compared with about 5% to 15% for tumors that are negative for both receptors. A longer disease-free interval is associated with higher response rates to progestins. The response rate to progestins ranged from 6% in patients with an interval from primary treatment to recurrence of less than 6 months to 65% in patients in whom disease recurred more than 5 years after initial treatment (359). Other observed but less well-documented factors that may have an adverse effect on response to progestins are disease recurrence within a prior radiation field, large tumor burden, and advanced primary versus recurrent disease (360, 363).

A phase II investigation of the aromatase inhibitor anastrozole showed minimal activity in an unselected subset of patients with advanced or recurrent endometrial cancer (364).

Tamoxifen, a nonsteroidal antiestrogen with some estrogenic properties, was evaluated for treatment of metastatic endometrial carcinoma based on experience in using this agent in breast cancer treatment. Its use as either a single agent or in combination with a progestin is related to its ability to inhibit the binding of estradiol to the estrogen receptor and to increase progesterone-receptor expression. In a review of eight studies using tamoxifen, 20 to 40 mg per day, in patients with metastatic endometrial carcinoma, the overall response rate was 22%, with a range of 0% to 53% (365). Responses to tamoxifen were more likely to be observed in patients with low-grade, hormone receptor–positive tumors who had a prior response to progestin therapy. In an attempt to reverse the hormone receptor down-regulation seen with progestin therapy, tamoxifen was given along with progestins, but the overall responses to combined tamoxifen and progestin therapy were similar to those noted for single-agent progestin therapy.

Progestins are recommended as initial treatment for all patients with recurrent endometrioid tumors with hormone receptor–positive tumors. Radiation therapy, surgery, or both should be used whenever feasible for treatment of localized recurrent cancer such as vaginal, pelvic, bone, and peripheral lymph node disease; however, these patients should also be given long-term progestin therapy unless they are known to have a progesterone-receptor–negative tumor. Patients with nonlocalized recurrent tumors, especially if progesterone receptors are known to be positive, are candidates for progestin therapy, either megestrol acetate, 80 mg twice daily, or medroxyprogesterone acetate, 50 to 100 mg three times daily. Progestin therapy should be continued for at least 2 to 3 months before assessing response. If a response is obtained, the progestin should be continued for as long as the disease is static or in remission. In the presence of a relative contraindication to high-dose progestin therapy (e.g., prior or current thromboembolic disease, severe heart disease, or inability of the patient to tolerate progestin therapy), tamoxifen, 20 mg twice daily, is recommended. Failure to respond to hormonal therapy is an indication for initiating chemotherapy.

Chemotherapy
Several chemotherapeutic agents or combinations of agents are capable of inducing objective responses and even remissions in patients with metastatic endometrial carcinoma, but all cytotoxic therapy should be considered palliative because response and survival times are short (365–368). The most active chemotherapeutic agents are doxorubicin, the platinum compounds cisplatin and carboplatin, and paclitaxel (Taxol). Doxorubicin, 50 to 60 mg/m² every 3 weeks (366–368); cisplatin, 60 to 75 mg/m² every 3 weeks; and carboplatin, 350 to 400 mg/m² every 4 weeks are associated with response rates of 21% to 29%. Paclitaxel, 250 mg/m² as a 24-hour infusion with granulocyte colony-stimulating factor support, or 175 mg/m² as a 3-hour infusion every 3 weeks, produced response rates of about 36% (369–371). Alkylating agents such as cyclophosphamide and melphalan, 5-fluorouracil, altretamine (hexamethylmelamine), liposomal doxorubicin, and topotecan show activity against endometrial cancer (371–374). Most responses obtained with use of these agents were partial, averaging only 3 to 6 months, with the median survival time ranging from 4 to 8 months.

**Combination chemotherapy regimens employing doxorubicin and cisplatin; cyclophosphamide, doxorubicin, and cisplatin; paclitaxel and cisplatin with or without doxorubicin; and carboplatin and paclitaxel resulted in response rates ranging from 38% to 76% (375–390).** Despite these fairly impressive response rates, most responses are partial, with durations of 4 to 8 months, and the median survival time is less than 12 months.

Response to chemotherapy in patients with metastatic endometrial cancer does not appear to be affected by prior or concurrent progestin therapy. Metastatic site, age, disease-free interval, histology, and tumor grade appear to have no effect on chemotherapy response. Patients with long disease-free intervals and better performance status may live longer.
Treatment Results

Comprehensive survival data for endometrial cancer are provided by the FIGO (391). Survival in relation to the old clinical and surgical stage is shown in Table 35.13 and in relation to surgical stage and grade in Table 35.14. The overall 5-year survival rate was 76%. Patients who underwent surgical staging had much better 5-year survival rates than those staged clinically across all stages (respectively): stage I, 87% versus 54%; stage II, 76% versus 41%; stage III, 57% versus 23%; stage IV, 18% versus 12%. Survival in surgical stage I disease ranged from more than 90% for patients with grade 1 and 2 tumors without myometrial invasion to 63% for stage IB grade 3.

Follow-Up after Treatment

History and physical examination remain the most effective methods of follow-up in patients treated for endometrial cancer (392–394). Patients should be examined every 3 to 4 months during the first 2 years and every 6 months thereafter. About one-half of patients discovered to have recurrent cancer have symptoms, and 75% to 80% of recurrences are detected initially on physical examination. Particular attention should be given to peripheral lymph nodes, the abdomen, and the pelvis. Very few asymptomatic recurrences are detected by vaginal cytology.

Chest x-ray every 12 months is an important method of posttreatment surveillance. Almost one-half of all asymptomatic recurrences are detected by chest x-ray. Other radiologic studies, such as CT scans, are not indicated for routine follow-up of patients who do not have symptoms.

Serum CA125 measurement was suggested for posttreatment surveillance of endometrial cancer (392–394). Elevated CA125 levels were documented in patients with recurrent tumor, and these levels correlated with the clinical course of disease. However, CA125 levels may be normal in the presence of small recurrences, making the utility of CA125 measurements for follow-up of patients after treatment of early-stage disease suspect. Determinations of CA125 should be obtained in patients with elevated levels at the time of diagnosis or with known extrauterine disease.
Ovarian Preservation and Estrogen Replacement

Twenty-five percent of women with endometrial cancer are premenopausal and 5% are under the age of 40, indicating that interest in ovarian preservation or postoperative estrogen replacement is not uncommon (395). Isolated investigations suggest that premenopausal women have a much higher likelihood (23%) of a synchronous ovarian cancer (396). If both ovaries appear grossly normal, the risk of adnexal malignancy decreases to less than 1% (397). Careful inspection of the adnexa is imperative when ovarian preservation is considered (23,396–398).

Most endometrial cancers are associated with excess estrogen exposure, calling into question the appropriateness of estrogen therapy for premenopausal patients with endometrial cancer following hysterectomy and bilateral salpingo-oophorectomy. In 1986, Creasman et al. and others reported that estrogen therapy appeared safe with no documented increase in the risk of recurrence following surgical treatment for endometrial carcinoma (397,399,400). Some investigations reported higher intercurrent death rates, such as from myocardial infarction, in the group in which estrogen was withheld (397,401). A randomized, double-blind, placebo-controlled study was designed to determine whether estrogen replacement increased rates of disease recurrence in women with stage I or II endometrial cancer. This investigation closed early because of a fall off in accrual after the findings of the Women’s Health Initiative were made public in 2002. At the time of closure, the enrollment of over 1,200 patients in the study was insufficient, given the exceptionally low recurrence rate is this low-risk group (399).

Although the safety of estrogen therapy in patients with endometrial cancer was not verified with level 1 evidence, this investigation provided sufficient reassurance to justify the practice of offering estrogen therapy to patients with low-grade, FIGO 2009 stage IA disease in the absence of other contraindications. The American College of Obstetricians and Gynecologists issued a committee opinion recommending that providers should take into consideration prognostic indicators such as depth of invasion, grade, and stage when deciding to administer estrogen therapy to these patients (402).

For women who decline systemic estrogen replacement, symptoms of vaginal dryness and dyspareunia may be judiciously treated with topical estrogen alone. Symptomatic relief of hot flashes can be achieved by prescribing progestins such as medroxyprogesterone acetate, 10 mg orally daily or 150 mg intramuscularly every 3 months, or nonhormonal agents such as Bellergal, clonidine, and venlafaxine.
Uterine Sarcoma

Uterine sarcomas are relatively rare tumors of mesodermal origin. They constitute 2% to 6% of uterine malignancies (403–405). There is an increased incidence of uterine sarcomas after radiation therapy to the pelvis for either carcinoma of the cervix or a benign condition. The relative risk of uterine sarcoma after pelvic radiotherapy is estimated to be 5.38, with an interval of 10 to 20 years (405). Uterine sarcomas are, in general, the most malignant group of uterine tumors and differ from endometrial cancers with regard to diagnosis, clinical behavior, pattern of spread, and management.
The three most common histologic variants of uterine sarcoma are endometrial stromal sarcoma (ESS), leiomyosarcoma, and carcinosarcoma (malignant mixed müllerian tumor, or MMMT) of both homologous and heterologous type (Table 35.15). Variations in the relative incidences of uterine sarcomas occur in published series, probably related to the strictness of criteria used to classify smooth muscle and endometrial stromal tumors as sarcomas. Leiomyosarcoma and carcinosarcoma each constitute approximately 40% of tumors, with carcinosarcoma predominating in more recent reports, followed by ESS (15%) and other sarcomas (5%).

Stage IV

IVA Tumor invades bladder and/or rectum
IVB Distant metastasis
Carcinosarcomas should be staged as carcinomas of the endometrium.

**FIGO Committee on Gynecologic Oncology.** FIGO staging for uterine sarcomas. Int J Gynecol Obstet 2009;104:179.

*Note: Simultaneous tumors of the uterine corpus and ovary/pelvis in association with ovarian/pelvic endometriosis should be classified as independent primary tumors.

**Endometrial Stromal Tumors**

Stromal tumors occur primarily in perimenopausal women between ages 45 and 50 years; about one-third occurs in postmenopausal women. There is no relationship to parity, associated diseases, or prior pelvic radiotherapy. These tumors are rare in African-American women. The most frequent symptom is abnormal uterine bleeding; abdominal pain and pressure caused by an enlarging pelvic mass occur less often, and some patients do not have symptoms. Pelvic examination usually reveals regular or irregular uterine enlargement, sometimes associated with rubbery parametrial induration. The diagnosis may be determined by endometrial biopsy, but the usual preoperative diagnosis is uterine leiomyoma. At surgery, the diagnosis is suggested by the presence of an enlarged uterus filled with soft, gray-white to yellow necrotic and hemorrhagic tumors with bulging surfaces associated with wormlike elastic extensions into the pelvic veins.

Endometrial stromal tumors are composed purely of cells resembling normal endometrial stroma. They are divided into three types on the basis of mitotic activity, vascular invasion, and observed differences in prognosis: (i) endometrial stromal nodule, (ii) endometrial stromal sarcoma, and (iii) high-grade or undifferentiated sarcoma.

**Endometrial stromal nodule** is an expansive, noninfiltrating, solitary lesion confined to the uterus with pushing margins, no lymphatic or vascular invasion, and usually less than 5 mitotic figures per 10 high-power microscopic fields (5 MF/10 HPF). These tumors should be considered benign because there are no recurrences or tumor-associated deaths reported after surgery (406,407).

**Endometrial stromal sarcoma** (formerly termed low-grade ESS or endolympathic stromal myosis) is distinguished from high-grade ESS or undifferentiated endometrial sarcoma microscopically by a mitotic rate of less than 10 MF/10 HPF and a more protracted clinical course. Recurrences typically occur late, and local recurrence is more common than distant metastases (408--412). Although endometrial stromal sarcoma often behaves in a histologically aggressive fashion, it lacks the aneuploid DNA content and high proliferative index associated with high-grade stromal sarcoma. Flow cytometric analysis can be used to differentiate the two conditions and predict response to therapy.

Endometrial stromal sarcoma extends beyond the uterus in 40% of cases at the time of diagnosis, but the extraterine spread is confined to the pelvis in two-thirds of the cases.
Upper-abdominal, pulmonary, and lymph node metastases are uncommon. Recurrence occurs in almost one-half of cases at an average interval of 5 years after initial therapy. Prolonged survival and cure are common even after the development of recurrent or metastatic disease.

**Optimum initial therapy for patients with endometrial stromal sarcoma consists of surgical excision of all grossly detectable tumor.** Total abdominal hysterectomy and bilateral salpingo-oophorectomy should be performed. The adnexa should always be removed because of the propensity for tumor extension into the parametria, broad ligaments, and adnexal structures, and the possible estrogen-stimulating effect on the tumor cells if ovaries are retained. A beneficial effect of radiation therapy is reported, and pelvic radiation is recommended for inadequately excised or locally recurrent pelvic disease (408). There is evidence that endometrial stromal sarcoma is hormone dependent or responsive. Objective responses to progestin therapy were reported in 48% of patients in one series (410). Recurrent or metastatic lesions may be amenable to surgical excision. Long-term survival and apparent cures were noted in patients with pulmonary metastases (413).

**High-grade ESS or undifferentiated endometrial sarcoma is a highly malignant neoplasm.** Histologically, it exhibits greater than 10 MF/10 HPF and often completely lacks recognizable stromal differentiation. This tumor has a much more aggressive clinical course and poorer prognosis than endometrial stromal sarcoma (406,408,413–416). The 5-year disease-free survival is about 25%. Treatment of undifferentiated endometrial sarcoma should consist of total abdominal hysterectomy and bilateral salpingo-oophorectomy. The poor therapeutic results suggest that radiation therapy, chemotherapy, or both should be used in combination with surgery. These tumors, unlike endometrial stromal sarcoma, are not responsive to progestin therapy.

**Uterine tumor resembling ovarian sex-cord tumor (UTROSCT) is a rare variant of endometrial stromal sarcoma in which benign glands and epithelial cells are found.** Immunohistochemically, these tumors express cytokeratin, epithelial membrane antigen, vimentin, and smooth muscle actin. Although some of these tumors have infiltrative margins, almost all of them behave benignly. The so-called mixed UTROSCT have a significant endometrial stromal sarcoma component and tend to behave more aggressively (417,418).

**Leiomyosarcoma**

The median age for women with leiomyosarcoma (43 to 53 years) is somewhat lower than for other uterine sarcomas, and premenopausal patients have a **better chance of survival.** This malignancy has no relationship with parity, and the incidence of associated diseases is not as high as in carcinosarcoma or endometrial adenocarcinoma. African American women have a higher incidence and a poorer prognosis than women of other races. A history of prior pelvic radiation therapy can be elicited in about 4% of patients with leiomyosarcoma. The incidence of sarcomatous change in
benign uterine leiomyomas is reported to be between 0.13% and 0.81% (419–429).

**Presenting symptoms, which are of short duration (mean, 6 months) and not specific to the disease, include vaginal bleeding, pelvic pain or pressure, and awareness of an abdominopelvic mass.** The principal physical finding is the presence of a pelvic mass. The diagnosis should be suspected if severe pelvic pain accompanies a pelvic tumor, especially in a postmenopausal woman. Endometrial biopsy, although not as useful as in other sarcomas, may establish the diagnosis in as many as one-third of cases when the lesion is submucosal.

**Survival rates for patients with uterine leiomyosarcoma range from 20% to 63% (mean, 47%).** The pattern of tumor spread is to the myometrium, pelvic blood vessels and lymphatics, contiguous pelvic structures, abdomen, and then distantly, most often to the lungs. The number of mitoses in the tumor traditionally was the most reliable microscopic indicator of malignant behavior (Fig. 35.8).

**Figure 35.8 Leiomyosarcoma of the uterus.** Interlacing bundles of spindle cells have fibrillar cytoplasm, irregular and hyperchromatic nuclei, and multiple mitotic figures. (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)

Tumors with less than 5 MF/10 HPF behave in a benign fashion, and tumors with more than 10 MF/10 HPF are frankly malignant with a poor prognosis. Tumors with 5 to 10 MF/10 HPF, termed cellular leiomyomas or smooth muscle tumors of uncertain malignant potential, are less predictable. In addition to mitotic index greater than 10, other histologic indicators used to classify
uterine smooth muscle tumors as malignant are severe cytologic atypia and coagulative tumor cell necrosis (430). Uterine smooth muscle tumors with any two of these three features are associated with a poor prognosis. Gross presentation of the tumor at the time of surgery is an important prognostic indicator. Tumors with infiltrating tumor margins or extension beyond the uterus are associated with poor prognosis, whereas tumors less than 5 cm, originating within myomas, or with pushing margins are associated with prolonged survival.

Five other clinical pathologic variants of uterine smooth muscle tumors deserve special comment: (i) myxoid leiomyosarcoma, (ii) leiomyoblastoma, (iii) intravenous leiomyomatosis, (iv) benign metastasizing uterine leiomyoma, and (v) disseminated peritoneal leiomyomatosis.

Myxoid leiomyosarcoma is characterized grossly by a gelatinous appearance and apparent circumscribed border. Microscopically, the tumors have a myxomatous stroma and extensively invade adjacent tissue and blood vessels (431). The mitotic rate is low (0 to 2 MF/10 HPF), which belies their aggressive behavior and poor prognosis. Surgical excision by hysterectomy is the mainstay of treatment. The low mitotic rate and abundance of intracellular myxomatous tissue suggest that these tumors would not be responsive to radiation therapy or chemotherapy.

Leiomyoblastoma includes smooth muscle tumors designated as epithelioid leiomyomas, clear cell leiomyomas, and plexiform tumorlets (432,433). This group of atypical smooth muscle tumors is distinguished by the predominance of rounded rather than spindle-shaped cells and by a clustered or cordlike pattern. These lesions should be regarded as specialized low-grade leiomyosarcomas with fewer than 5 MF/10 HPF. Leiomyoblastoma is treated with hysterectomy, and the prognosis is excellent.

Intravenous leiomyomatosis is characterized by the growth of histologically benign smooth muscle into venous channels within the broad ligament and then into uterine and iliac veins (434-437). The intravascular growth takes the form of visible, wormlike projections that extend out from a myomatous uterus into the parametria toward the pelvic sidewalls. It may be confused with low-grade stromal sarcoma. Symptoms are related to the associated uterine myomas. Most patients are in the late fifth and early sixth decades of life. The prognosis is excellent, even when tumor is left in pelvic vessels. Late local recurrences can occur, and deaths from extension into the inferior vena cava or metastases to the heart were reported. Estrogen may stimulate the proliferation of these intravascular tumors. Treatment should be total abdominal hysterectomy and bilateral salpingo-oophorectomy with removal of as much of the tumor as possible.

Benign metastasizing uterine leiomyoma is a rare condition in which a histologically benign uterine smooth muscle tumor acts in a somewhat malignant fashion and produces benign metastases, usually to the lungs or lymph nodes (438). In most instances, intravenous leiomyomatosis is not apparent. The metastasizing myomas are capable of growth at distant sites, whereas the intravenous
tumors spread only by direct extension within blood vessels. Both experimental and clinical evidence suggests that these tumors are stimulated by estrogen. Removing the source of estrogen, by castration or withdrawal of exogenous estrogen, or by treatment with progestins, tamoxifen, or a gonadotropin agonist, has an ameliorating effect (439). Surgical treatment should consist of total abdominal hysterectomy and bilateral salpingo-oophorectomy and resection of pulmonary metastases, if possible.

**Disseminated peritoneal leiomyomatosis is a rare clinical entity characterized by benign smooth muscle nodules scattered throughout the peritoneal cavity** (440). This condition probably arises as a result of metaplasia of subperitoneal mesenchymal stem cells to smooth muscle, fibroblasts, myofibroblasts, and decidual cells under the influence of estrogen and progesterone. Most reported cases occurred in 30- to 40-year-old women who are or who recently were pregnant or who have a long history of oral contraceptive use. Intriguing features of this disease are its grossly malignant appearance, benign histology, and favorable clinical outcome. Intraoperative diagnosis requires frozen-section examination. Extirpative surgery, including total abdominal hysterectomy, bilateral salpingo-oophorectomy, omentectomy, and excision of as much gross disease as possible, may be indicated in menopausal women. Removal of the source of excess estrogen, treatment with progestins, or both resulted in regression of unresected tumor masses. Almost all patients have a good prognosis.

**Carcinosarcoma**

*Carcinosarcoma* is composed histologically of a mixture of sarcoma and carcinoma. The carcinomatous element is usually glandular, whereas the sarcomatous element may resemble the normal endometrial stroma (homologous or the so-called carcinosarcoma), or it may be composed of tissues foreign to the uterus, such as cartilage, bone, or striated muscle (heterologous). These tumors are most likely derived from totipotential endometrial stromal cells (441--444).

Almost all of these tumors occur after menopause, at a median age of 62 years. The incidence is higher in African American women. These tumors are often found in association with other medical conditions, such as obesity, diabetes mellitus, and hypertension. A history of previous pelvic radiation can be obtained in 7% to 37% of patients.

The most frequent presenting symptom is postmenopausal bleeding, which occurs in 80% to 90% of cases. Other less common symptoms are vaginal discharge, abdominal or pelvic pain, weight loss, and passage of tissue from the vagina. The duration of symptoms usually is only a few months. On physical examination, uterine enlargement is present in 50% to 95% of patients, and a polypoid mass may be seen within or protruding from the endocervical canal in up to 50% of patients. Diagnosis can usually be determined by biopsy of an endocervical mass or endometrial curettage.

The tumor grows as a large, soft, polypoid mass, filling and distending the uterine cavity; necrosis and hemorrhage are prominent features. The myometrium is invaded to various
degrees in almost all cases. The most frequent areas of spread are the pelvis, lymph nodes, peritoneal cavity, lungs, and liver. This metastatic pattern suggests that these neoplasms spread by local extension and regional lymph node metastasis in a manner similar to that of endometrial adenocarcinoma, although they behave more aggressively.

**The most important single factor affecting prognosis in patients with carcinosarcoma is the extent of tumor at the time of treatment.** One study noted that in patients with tumor apparently confined to the uterine corpus (stage I), the 2-year survival rate was 53%, whereas the survival rate dropped to 8.5% when disease had extended to the cervix, vagina, or parametria (stage II and III); no patients with disease outside the pelvis (stage IV) survived (445). In another study, 5-year survival for patients with disease confined to the corpus (74%) was significantly greater than for those with more advanced disease (24%) (446).

**Disease extends outside the uterus in 40% to 60% of cases at the time of diagnosis, indicating the highly malignant nature of this lesion.** Even when disease is believed to be confined to the uterus preoperatively, surgical and pathologic staging identifies extraperitoneal spread of disease in a significant number of cases. In one study, 55% of women with clinical stage I carcinosarcoma had a higher surgical–pathologic stage. Only 28% of tumors were actually confined to the uterine corpus, 16% had extension to the cervix, and 56% showed extraperitoneal spread (447). In a significant number of patients, lymph node metastases and positive peritoneal cytology were found with early-stage carcinosarcoma (446,448,449). Deep myometrial invasion, which is present in about one-half of stage I cases, is associated with poor prognosis. Almost all patients in whom tumor involves the outer one-half of the myometrium die from the disease. Patients who die from carcinosarcoma tend to have larger tumors and a higher incidence of LVSI. Patients with a history of prior pelvic radiation have a poorer prognosis. Overall, the 5-year survival rate for patients with carcinosarcoma is about 20% to 30%.

**Adenosarcoma is an uncommon variant of carcinosarcoma** (450,451). It consists of an admixture of benign-appearing neoplastic glands and a sarcomatous stroma. Most patients present with postmenopausal vaginal bleeding, and the disease is diagnosed or suspected based on endometrial curettage. Most adenosarcomas are well circumscribed and limited to the endometrium or superficial myometrium. The treatment is hysterectomy and bilateral salpingo-oophorectomy, with or without adjuvant radiotherapy. Because recurrences, mostly in the form of local pelvic or vaginal disease, are reported in 40% to 50% of cases, adjuvant postoperative intravaginal or pelvic radiation is recommended.
Treatment

Recurrences develop in more than one-half of cases of uterine sarcoma, even when disease is apparently localized at the time of treatment (452–454). At least one-half of recurrences occur outside the pelvis, with isolated pelvic failures accounting for less than 10% of recurrences. The most common sites of recurrence are the abdomen and lungs. These data emphasize that the major limitation to cure of uterine sarcomas is distant spread.

Based on this evidence, treatment of most stage I and II uterine sarcomas should include hysterectomy, bilateral salpingo-oophorectomy, and treatment of the pelvic lymphatics by radiation or surgery. Strong consideration should be given to the use of adjuvant chemotherapy to decrease the incidence of distant metastases. Stage III uterine sarcomas are probably best treated by an aggressive combined approach of surgery, radiation therapy, and chemotherapy, while patients with stage IV disease are candidates for combination chemotherapy.

Surgery

The first step in the treatment of early uterine sarcoma should be exploration. Because extirpative survey is the most important aspect of treatment, and knowledge of the extent and spread of the disease is important for further management, one should not forgo or delay surgery by using radiation therapy or chemotherapy first. At the time of surgery, the peritoneal cavity should be carefully explored and peritoneal washings obtained. Special attention should be given to the pelvic and para-aortic lymph nodes; lymphadenectomy should be performed with ESS and carcinosarcoma, but may be omitted in leiomyosarcoma, in which the risk of lymph node metastases is low and the therapeutic and diagnostic value is questionable (428). Total abdominal hysterectomy is the standard procedure, and bilateral salpingo-oophorectomy should be performed in all patients except premenopausal women with leiomyosarcoma. Based on the surgical and pathologic findings, additional therapy with radiation therapy or chemotherapy can be planned. Rarely, a patient may be cured by excision of an isolated pulmonary metastasis (455,456).

Radiation Therapy

Several studies showed that adjuvant preoperative or postoperative radiation therapy is beneficial in decreasing pelvic recurrences and increasing quality of life in patients with localized ESS and carcinosarcoma, but not with leiomyosarcoma (457–465). Radiation was not demonstrated to improve survival. One trial randomized patients with uterine sarcomas to pelvic radiotherapy versus observation. Although the risk of local relapse significantly decreased from 24% to 14%, there was no difference in survival between groups (466). The GOG randomized patients to whole abdomen radiation versus three cycles of cisplatin, ifosfamide, and mesna in patients with less than 1 cm of residual disease (467). Whole-abdomen radiation was associated with significant toxicity and the
Chemotherapy regimen appeared to confer a nonsignificant survival advantage.

**Chemotherapy**

Several chemotherapeutic agents have activity in sarcomas, including vincristine, actinomycin D, cyclophosphamide, doxorubicin, dimethyl triazeno imidazole carboxamide (dacarbazine, DTIC), cisplatin, ifosfamide paclitaxel, gemcitabine, and liposomal doxorubicin (468). Doxorubicin appears to be the most active single agent in the treatment of leiomyosarcoma, producing a 25% response rate (469). Ifosfamide has a lesser degree of activity (470). Cisplatin and ifosfamide demonstrated clear activity in carcinosarcoma, with response rates of 18% to 42% and 32%, respectively (471–473). Doxorubicin demonstrated less than a 10% response rate in carcinosarcoma (469). Paclitaxel yielded an 18% response rate with carcinosarcoma, but had limited activity in leiomyosarcomas (474,475). Gemcitabine and liposomal doxorubicin showed activity in leiomyosarcomas (476,477).

Combination chemotherapy with doxorubicin and DTIC, or these two drugs plus vincristine and cyclophosphamide, was yielded somewhat higher response rates (478–480). Similarly, ifosfamide was combined with mesnauroprotection, doxorubicin, and DTIC to treat metastatic pure sarcomas (481). **Gemcitabine combined with docetaxel for treatment of metastatic leiomyosarcoma yielded an overall response rate of 53%, including patients previously treated with doxorubicin (482). Median time to progression was 5.6 months. Several retrospective investigations concluded that neither chemotherapy nor radiation impacts survival for patients with ESS or leiomyosarcoma (428,483,484).**

Combined ifosfamide and cisplatin chemotherapy resulted in a higher response rate (54% versus 36%) and a longer progression-free survival than ifosfamide chemotherapy alone for treatment of advanced carcinosarcoma (485). Overall survival was unchanged (8 versus 9 months), and the combined regimen was significantly more toxic. A 3-day regimen of ifosfamide with or without paclitaxel in patients with advanced and recurrent carcinosarcoma demonstrated improved response rates (29% versus 45%) and median overall survival (8 versus 13 months) in the combination chemotherapy arm (486). This regimen appears to be the most efficacious for patients with advanced or recurrent carcinosarcoma. **A combination of paclitaxel and carboplatin for treatment of advanced uterine carcinosarcoma resulted in a complete response rate of 80% and a median progression-free interval of 18 months (487).** The GOG completed a phase II evaluation of paclitaxel and carboplatin with the results awaiting maturation. A randomized phase III evaluation of paclitaxel plus carboplatin versus ifosfamide plus paclitaxel in chemotherapy naive patients with carcinosarcoma is accruing.
Adjuvant Treatment

Because of the relatively low survival rate in localized uterine sarcomas and the high incidence of failure resulting from subsequent distant metastasis, adjuvant treatment programs employing chemotherapy were tested (487–490). **Most reports were unable to show a clear improvement in survival by the addition of postoperative adjuvant chemotherapy in early uterine sarcoma.** The GOG conducted a trial of postoperative adjuvant doxorubicin in stage I and II uterine sarcoma patients. Of the 75 patients randomized to receive doxorubicin, 41% developed a recurrence, compared with 53% of 81 patients receiving no adjuvant chemotherapy, but these differences were not significant (487). Other smaller, nonrandomized adjuvant chemotherapy studies employing cyclophosphamide, cisplatin plus doxorubicin, and ifosfamide plus cisplatin reported recurrence rates of 33%, 24%, and 31%, respectively (488–490).

Human papillomavirus (HPV) infection is the causal agent of cervical cancer. Screening programs are effective at decreasing the incidence of cervical cancer. Vaccines also help decrease the incidence of cervical cancer. The most common histologic type of cervical cancer is squamous, and the relative and absolute incidence of adenocarcinoma is increasing; both histologies are caused by HPV infection.

Cervical cancer is clinically staged, although modern radiographic modalities such as computed tomography, magnetic resonance imaging, ultrasound, or positron emission tomography may be beneficial for individual treatment planning.

Treatment of cervical cancer is based on stage of disease. Early stage disease (stages I to IIA) can be treated with either radical surgery or radiation therapy. Advanced stage disease (stages IIB to IV) is best treated with chemoradiation.

Vaginal cancer is a rare disease with many similarities to cervical cancer. Radiation therapy is the mainstay of treatment for most patients; however, select patients may be treated with radical surgery.

Cervical cancer ranks as the third most common gynecologic neoplasm in the United States, behind cancer of the corpus and ovary, mainly as a result of the effectiveness of screening programs. Worldwide, cervical carcinoma continues to be a significant health care problem. In developing countries, where health care resources are limited, cervical carcinoma is the second most frequent cause of cancer death in women. Because cervical cancer is preventable, it is imperative that gynecologists and other primary health care providers to women be familiar with vaccination programs, screening techniques, diagnostic procedures, and risk factors for cervical cancer and management of preinvasive disease. Vaginal cancer is a rare tumor that shares an
epidemiology and risk factor profile that is similar to cervical cancer.
Cervical Cancer

Epidemiology and Risk Factors

Invasive cancer of the cervix is considered a preventable disease because it has a long preinvasive state, cervical cytology screening programs are currently available, and the treatment of preinvasive lesions is effective. In spite of the preventable nature of this disease, 12,710 new cases of invasive cervical cancer resulting in 4290 deaths were anticipated in the United States in 2011 (1). Nationally, the lifetime probability of developing cervical cancer is 1:128. Although screening programs in the United States are well established, it is estimated that 30% of cervical cancer cases will occur in women who have never had a Papanicolaou (Pap) test. In developing countries, this percentage approaches 60% (2). Nevertheless, the worldwide incidence of invasive disease is decreasing, and cervical cancer is being diagnosed earlier, leading to better survival rates (1,3). The mean age for cervical cancer in the United States is 47 years, and the distribution of cases is bimodal, with peaks at 35 to 39 years and 60 to 64 years of age (1).

There are numerous risk factors for cervical cancer: young age at first intercourse (younger than 16 years), multiple sexual partners, cigarette smoking, race, high parity, low socioeconomic status, and chronic immune suppression. The relationship to oral contraceptive use was debated. Some investigators proposed that use of oral contraceptives might increase the incidence of cervical glandular abnormalities; however, this hypothesis was not consistently supported (4,5). Many of these risk factors are linked to sexual activity and exposure to sexually transmitted diseases. Infection with the herpes virus was thought to be the initiating event in cervical cancer; however, infection with human papillomavirus (HPV) was determined to be the causal agent in the development of cervical cancer, with herpes virus and Chlamydia trachomatis likely acting as cofactors. The role of human immunodeficiency virus (HIV) in cervical cancer is mediated through immune suppression (4). The Centers for Disease Control and Prevention described cervical cancer as an acquired immune deficiency syndrome (AIDS)–defining illness in patients infected with HIV (6).

The initiating event in cervical dysplasia and carcinogenesis is infection with HPV. HPV infection was detected in up to 99% of women with squamous cervical carcinoma. HPV is the causative agent in both squamous and adenocarcinoma of the cervix, but the respective tumors may have different carcinogenic pathways (7). There are more than 100 different types of HPV, more than 30 of which can affect the lower genital tract. There are 14 high-risk HPV subtypes; two of the high-risk subtypes, 16 and 18, are found in up to 62% of cervical carcinomas. The mechanism by which HPV affects cellular growth and differentiation is through the interaction of viral E6 and E7 proteins with tumor suppressor genes p53 and Rb, respectively. Inhibition of p53 prevents cell cycle arrest and cellular apoptosis, which normally occurs when damaged DNA is present,
whereas inhibition of Rb disrupts transcription factor E2F, resulting in unregulated cellular proliferation (8). Both steps are essential for the malignant transformation of cervical epithelial cells. Two HPV vaccines, the quadrivalent Gardasil and the bivalent Cervarix, are approved by the U.S. Food and Drug Administration (FDA) and protect against subtypes 16 and 18. After 3 years, the efficacy of Gardasil was 99% for preventing cervical intraepithelial neoplasia grades 2 and 3 caused by HPV 16 or 18 in females who were not previously infected with either HPV 16 or 18 before vaccination; however, efficacy was only 44% in those who were infected prior to vaccination (9). Because the quadrivalent and bivalent HPV vaccines both protect only against certain types of HPV, vaccinated women need to continue to receive Pap test screening according to guidelines.
Evaluation

Vaginal bleeding is the most common symptom occurring in patients with cancer of the cervix. Most often, this is postcoital bleeding, but it may occur as irregular or postmenopausal bleeding. Patients with advanced disease may present with a malodorous vaginal discharge, weight loss, or obstructive uropathy. In asymptomatic women, cervical cancer is most commonly identified through evaluation of abnormal cytologic screening tests. The false-negative rate for Pap tests in the presence of invasive cancer is up to 50%, so a negative Pap test should never be relied on in a symptomatic patient (10).

Initially, all women suspected of having cervical cancer should have a general physical examination performed to include evaluation of the supraclavicular, axillary, and inguinal-femoral lymph nodes to exclude the presence of metastatic disease. On pelvic examination, a speculum is inserted into the vagina, and the cervix is inspected for suspicious areas (Fig. 36.1). The vaginal fornices also should be closely inspected. With invasive cancer, the cervix is usually firm and expanded, and these features should be confirmed by digital examination. Rectal examination is important to help establish cervical consistency and size, particularly in patients with endocervical carcinomas. Rectal examination is the only way to determine cervical size if the vaginal fornices have been obliterated by menopausal changes or by the extension of disease. Parametrial extension of disease is best determined by the finding of nodularity beyond the cervix on rectal examination.

Figure 36.1 Gross appearance of cervical cancer on examination.

When obvious tumor growth is present, a cervical biopsy is usually sufficient for diagnosis. If gross disease is not present, a colposcopic examination with cervical biopsies and endocervical curettage is warranted. If the diagnosis
cannot be established conclusively with colposcopy and directed biopsies, which may be the case with adenocarcinoma, cervical conization may be necessary.

**Colposcopic Findings of Invasion**

Colposcopic examination is mandatory for patients with suspected early invasive cancer based on cervical cytology and a grossly normal-appearing cervix. Colposcopic findings that suggest invasion are (i) abnormal blood vessels, (ii) irregular surface contour with loss of surface epithelium, and (iii) color tone change. Colposcopically directed biopsies may permit the diagnosis of frank invasion and thus avoid the need for diagnostic cone biopsy, allowing treatment to be administered without delay. If there is debate about the depth of invasion based on the cervical biopsies, and if the clinical stage may be upstaged to stage IA2 or IB1, the patient should undergo a conization. In the presence of a large cervical biopsy specimen showing invasion greater than 3 mm, or two biopsy specimens separated by 7 mm showing invasive cervical carcinoma, therapy should proceed without delay, and the patient could undergo radical surgery or radiation therapy.

**Abnormal Blood Vessels**

Abnormal vessels may be looped, branched, or reticular. **Abnormal looped vessels are the most common colposcopic finding and arise from the punctated and mosaic vessels present in cervical intraepithelial neoplasia (CIN).** As the neoplastic growth process proceeds and the need for oxygen and nutrition increases, angiogenesis occurs as a result of tumor and local tissue production of vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), epidermal growth factor (EGF), and other cytokines, resulting in the proliferation of blood vessels and neovascularization. Punctate vessels push out over the surface of the epithelium in an erratic fashion, producing the looped, corkscrew, or J-shaped pattern of abnormal vessels characteristic of invasive disease. Abnormal blood vessels arise from the cervical stroma and are pushed to the surface as the underlying cancer invades. The normally branching cervical stromal vessels are best observed over nabothian cysts. In this area, the branches are generally at acute angles, with the caliber of vessels becoming smaller after branching, much like the arborization of a tree. The abnormal branching blood vessels seen with cancer tend to form obtuse or right angles, with the caliber sometimes enlarging after branching. Sharp turns, dilations, and luminal narrowing also characterize these vessels. The surface epithelium may be lost in these areas, leading to irregular surface contour and friability.

**Abnormal reticular vessels represent the terminal capillaries of the cervical epithelium.** Normal capillaries are best seen in postmenopausal women with atrophic epithelium. When cancer involves this epithelium, the surface is eroded, and the capillary network is exposed. These vessels are very fine and short and appear as small comma-shaped vessels without an organized pattern. They are not specific to invasive cancer;
atrophic cervicitis may also have this appearance.

**Irregular Surface Contour**

Abnormal surface patterns are observed as tumor growth proceeds. The surface epithelium ulcerates as the cells lose intercellular cohesiveness secondary to loss of desmosomes. Irregular contour may occur as a result of papillary characteristics of the lesion. **This finding can be confused with a benign HPV papillary growth on the cervix. For that reason, biopsies should be performed on all papillary cervical growths to avoid missing invasive disease.**

**Color Tone**

Color tone may change as a result of increasing vascularity, surface epithelial necrosis, and in some cases, production of keratin. The color tone is yellow-orange rather than the expected pink of intact squamous epithelium or the red of the endocervical epithelium.

**Adenocarcinoma**

Adenocarcinoma of the cervix does not have a specific colposcopic appearance. All of the aforementioned blood vessels may be seen in these lesions. Because adenocarcinomas tend to develop within the endocervix, endocervical curettage is required as part of the colposcopic examination, and traditional screening methods are less reliable (10).

**Histologic Appearance of Invasion**

Cervical conization is required to assess correctly the depth and the linear extent of involvement when microinvasion is suspected. Early invasion is characterized by a protrusion of malignant cells from the stromal–epithelial junction. This focus consists of cells that appear better differentiated than the adjacent noninvasive cells and have abundant pink-staining cytoplasm, hyperchromatic nuclei, and small- to medium-sized nucleoli (11). **These early invasive lesions form tonguelike processes without measurable volume and are classified as International Federation of Gynecology and Obstetrics (FIGO) stage IA1.** With further progression, more tonguelike processes and isolated malignant cells appear in the stroma, followed by a proliferation of fibroblasts (desmoplasia) and a bandlike infiltration of chronic inflammatory cells (Fig. 36.2). **With increasing depth of invasion, lesions occur at multiple sites, and the growth becomes measurable by depth and linear extent. Lesions that are less than 3 mm in depth are classified as FIGO stage IA1. Lesions that are 3 to 5 mm or more in depth and up to 7 mm in linear extent are classified as FIGO stage IA2 (12).** As the depth of stromal invasion increases, so does the risk of capillary lymphatic space involvement. Dilated capillaries, lymphatic spaces, and foreign-body multinucleated giant cells containing keratin debris are often seen in the stroma.
The depth of invasion should be measured with a micrometer from the base of the epithelium to the deepest point of invasion. **Depth of invasion is a significant predictor for the development of pelvic lymph node metastasis and tumor recurrence.** Although lesions that have invaded 3 mm or less rarely metastasize, patients in whom lesions invade between 3 to 5 mm have positive pelvic lymph nodes in 3% to 8% of cases. The significance of the cutoff at 3 mm is not identified completely; it was postulated that small capillary–lymphatic spaces at this level are incapable of facilitating the transport of malignant cells. Uneven shrinkage of tissue by fixative often creates space between the tumor nests and the surrounding fibrous stroma, simulating vascular lymphatic invasion. Therefore, suspected vascular–lymphatic involvement with invasion of less than 3 mm should be interpreted with care. A lack of endothelial lining indicates that the space is a fixation artifact rather than true vascular invasion.
Staging

Cervical cancer is a clinically staged disease. The FIGO staging system is the standard and applicable to all histologic types of cervical cancer. The FIGO staging system is presented in Table 36.1 and Figure 36.3. The staging procedures allowed by FIGO are listed in Table 36.2. When there is doubt concerning the stage to which a cancer should be allocated, the earlier stage should be selected. After a clinical stage is assigned and treatment is initiated, the stage must not be changed because of subsequent findings by either extended clinical staging or surgical staging. The upstaging of patients during treatment will produce an erroneous perception of improvement in the results of treatment of low-stage disease. Following is a breakdown of the incidence of cervical cancer by stage at diagnosis: 38%, stage I; 32%, stage II; 26%, stage III; and 4%, stage IV (3,13,14).

Additional Staging Modalities

Various investigators used lymphangiography, computed tomography (CT), ultrasonography, magnetic resonance imaging (MRI), and positron emission tomography (PET) in an attempt to improve the accuracy of clinical staging (15–25). These modalities suffer from poor sensitivity and high false-negative rates. Evaluation of the para-aortic lymph nodes with lymphangiography is associated with a false-positive rate of 20% to 40% and a false-negative rate of 10% to 20% (15–17). Overall, lymphangiography has a sensitivity of 79% and specificity of 73% (20). CT has poor sensitivity (34%) but excellent specificity (97%) (21). The accuracy of CT scanning is 80% to 85%; the false-negative rate is 10% to 15%, and the false-positive rate is 20% to 25% (16–18). Ultrasound has a high false-negative rate (30%), low sensitivity (19%), but high specificity (99%) (19). Early data showed that MRI results were comparable to those of CT scanning, a finding confirmed on meta-analysis (21,22). However, a systematic review comparing CT scan with MRI showed that MRI is significantly more sensitive with equivalent specificity. Additionally, MRI has excellent sensitivity on T2-weighted images for the detection of parametrial disease (23). As a result, MRI is the preferred study to evaluate tumor size, lymph node metastasis, and local tumor extension.

</table>
IB  greater than stage IA
IB1 Clinically visible lesion ≤4.0 cm in greatest dimension
IB2 Clinically visible lesion >4.0 cm in greatest dimension

Stage Cervical carcinoma invades beyond the uterus, but not to the pelvic wall or to the lower third of the vagina

II Without parametrial invasion
IIA Clinically visible lesion ≤4.0 cm in greatest dimension
IIB With obvious parametrial invasion

Stage The tumor extends to the pelvic wall and/or involves lower third of the vagina and/or causes hydronephrosis or non-functioning kidney

IIIA Tumor involves lower third of the vagina, with no extension to the pelvic wall
IIB Extension to the pelvic wall and/or hydronephrosis or non-functioning kidney

Stage The carcinoma has extended beyond the true pelvis or has involved (biopsy proven) the mucosa of the bladder or rectum. A bullous edema, as such, does not permit a case to be allotted to Stage IV

IVA Spread of the growth to adjacent organs
IVB Spread to distant organs

a All macroscopically visible lesions, even those with superficial invasion, are allotted to stage IB carcinomas. Invasion is limited to a measured stroma invasion with a maximal depth of 5.0 mm and a horizontal extension greater than 7.0 mm. Dept of invasion should not be greater than 5 mm taken from the base of the epithelium of the original tissue squamous or glandular. The depth of invasion should always be reported in millimeters, even those cases with “early minimal stromal invasion” (~1 mm). The involvement of vascular/lymphatic spaces should not change stage allotment.

b On rectal examination, there is no cancer-free space between the tumor and the pelvic wall. All cases with hydronephrosis or non-functioning kidney are included, unless they are known to be due to another cause.

- Colposcopy
- Endocervical curettage
PET scans are increasingly being utilized either alone or in conjunction with CT or MRI to detect metastatic disease; however, large prospective data series are limited. Early studies suggest that PET may be more useful than other techniques for the detection of abdominal and extrapelvic disease, with comparable or better sensitivity (76% to 100%) and specificity (94%) ([24],[25]). In addition, PET scans may be better predictors of treatment outcome. Although early studies show promise for the use of PET scans in evaluating cervical cancer, the sensitivity for detecting metastatic disease less than 1 cm in size appears to be limited ([26]).

When abnormalities are noted on CT, MRI, or PET, radiographic-guided fine-needle aspirations (FNA) can be performed to confirm metastatic disease and individualize treatment planning. Because these tests are not available equally throughout the world and the interpretation of results can be variable, these studies are not used for staging. They may be useful in individual treatment planning.

The clinical staging system developed by FIGO is based on the belief that cervical cancer is a local disease until rather late in its course. The accuracy of clinical staging is limited, and surgical evaluation, although not practical or feasible in all patients, can more accurately identify metastatic disease. Surgical staging is advocated by providers who believe that surgical information details the extent of disease, allowing the treatment to be tailored to the individual ([27]). However, other providers believe that surgical staging should be limited to patients who are enrolled in clinical trials. These beliefs are based on the lack of randomized controlled studies demonstrating a survival benefit in patients who had surgical staging.
Invasive squamous cell carcinoma is the most common variety of invasive cancer in the cervix. Histologically, variants of squamous cell carcinoma include large cell keratinizing, large cell nonkeratinizing, and small cell types (28). Large cell keratinizing tumors consist of tumor cells forming irregular infiltrative nests with laminated keratin pearls in the center. Large cell nonkeratinizing carcinomas reveal individual cell keratinization but do not form keratin pearls (Fig. 36.4). The category of small cell carcinoma includes poorly differentiated squamous cell carcinoma and small cell anaplastic carcinoma. If possible, these two tumors should be differentiated. The former contains cells that have small- to medium-sized nuclei and more abundant cytoplasm than those of the latter. The designation of small cell anaplastic carcinoma should be reserved for lesions resembling oat cell carcinoma of the lung. Small cell anaplastic carcinoma infiltrates diffusely and consists of tumor cells that have scanty cytoplasm, round to oval small nuclei, coarsely granular chromatin, and high mitotic activity. The nucleoli are absent or small. Immunohistochemistry or electron microscopy can differentiate the small cell neuroendocrine tumors. Patients with the large cell type of carcinoma, with or without keratinization, have a better prognosis than those with the small cell variant. Small cell anaplastic carcinomas behave more aggressively than poorly differentiated squamous carcinomas that contain small cells. Infiltration of parametrial tissue and pelvic lymph node metastasis affect the prognosis.

Figure 36.4 Invasive squamous cell carcinoma, large cell nonkeratinizing type. Tumor cells form irregular nests and have abundant eosinophilic cytoplasm and distinct cell borders indicative of squamous differentiation.

Other less common variants of squamous carcinoma include verrucous carcinoma and papillary (transitional) carcinoma. Verrucous carcinomas may resemble giant
condyloma acuminatum, are locally invasive, and rarely metastasize. Papillary carcinomas histologically resemble transitional cells of the bladder and may have more typical squamous cell invasion at the base of the lesion. Papillary carcinomas behave and are treated in a manner similar to traditional squamous cell cancers, except that late recurrences were noted.

Adenocarcinoma

There is an increasing number of cervical adenocarcinomas reported in women in their 20s and 30s. Although the total number of cases of adenocarcinoma is relatively stable, this disease is appearing more frequently in young women, especially as the number of cases of invasive squamous cell carcinoma decreases. Older reports indicated that 5% of all cervical cancers were adenocarcinomas, whereas newer reports show a proportion as high as 18.5% to 27% (29–31). Much of this proportional increase is related to a decreasing incidence of squamous carcinoma secondary to screening programs (which are less accurate at identifying preinvasion adenocarcinoma), greater exposure to oral contraceptives, and a greater exposure to HPV (4,5).

Adenocarcinoma in situ (AIS) is believed to be the precursor of invasive adenocarcinoma, and it is not surprising that the two often coexist (32). In addition to AIS, intraepithelial or invasive squamous neoplasia occurs in 30% to 50% of cervical adenocarcinomas (33). A squamous intraepithelial lesion may be observed colposcopically on the ectocervix, and the coexistent adenocarcinoma often is higher in the cervical canal.

Patients with AIS who are treated with conization should undergo close clinical follow-up. Endocervical curettage, often used in surveillance, may miss residual or invasive disease, and false-negative rates as high as 50% were reported (34). In addition, skip lesions not resected at the time of conization may be present. For these reasons, hysterectomy should be considered the standard therapy for patients who have completed their childbearing. In two reports, patients with negative cone biopsy margins were followed conservatively, with few requiring repeat surgical procedures (35,36). Because cervical AIS tends to affect women during their reproductive years, a thorough discussion of risks and benefits should take place, and treatment should be individualized.

Adenocarcinoma of the cervix is managed in the same manner used for squamous cell carcinoma. Adenocarcinoma was believed to be associated with a worse prognosis and outcome when compared with squamous cell carcinoma. A study of 203 women with adenocarcinoma and 756 women with squamous carcinoma supported this assertion (30). This study showed 5-year survival rates of 90% versus 60%, 62% versus 47%, and 36% versus 8% for stages I, II, and III, respectively. Although some attributed these rates to a relative resistance to radiation, they are more likely a reflection of the tendency of adenocarcinomas to grow endophytically and to be undetected until a large volume of tumor is present. When adjusted for tumor size, it
appears that there is no difference in prognosis between the two histologic subtypes. Adenocarcinoma may be detected by cervical sampling, but less reliably so than squamous carcinomas. A definitive diagnosis may require cervical conization.

The clinical features of stage I adenocarcinomas are well studied (30,37–39). These studies identified size of tumor, depth of invasion, grade of tumor, and age of the patient as significant correlates of lymph node metastasis and survival. When matched with squamous carcinomas for lesion size, age, and depth of invasion, the incidence of lymph node metastases and the survival rate appear to be the same (38,39). Patients with stage I adenocarcinomas can be selected for treatment according to the same criteria as for those with squamous cancers (39).

The choice of treatment for bulky stage I and II tumors is controversial. Some advocated treatment with radiation alone, whereas others support radiation plus extrafascial hysterectomy (40–42). In 1975, Rutledge et al. reported an 85.2% 5-year survival rate for all patients with stage I disease treated with radiation alone and an 83.8% survival rate for those who had radiation plus surgery (41). The central persistent disease rate was 8.3%, compared with 4% for those who had radiation plus surgery. In stage II disease, the 5-year survival rate was 41.9% for radiation alone and 53.7% for radiation plus surgery. A subsequent report revealed no significant difference in survival among patients treated with radiation alone or radiation plus extrafascial hysterectomy (43).

Invasive adenocarcinoma may be pure (Fig. 36.5A, B) or mixed with squamous cell carcinoma. Within the category of pure adenocarcinoma, the tumors are quite heterogeneous, with a wide range of cell types, growth patterns, and differentiation (30). About 80% of cervical adenocarcinomas consist predominantly of the endocervical type cells with mucin production. The remaining tumors are populated by endometrioid cells, clear cells, intestinal cells, or a mixture of more than one cell type. By histologic examination alone, some of these tumors are indistinguishable from those arising elsewhere in the endometrium or ovary. Within each cell type, the growth patterns and nuclear abnormalities vary according to the degree of differentiation. In well-differentiated tumors, tall columnar cells line the well-formed branching glands and papillary structures, whereas pleomorphic cells tend to form irregular nests and solid sheets in poorly differentiated neoplasms. The latter may require mucicarmine and periodic acid–Schiff (PAS) staining to confirm their glandular differentiation.

Figure 36.5 Invasive adenocarcinoma of the cervix, well-differentiated. A. Irregular glands are lined with tall columnar cells with vacuolated mucinous cytoplasm resembling endocervical cells. B. Nuclear stratification, mild nuclear atypism, and mitotic figures are evident in higher power.
There are several special variants of adenocarcinoma. **Minimal deviation adenocarcinoma (adenoma malignum)** is an extremely well-differentiated form of adenocarcinoma in which the branching glandular pattern strongly simulates that of the normal endocervical glands. The lining cells have abundant mucinous cytoplasm and uniform nuclei (44,45). Because of this, the tumor may not be recognized as malignant in small biopsy specimens, thereby causing considerable delay in diagnosis. Special immunohistochemical staining may be required to establish the diagnosis. Earlier studies reported a dismal outcome for women with this tumor, but more recent studies found a favorable prognosis if the disease is detected early (46). Although rare, similar tumors were reported in association with endometrioid, clear, and mesonephric cell types (47). An entity described as **villoglandular papillary adenocarcinoma** deserves special
Attention (48). It primarily affects young women, some of whom are pregnant or users of oral contraceptives. Histologically, the tumors have smooth, well-defined borders, are well differentiated, and are either in situ or superficially invasive. Follow-up information is encouraging. None of these tumors recurred after cervical conization or hysterectomy, and no metastasis was detected among women undergoing pelvic lymphadenectomy. This tumor appears to have limited risk for spread beyond the uterus.

**Adenosquamous Carcinoma**

Carcinomas with a mixture of malignant glandular and squamous components are known as **adenosquamous carcinomas**. Patients with adenosquamous carcinoma of the cervix were reported to have a poorer prognosis than those with pure adenocarcinoma or squamous carcinoma (49). Whether this is true when corrected for size of lesion is controversial (38,39).

In mature adenosquamous carcinomas, the glandular and squamous carcinomas are readily identified on routine histologic evaluation and do not cause diagnostic problems. **In poorly differentiated or immature adenosquamous carcinomas, however, glandular differentiation can be appreciated only with special stains, such as mucicarmine and PAS.** In one study, 30% of squamous cell carcinomas demonstrated mucin secretion when stained with mucicarmine (47). These squamous cell carcinomas with mucin secretion have a higher incidence of pelvic lymph node metastases than do squamous cell carcinomas without mucin secretion, and they are similar to the signet-ring variant of adenosquamous carcinoma (47,50).

**Glassy cell carcinoma** is recognized as a poorly differentiated form of adenosquamous carcinoma (51). Individual cells have abundant eosinophilic, granular, ground-glass cytoplasm, large round to oval nuclei, and prominent nucleoli. The stroma is infiltrated by numerous lymphocytes, plasma cells, and eosinophils. Approximately half of these tumors contain glandular structures or stain positive for mucin. The poor diagnosis of this tumor is linked to understaging and resistance to radiotherapy.

Other variants of adenosquamous carcinoma include **adenoid basal carcinoma** and **adenoid cystic carcinoma**. Adenoid basal carcinoma simulates the basal cell carcinoma of the skin (51). Nests of basaloid cells extend from the surface epithelium deep into the underlying tissue. Cells at the periphery of tumor nests form a distinct parallel nuclear arrangement, so-called peripheral palisading. An “adenoid” pattern occasionally develops, with “hollowed-out” nests of cells. Mitoses are rare, and the tumor often extends deep into the cervical stroma.

Adenoid cystic carcinoma of the cervix behaves much like such lesions elsewhere in the body. The tumors tend to invade into the adjacent tissues and metastasize late, often 8 to 10 years after the primary tumor was removed. Like other adenoid cystic tumors, they may metastasize directly to the lung. The pattern simulates that of the adenoid basal tumor, but there is a cystic component, and the glands of the cervix are involved (51). Mitoses may be seen but are not numerous.
Sarcoma

The most important sarcoma of the cervix is embryonal rhabdomyosarcoma, which occurs in children and young adults. The tumor has grapelike polypoid nodules, known as botryoid sarcoma, and the diagnosis depends on the recognition of rhabdomyoblasts. Leiomyosarcomas and mixed mesodermal tumors involving the cervix may be primary but are more likely to be secondary to uterine tumors. Cervical adenosarcoma is described as a low-grade tumor with a good prognosis (52). If recurrence develops, it is generally a central recurrence that may be treated with resection and hormonal therapy.

Malignant Melanoma

On rare occasions, melanosis is seen in the cervix. Malignant melanoma may arise de novo in this area. Histopathologically, it simulates melanoma elsewhere, and the prognosis depends on the depth of invasion into the cervical stroma.

Neuroendocrine Carcinoma

The classification of neuroendocrine cervical carcinoma includes four histologic subtypes: (i) small cell, (ii) large cell, (iii) classical carcinoid, and (iv) atypical carcinoid (53). Neuroendocrine tumors of the cervix are rare, and treatment regimens are based on small case series of patients.

Small cell (neuroendocrine type) carcinoma of the cervix is aggressive in nature and is similar to cancer arising from the bronchus (54). The hallmark of neuroendocrine tumors is their aggressive malignant behavior with the propensity to metastasize. At the time of diagnosis, it is usually disseminated, with bone, brain, liver, and bone marrow being the most common sites of metastases. In one study of 11 patients with disease apparently confined to the cervix, a high rate of lymph node metastasis was noted (55). Pathologically, the diagnosis is aided by the finding of neuroendocrine granules on electron microscopy and by immunoperoxidase studies that are positive for a variety of neuroendocrine proteins such as calcitonin, insulin, glucagon, somatostatin, gastrin, and adrenocorticotropic hormone (ACTH). In addition to the traditional staging for cancer of the cervix, these patients should undergo bone, liver and brain scanning and bone marrow aspiration and biopsy to evaluate the possibility of metastatic disease. Therapy consists of surgery, chemotherapy, and radiation. Because patients with early-stage disease have distant metastases, multimodal therapy is recommended. The main active chemotherapeutic agent is etoposide.

Local therapy alone gives almost no chance of cure of small cell carcinoma. Regimens of combination chemotherapy improved the median survival rates in small cell bronchogenic carcinoma, and these regimens are used for treatment of small cell carcinoma of the cervix. Combination chemotherapy may consist of vincristine, doxorubicin, and cyclophosphamide (VAC) or VP-16 (etoposide) and cisplatin (EP) (56). Patients must be monitored carefully because they are at high risk for developing recurrent metastatic disease (57).
Patterns of Spread

Cancer of the cervix spreads by (i) direct invasion into the cervical stroma, corpus, vagina, and parametrium; (ii) lymphatic metastasis; (iii) blood-borne metastasis; and (iv) intraperitoneal implantation. The incidence of pelvic and para-aortic nodal metastasis is shown in Table 36.3.

The cervix is commonly involved in cancer of the endometrium and vagina. The latter is rare, and most lesions that involve the cervix and vagina are designated cervical primaries. Consequently, the clinical classification is that of cervical neoplasia extending to the vagina, rather than vice versa. Endometrial cancer may extend into the cervix by three modes: direct extension from the endometrium, submucosal involvement by lymph vascular extension, and multifocal disease. The latter is most unusual, but occasionally a focus of adenocarcinoma may be seen in the cervix, separate from the endometrium. This lesion should not be diagnosed as metastasis but rather as multifocal disease. Malignancies involving the peritoneal cavity (e.g., ovarian cancer) may be found in the cul-de-sac and extend directly into the vagina and cervix. Carcinomas of the urinary bladder and colon occasionally extend into the cervix. Cervical involvement by lymphoma, leukemia, and carcinoma of the breast, stomach, and kidney is usually part of the systemic pattern of spread for these malignancies. Isolated metastasis to the cervix in such cases may be the first sign of a primary tumor elsewhere in the body.
Treatment Options

The treatment of cervical cancer is similar to the treatment of any other type of malignancy in that both the primary lesion and potential sites of spread should be evaluated and treated. The therapeutic modalities for achieving this goal include primary treatment with surgery, radiotherapy, chemotherapy, or chemoradiation. Whereas radiation therapy can be used in all stages of disease, surgery is limited to patients with stage I to IIa disease. The 5-year survival rate for stage I cancer of the cervix is approximately 85% with either radiation therapy or radical hysterectomy. A study using the National Cancer Institute’s Surveillance Epidemiology and End Results data by an intent-to-treat analysis showed that patients in the surgery arm had an improved survival when compared with patients in the radiation arm (58). Optimal therapy consists of radiation, or surgery alone, to limit the increased morbidity that occurs when the two treatment modalities are combined. Recent improvements in the treatment of cervical carcinoma include adjuvant chemoradiation in patients discovered to have high-risk cervical carcinoma after radical hysterectomy and in patients with locally advanced cervical carcinoma.
Surgery

There are advantages to the use of surgery instead of radiotherapy, particularly in younger women for whom conservation of the ovaries is important. Chronic bladder and bowel problems that require medical or surgical intervention occur in up to 8% of patients undergoing radiation therapy (59). Such problems are difficult to treat because they result from fibrosis and decreased vascularity. This is in contrast to surgical injuries, which usually can be repaired without long-term complications. Sexual dysfunction is less likely to occur after surgical therapy than radiation, because of vaginal shortening, fibrosis, and atrophy of the epithelium associated with radiation. Surgical therapy shortens the vagina, but gradual lengthening can be brought about by sexual activity. The epithelium does not become atrophic because it responds either to endogenous estrogen or to exogenous estrogens if the patient is postmenopausal.

Radical hysterectomy is reserved for women who are in good physical condition. Advanced chronologic age should not be a deterrent. With improvements in anesthesia, elderly patients withstand radical surgery almost as well as their younger counterparts (60). It is prudent not to operate on lesions that are larger than 4 cm in diameter because these patients will require postoperative radiation therapy. When selected in this manner, the urinary fistula rate is less than 2%, and the operative mortality rate is less than 1% (61,62). A summary of the management of cervical cancer is presented in Table 36.4.

If radiation therapy is needed, transposing the ovaries out of the planned radiation field may preserve ovarian function. Although transposition provides some protection, studies suggest that normal ovarian function is preserved in fewer than 50% of patients (63,64). Metastasis to the ovaries occurs in 0.9% of cases of early stage cervical cancer, so preservation of the ovaries, particularly with adenocarcinoma, may confer a small recurrence risk (65).

Cone Biopsy of the Cervix

Cone biopsy of the cervix serves both a diagnostic and therapeutic role in cervical cancer. The procedure is indicated to confirm the diagnosis of cancer, and to definitively treat stage Ia1 disease when preservation of fertility is desired. For effective treatment, there must be no evidence of lymph–vascular space invasion, and both endocervical margins and curettage findings must be negative for cancer or dysplasia. Because stage Ia1 cancers have less than a 1% risk of lymph node metastasis, lymphadenectomy is not necessary. If the endocervical margin or curettage is positive for dysplasia or malignancy, further treatment is necessary because these findings are strong predictors of residual disease. For squamous cell carcinoma, the risk of residual disease is 4% if both the endocervical margin and curettage are negative for dysplasia or malignancy, 22% if the endocervical margin alone is positive, and 33% if both are positive (66). In cases of AIS, the status of the cone margins is particularly important, with residual preinvasive and invasive disease noted in up to 25% and 3%, respectively, of cases with negative margins, and up to 80% and 7%, respectively, in cases with positive margins (67,68).

Figure 36.6 Abdominal radical trachelectomy.
Simple (Extrafascial) Hysterectomy

Type I hysterectomy is an appropriate therapy for patients with stage Ia1 tumors without lymph–vascular space invasion who are not desirous of future fertility. In such cases, lymphadenectomy is not recommended. If lymph–vascular space invasion is found, a modified radical hysterectomy with pelvic lymphadenectomy is appropriate and effective therapy.

Radical Trachelectomy

Radical trachelectomy is a procedure that is gaining popularity as a surgical management option for women with stage 1A2 and IB1 disease who desire uterine preservation and fertility. This procedure may be performed vaginally, abdominally, laparoscopically, or robotically (Fig. 36.6), and it usually is accompanied by pelvic lymphadenectomy and cervical cerclage placement. The risk of positive pelvic lymph nodes with stage Ia2 cancer may be as high as 8%, indicating the need for lymphadenectomy. Lymphadenectomy may be performed laparoscopically, robotically, or by the open laparotomy technique. Experience with this therapeutic modality is limited, although early results are promising, and it is uncertain whether the long-term outcome is similar to that of traditional therapy. **Patients who are ideal candidates for this procedure have tumors less than 2 cm in diameter and have negative lymph nodes.** Lymphadenectomy can be performed at the beginning of the procedure, and depending on those results, the procedure can be continued or abandoned. A retrospective trial comparing patients who had tumors with these attributes and were treated with either laparoscopic radical hysterectomy or laparoscopic radical trachelectomy showed similar outcomes and recurrence (69). There are limited data on subsequent pregnancy outcomes after radical trachelectomy; however, successful outcomes were reported. A study found that for women attempting
to conceive after radical trachelectomy, the 5-year cumulative pregnancy rate was 52.8%, with an increased risk of miscarriage (70). Although radical trachelectomy and lymphadenectomy are performed with curative intent, it should be remembered that if a recurrence develops, definitive therapy with surgery or radiation is necessary.

**Radical Hysterectomy**

The **radical hysterectomy** (Fig. 36.7A, B) performed most often in the United States is that described by Meigs in 1944 (71). The operation includes pelvic lymphadenectomy along with removal of most of the uterosacral and cardinal ligaments and the upper one-third of the vagina. This operation is referred to as the type III radical hysterectomy (72).

The hysterectomy described by Wertheim is less extensive than a radical hysterectomy and removes the medial half of the cardinal and uterosacral ligaments (62). This procedure is often referred to as the modified radical or type II hysterectomy. Wertheim’s original operation did not include pelvic lymphadenectomy but instead included selective removal of enlarged lymph nodes. The modified radical hysterectomy (type II) differs from the radical hysterectomy (type III) in the following ways:

**Figure 36.7 A: Radical hysterectomy.** An intraoperative photograph showing the lateral dissection during a radical hysterectomy. Note the ureter running beneath the uterine artery (tissue in the clamp). **B: Radical hysterectomy specimen.**
The uterine artery is transected at the level of the ureter, thus preserving the ureteral branch to the ureter.
The cardinal ligament is not divided near the sidewall but instead is divided close to its midportion near the ureteral dissection.
The anterior vesicouterine ligament is divided, but the posterior vesicouterine ligament is conserved.
A smaller margin of vagina is removed.
Radical hysterectomies can be further classified as extended radical hysterectomy (type IV and type V). In the type IV operation, the periureteral tissue, superior vesicle artery, and as much as three-fourths of the vagina are removed. In the type V operation, portions of the distal ureter and bladder are removed.
resected. This procedure is rarely performed because radiotherapy should be used when such extensive disease is encountered (72).

The abdomen is opened through either a midline incision or a low transverse incision after the methods of Maylard or Cherney. The low transverse incision requires division of the rectus muscles and provides excellent exposure of the lateral pelvis. It allows adequate pelvic lymphadenectomy and wide resection of the primary tumor. After the abdomen is entered, the peritoneal cavity is explored to exclude metastatic disease. The stomach is palpated to ensure that it has been decompressed to facilitate packing of the intestines. The liver is palpated, and the omentum is inspected for metastases. Both kidneys are palpated to ensure their proper placement and lack of congenital and other abnormalities. The para-aortic nodes are palpated transperitoneally.

During exploration of the pelvis, the fallopian tubes and ovaries are inspected for any abnormalities. In premenopausal patients, the ovaries can be conserved. The peritoneum of the vesicouterine fold and the rectouterine pouch should be inspected for signs of tumor extension or implantation. The cervix is palpated between the thumb anteriorly and the fingers posteriorly to determine its extent, and the cardinal ligaments are palpated for evidence of lateral tumor extension or nodularity.

Lymphadenectomy

After inspection of the abdomen and pelvis, the pelvic and para-aortic lymph nodes should be inspected and palpated. Lymph nodes suspicious for gross disease should be excised and evaluated by frozen section. If metastatic disease is identified, consideration should be given to abandoning radical surgery in favor of primary chemoradiation therapy. If the patient has no gross evidence of metastatic disease, the pelvic lymphadenectomy is begun.

Pelvic Lymphadenectomy

The pelvic lymphadenectomy is begun by opening the round ligaments at the pelvic sidewall and developing the paravesical and pararectal spaces. The ureter is elevated on the medial flap by a Deaver retractor to expose the common iliac artery. The common iliac and external iliac nodes are dissected, with care taken to avoid injuring the genitofemoral nerve, which lies laterally on the psoas muscle. At the bifurcation of the common iliac artery, the external iliac node chain is divided into lateral and medial portions.

The lateral chain is stripped free from the artery to the circumflex iliac vein distally. A hemoclip is placed across the distal portion of the lymph node chain to reduce the incidence of lymphocyst formation. The medial chain is dissected. The obturator lymph nodes are dissected; for this procedure, the lymph nodes are grasped just under the external iliac vein, and traction is applied medially. In most patients the obturator artery and vein are dorsal to the obturator nerve; however, 10% have an aberrant vein arising from the external iliac vein. The node chain is separated from the nerve and vessels and
clipped caudally. Dissection continues cephalad to the hypogastric artery. The cephalad portion of the obturator space should be entered lateral to the external iliac artery and medial to the psoas muscle, where the remainder of the obturator node tissue can be dissected as far cephalad as the common iliac artery. Drainage of the pelvic and para-aortic lymph node beds is not performed because of the increase in complications in patients in whom drains were used (73).

Figure 36.8 The pelvic ligaments and spaces. (From Berek JS, Hacker NF. Berek & Hacker’s Gynecologic Oncology. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010:360, with permission.)

Patients who have bulky cervical tumors or grossly positive pelvic nodes, or for whom frozen section evaluation will be performed, should undergo para-aortic lymph node evaluation to determine the full extent of disease and to guide adjuvant therapy.

Para-aortic Lymph Node Evaluation

The bowel is packed to expose the peritoneum overlying the bifurcation of the aorta. The peritoneum is incised medial to the ureter and over the right common iliac artery. A retractor is placed retroperitoneally to expose the aorta and the vena cava. Any enlarged para-aortic lymph nodes are removed, hemoclips are applied for hemostasis, and specimens are sent for analysis by frozen section. If the lymph nodes are positive for metastatic cancer, an option is to discontinue the operation and treat the patient with radiation therapy (71). If the lymph nodes are negative for disease, the left side of the aorta is palpated through the peritoneal incision with a finger passed under the inferior mesenteric artery. The lymph nodes on this side of the aorta are more lateral and nearly behind the aorta and the common iliac artery. If the left para-aortic lymph nodes appear healthy and the cervical tumor is small with no suspicious pelvic lymph nodes, these additional lymph nodes are not submitted for frozen-section analysis. If they are
removed, they may be dissected through the incision made for the right para-aortic nodes, or they may be dissected after reflection of the sigmoid colon medially.

**Development of Pelvic Spaces**

*The pelvic spaces are developed by sharp and blunt dissection (Fig. 36.8).*

**The paravesical space is bordered by the following structures:**

- The obliterated umbilical artery running along the bladder medially.
- The obturator internus muscle along the pelvic sidewall laterally.
- The cardinal ligament posteriorly.
- The pubic symphysis anteriorly.

The attachments of the vagina to the tendinous arch form the floor of the paravesical space.

**The pararectal space is bordered by the following structures:**

- Rectum medially
- Cardinal ligament anteriorly
- Hypogastric artery laterally
- Sacrum posteriorly

The coccygeus (levator ani) muscle forms the floor of the pararectal space.

The development of these spaces before pelvic lymphadenectomy will aid in identification and dissection of the pelvic lymph nodes and dissection of the ureter as it passes into the vesicouterine ligament tunnel.

**Dissection of the Bladder**

*The dissection of the bladder from the anterior part of the cervix and vagina is a critical step. Occasionally, tumor extension into the base of the bladder (which cannot be detected with cystoscopy) precludes adequate mobilization of the bladder flap, leading to the abandonment of the operation. Therefore, this portion of the operation should be undertaken early in the procedure.* The bladder should be mobilized off of the upper third of the vagina to remove the tumor safely and with adequate margins.

**Dissection of the Uterine Artery**

The superior vesicle artery is dissected away from the cardinal ligament at a point near the uterine artery. *The uterine artery, which usually arises from the superior vesicle artery, is thus isolated and divided, preserving the superior vesicle arteries.* The uterine vessels are brought over the ureter by application of gentle traction. Occasionally, the uterine vein passes under the ureter.

**Dissection of the Ureter**
The ureter is dissected free from the medial peritoneal flap at the level of the uterosacral ligament. As the ureter passes near the uterine artery, there is a consistent arterial branch from the uterine artery to the ureter. This branch is sacrificed in the standard radical (type III) hysterectomy but preserved in the modified radical (type II) hysterectomy. Dissection of the ureter from the vesicouterine ligament (ureteral tunnel) may now be accomplished. If the patient has a deep pelvis, ligation of the uterosacral and cardinal ligaments may be undertaken first to bring the ureteral tunnel dissection closer to the operator. The roof of the ureteral tunnel is the anterior vesicouterine ligament. It should be ligated and divided to expose the posterior ligament. The posterior ligament is divided in the radical (type III) hysterectomy but conserved in the modified radical (type II) hysterectomy.

Posterior Dissection

The peritoneum across the cul-de-sac is incised, exposing the uterosacral ligaments. The rectum is rolled free from the uterosacral ligaments, which are divided midway to the sacrum in a radical (type III) hysterectomy and near the rectum in the modified radical (type II) operation. This allows the operator to isolate and separate the cardinal ligament from the rectum. A surgical clamp is placed on the cardinal ligament at the lateral pelvic sidewall in a radical hysterectomy and at the level of the ureteral bed in the modified radical procedure. A clamp is placed on the specimen side to maintain traction and to ensure that the full cardinal ligament is excised with the specimen. A right-angled clamp is placed caudad to this clamp across the paravaginal tissues. A second paravaginal clamp is usually needed to reach the vagina.

The vagina is entered anteriorly, and a suitable margin of proximal vagina is removed with the specimen. More vaginal epithelium can be excised if necessary, depending on the previous colposcopic findings. The vaginal edge may be sutured in a hemostatic fashion and left open with a drain from the pelvic space or closed with a suction drain placed percutaneously. The ureteral fistula and pelvic lymphocyst rates from these two techniques are similar.

Complications of Radical Hysterectomy

Acute Complications

The acute complications of radical hysterectomy include (74):

- Blood loss (average, 0.8 L)
- Ureterovaginal fistula (1% to 2%)
- Vesicovaginal fistula (1%)
- Pulmonary embolus (1% to 2%)
- Small bowel obstruction (1%)
- Febrile morbidity (25% to 50%)

Febrile morbidity is most often caused by pulmonary infection (10%) and is seen
frequently with pelvic cellulitis (7%) and urinary tract infection (6%). Wound infection, pelvic abscess, and phlebitis all occur in fewer than 5% of patients (75).

Subacute Complications

The subacute effects of radical hysterectomy are postoperative bladder dysfunction and lymphocyst formation. For the first few days after radical hysterectomy, bladder volume is decreased, and filling pressure is increased. The sensitivity to filling is diminished, and the patient is unable to initiate voiding. The cause of this dysfunction is unclear. It is important to maintain adequate bladder drainage during this time to prevent overdistention. Bladder drainage is usually accomplished with a suprapubic catheter. It is more comfortable for the patient and allows the physician to perform cystometrography and determine residual urine volume without the need for frequent catheterization. In addition, the patient is able to accomplish voiding trials at home by clamping the catheter, voiding, and releasing to check the residual urine level. Cystometrography may be performed 3 to 4 weeks after surgery. For the catheter to be discontinued, the patient must be able to sense the fullness of the bladder, initiate voiding, and void with a residual urine level of less than 75 to 100 mL. Otherwise, voiding trials should continue at home until these criteria can be fulfilled.

Lymphocyst formation occurs in fewer than 5% of patients, and the cause is uncertain (75). Adequate drainage of the pelvis after radical hysterectomy may be an important step in prevention. However, routine placement of retroperitoneal drains did not reduce this morbidity (73). Ureteral obstruction, partial venous obstruction, and thrombosis may occur from lymphocyst formation. Simple aspiration of the lymphocyst is generally not curative, but percutaneous catheters with chronic drainage may allow healing. If this treatment is unsuccessful, operative intervention with excision of a portion of the lymphocyst wall and placement of either large bowel or omentum into the lymphocyst should be performed.

Chronic Complications

The most common chronic effect of radical hysterectomy is bladder hypotonia or, in extreme instances, atony. This condition occurs in about 3% of patients, regardless of the method of bladder drainage used (76,77). It may be a result of bladder denervation and not simply a problem associated with bladder overdistention (78). Voiding every 4 to 6 hours, increasing intra-abdominal pressure with Credé’s maneuver, and intermittent self-catheterization may be used to manage bladder hypotonia.

Ureteral strictures are uncommon in the absence of postoperative radiation therapy, recurrent cancer, or lymphocyst formation (78). If the stricture is associated with lymphocyst formation, treatment of the lymphocyst usually alleviates the problem. Strictures that occur after radiation therapy should be managed with ureteral stenting. If a ureteral stricture is noted in the absence of radiotherapy or lymphocyst formation, recurrent carcinoma is the most common cause. A CT scan of the area of obstruction should be obtained and cytologic assessment by FNA should be performed if
there is a target lesion to exclude carcinoma. If the results of these tests are negative, a
ureteral stent may be placed to relieve the stricture. Close observation for recurrent
carcinoma is necessary, and the diagnosis of recurrence may ultimately require
laparotomy.

**Nerve-Sparing Radical Hysterectomy**

Nerve-sparing radical hysterectomies were described in recent years in an
tempt to diminish the bladder dysfunction, sexual dysfunction, and colorectal
motility disorders commonly encountered after traditional radical
hysterectomy. Multiple techniques were described involving the identification of the
pelvic autonomic nerves at the sacral promontory followed by various surgical methods of
nerve preservation as the nerves transit the cardinal ligaments. These techniques are
promising and in small series did reduce postoperative bladder dysfunction (79,80).

**Laparoscopic Radical Hysterectomy**

Laparoscopic-assisted radical vaginal hysterectomy is being performed with
creasing frequency in highly selected patients. In one large series of 200 women
with stages IA1 to IIB cervical cancer treated with laparoscopic lymphadenectomy
followed by radical vaginal hysterectomy, the authors found a 5-year survival rate
comparable to patients treated with a similar abdominal approach and a comparable rate
of intraoperative complications (81).

The use of laparoscopy in cervical cancer patients is appealing because it may lead to
less blood loss, improved cosmetic results, shorter duration of hospitalization, and faster
recovery.

**Robotic Laparoscopic Radical Hysterectomy**

Robotic laparoscopic radical hysterectomy is a relatively new technique. Proponents argue
that in highly selected patients it can decrease hospital admission time and decrease the
surgical morbidity in obese patients. One study reports comparable body mass index, operative
times, parametrial margin, and number of lymph nodes collected when compared to open cases. Robotic cases had significantly shorter hospital stays and blood
loss, while having significantly larger incidence of postoperative bladder dysfunction. The
technique is still too new to tabulate cancer outcome data (82,83).

**Sentinel Lymph Node Evaluation**

Sentinel lymph node detection has become an integral part of the management strategy
for breast cancer and melanoma and is being investigated as a diagnostic tool in multiple
human malignancies, including carcinoma of the cervix. The sentinel node is a specific
lymph node (or nodes) that is the first to receive drainage from a malignancy and is a
primary site of nodal metastasis. In theory, the presence or absence of metastatic
disease in the sentinel node should reflect the status of the nodal basin as a whole. Thus,
a negative sentinel lymph node would allow omission of lymphadenectomy of the involved nodal basin. Sentinel lymph nodes are detected through perilesional injection of radiolabeled technicium-99 or blue dye followed by intraoperative identification of the sentinel lymph nodes utilizing handheld gamma probes or visual identification of blue-stained nodes. These techniques are primarily applicable in patients with early-stage disease and clinically negative lymph nodes, in whom lymph node status may influence the extent of the procedure or the use of adjuvant treatment.

Although data utilizing sentinel lymph node detection techniques in cervical cancer are limited, several interesting conclusions can be drawn from completed studies. Sentinel nodes can be detected in 80% to 100% of cervical cancer patients, and these rates were confirmed by both laparotomy and laparoscopy. A combination of dye and radiolabeled techniques appears to be superior for the detection of sentinel lymph nodes over either technique used alone. Test sensitivity of 65% to 87% can be expected with a 90% to 97% negative predictive value. The likelihood of detecting sentinel nodes may depend on the tumor volume, the time from injection to retrieval of the sentinel nodes, and the volume of dye or radiolabeled tracer injected. Sentinel node detection rates do not appear to be influenced by prior cold knife cone biopsy. False-negative results were reported. The role of sentinel node detection in cervix cancer is investigational; although the technique is promising, complete lymphadenectomy, when indicated, remains the standard of care (84).
Postoperative Management

Prognostic Variables for Early-Stage Cervical Cancer (Ia2–IIa)
The survival of patients with early-stage cervical cancer after radical hysterectomy and pelvic lymphadenectomy depends on the presence or absence of several intermediate and high-risk pathologic factors (76,85–99).

Intermediate risk factors for recurrent disease are:
- Large tumor size
- Cervical stromal invasion to the middle or deep one-third
- Lymph–vascular space invasion

High risk factors for recurrent disease are:
- Positive or close margins
- Positive lymph nodes
- Microscopic parametrial involvement

Patients treated with radical hysterectomy who have intermediate or high risk factors have a 30% and 40% risk, respectively, of recurrence within 3 years (100–102).

Lesion Size
Lesion size is an independent predictor of survival. Patients with lesions smaller than 2 cm have a survival rate of approximately 90%, and patients with lesions larger than 2 cm have a 60% survival rate (89). When the primary tumor is larger than 4 cm, the survival rate drops to 40% (87,97). An analysis of a Gynecologic Oncology Group (GOG) prospective study of 645 patients showed a 94.6% 3-year disease-free survival rate for patients with occult lesions, 85.5% for those with tumors smaller than 3 cm, and 68.4% for patients with tumors larger than 3 cm (98).

Depth of Invasion
Patients in whom depth of invasion is less than 1 cm have a 5-year survival rate of approximately 90%, but the survival rate falls to 63% to 78% if the depth of invasion is more than 1 cm (76,98,102–105).

Parametrial Spread
Patients with spread to the parametrium have a 5-year survival rate of 69%, compared with 95% when the parametrium is negative. When the parametrium is involved and pelvic lymph nodes are positive, the 5-year survival rate falls to 39% to 42% (90,106).

Lymph–Vascular Space Involvement
The significance of finding lymph–vascular space involvement is somewhat controversial. Several reports show a 50% to 70% 5-year survival rate when lymph–vascular space invasion is present and a 90% 5-year survival rate when invasion is absent \((76,89,93,107,108)\). Others found no significant difference in survival if the study is controlled for other risk factors \((98,99,109–112)\). Lymph–vascular space involvement may be a predictor of lymph node metastasis and not an independent predictor of survival.

**Lymph Nodes**

The variable that is most independently predictive of survival is the status of the lymph nodes. Patients with negative nodes have an 85% to 90% 5-year survival rate, whereas the survival rate for those with positive nodes ranges from 20% to 74%, depending on the number of nodes involved and the location and size of the metastases \((94–96,99,102,105,111–113)\).

Data on lymph node status is summarized as follows:

- When the common iliac lymph nodes are positive, the 5-year survival rate is about 25%, compared with about 65% when only the pelvic lymph nodes are involved \((106,114,115)\).
- Bilateral positive pelvic lymph nodes portend a less favorable prognosis (22% to 40% survival rate) than unilateral positive pelvic nodes (59% to 70%) \((114,115)\).
- The presence of more than three positive pelvic lymph nodes is accompanied by a 68% recurrence rate, compared with 30% to 50% when three or fewer lymph nodes are positive \((94,112)\).
- Patients in whom tumor emboli are the only findings in the pelvic lymph node have an 82.5% 5-year survival rate, whereas the survival rate is 62.1% and 54% with microscopic invasion and macroscopic disease, respectively \((84)\).

Given the high risk of recurrent disease in surgically treated patients with early-stage cervical cancer who exhibit intermediate- or high-risk pathologic factors, adjuvant radiation or chemoradiation therapy should be considered.
Primary Radiation Therapy

Radiotherapy can be used to treat all stages of cervical cancer, with cure rates of about 70% for stage I, 60% for stage II, 45% for stage III, and 18% for stage IV (3). A comparison of surgery and radiation for treatment of low-stage disease is shown in Table 36.5. Primary radiation treatment plans consist of a combination of external teletherapy to treat the regional lymph nodes and to decrease the tumor volume, and brachytherapy delivered by intracavitary applicators or interstitial implants to provide a treatment boost to the central tumor. Intracavitary therapy alone may be used in patients with early disease when the incidence of lymph node metastasis is negligible.

The treatment sequence depends on tumor volume. Stage IB lesions smaller than 2 cm may be treated first with an intracavitary source to treat the primary lesion, followed by external therapy to treat the pelvic lymph nodes. Larger lesions require external radiotherapy first to shrink the tumor and to reduce the anatomic distortion caused by the cancer. Such a treatment strategy enables the therapist to achieve intracavitary dosimetry. The usual doses delivered are 7,000 to 8,000 cGy to point A (defined as 2 cm superior to the external cervical os and 2 cm lateral to the internal uterine canal) and 6,000 cGy to point B (defined as 3 cm lateral to point A), limiting the bladder and rectal dosage to less than 6,000 cGy. To achieve this level, it is necessary to adequately pack the bladder and bowel away from the intracavitary source. Localization films and careful calculation of dosimetry are mandatory to optimize the dose of radiation and to reduce the incidence of bowel and bladder complications. Local control
depends on delivering an adequate dose to the tumor from the intracavitary source.

**Although brachytherapy was traditionally prescribed using a low-dose rate technique, high-dose rate techniques are becoming more popular, and controversy exists over which technique is superior.** Low-dose rates use caesium-137 as the source, whereas high-dose rates use iridium-192. Proponents of high-dose rate techniques argue that the exposure of radiation to medical personnel is less, ambulatory therapy is possible, and total treatment time is less. Advocates of low-dose rate techniques cite literature suggesting that complication rates are higher with higher-dose rate therapy. Several published trials show that there may be slight stage-related differences in survival between patients treated with low- and high-dose rate regimens, but the techniques have comparable survival and complication rates (116–118).

As noted, clinical staging is imprecise and fails to accurately predict disease extension to the para-aortic nodes in 7% of patients with stage IB, 18% with stage IIB, and 28% with stage III disease (119). Such patients will have "geographic" treatment failures if standard pelvic radiotherapy ports are used. As a result, treatment plans for these patients are individualized based on CT scans, PET scans, and biopsies of the para-aortic lymph nodes for consideration of extended-field radiotherapy. The routine use of extended-field radiation for prophylactic para-aortic radiation without documentation of distant metastasis to the para-aortic nodes was evaluated and is not practiced because of the increased enteric morbidity associated with this treatment modality.

**Intensity Modulated Radiation Therapy**

A method of providing external beam therapy, known as intensity modulated radiation therapy (IMRT), may be a significant therapeutic development. This technique uses computer-generated algorithms that accurately distinguish between target treatment volumes and normal tissue. The radiation beam intensity is modulated to optimize the delivery of radiation to the specified treatment volume while sparing adjacent normal tissue. The result appears to be much more accurate treatment of the tumor with minimal toxicity. Emphasizing this point is a study in 40 gynecologic cancer patients in which IMRT was used. Excellent coverage of the planned treatment volume was obtained, with no patient suffering grade 3 toxicity, and only 60% of patients suffering grade 2 toxicity, compared with a historical rate of 90% toxicity with conventional techniques (120). This technique is especially promising for treating cervical cancer because it allows higher doses to be delivered much more precisely, allowing patients who are unable to undergo brachytherapy because of pelvic anatomy and tumor geometry a chance for curative therapy. Studies utilizing IMRT in treating patients with cervical cancer are limited, but experience with this technique is increasing. Initial papers comparing the two techniques report decreased toxicity with comparable locoregional control, but they do not have long-term data on 5-year survival rates, so this technique is yet to be validated (121).
Adjuvant Radiation

In an effort to improve survival rates, postoperative radiotherapy was recommended for patients with high and intermediate risk factors such as metastasis to pelvic lymph nodes, invasion of paracervical tissue, deep cervical invasion, or positive surgical margins (76,86,89,90,106,111,112,122). Although most authors agree that postoperative radiotherapy is necessary in the presence of positive surgical margins, the use of radiation in patients with other high risk factors is controversial. Increasing evidence supports the use of adjuvant radiation. Particularly controversial, but best studied, is the use of radiation in the presence of positive pelvic lymph nodes. The rationale for treatment is the knowledge that pelvic lymphadenectomy does not remove all of the nodal and lymphatic tissue and subsequent radiotherapy can eradicate microscopic disease. The hesitancy to recommend postoperative radiotherapy derives from the significant rate of postradiation bowel and urinary tract complications (123). Most of the available data are retrospective. However, a randomized study by the GOG comparing radiation with no further treatment for patients at high risk for recurrence with negative pelvic nodes revealed a 30% serious complication rate, 16% reoperation rate, and a 2% mortality rate as a result of treatment-related complications (124).

Based on retrospective studies, it appears that postoperative radiation therapy for positive pelvic nodes can decrease pelvic recurrence but does not improve 5-year actuarial survival rates. One multi-institutional study showed no difference in survival in patients with three or fewer positive pelvic nodes (59% versus 60%) (112). However, there seemed to be a benefit when radiotherapy was given to those with more than three positive nodes.

In a study of 60 pairs of irradiated and nonirradiated women matched for age, lesion size, number, and location of positive nodes after radical hysterectomy, no significant difference was found in projected 5-year survival rates (72% for surgery alone, 64% for surgery plus radiation) (125). The proportion of recurrences confined to the pelvis was 67% in patients treated with surgery only and 27% in patients treated with postoperative radiation (p = 0.03). In a Cox regression analysis of 320 women who underwent radical hysterectomy, for the 72 who received postoperative radiation, there was a significant decrease in pelvic recurrence but no survival benefit (95). A multi-institutional retrospective study was performed on 185 women with positive pelvic nodes after radical hysterectomy, including 103 who received postoperative radiotherapy (97). Multivariate analysis disclosed that radiotherapy was not an independent predictor of survival, whereas age, lesion diameter, and number of positive nodes did influence survival. These authors concluded that additional treatment is needed to improve survival rates. Because survival is limited by distant recurrence, the addition of chemotherapy to postoperative radiotherapy was proposed. A 75% disease-free survival rate was reported at 3 years in 40 high-risk patients given cisplatin, vinblastine, and bleomycin after radical hysterectomy, and a 46% disease-free survival rate was found in 79 comparable patients who refused treatment (126). Only 4 (11.8%) of 34 patients with positive pelvic nodes had recurrences, whereas disease recurred in 8 (33%) of 24 untreated patients with
positive nodes. An 82% rate of disease-free survival was reported at 2 years among 32 patients who were treated postoperatively with radiation therapy plus cisplatin and bleomycin (127).

**The location of lymph node metastases apparently is relevant to postirradiation recurrence rates.** When common iliac lymph nodes are involved, the survival rate drops to 20%. As the number of positive pelvic nodes increases, the percentage of positive common iliac and low para-aortic nodes increases (i.e., 0.6% when pelvic lymph nodes are negative, 6.3% with one positive pelvic node, 21.4% with two or three positive nodes, and 73.3% with four or more positive nodes). This information was used to recommend extended-field radiotherapy to patients with positive pelvic lymph nodes in an attempt to treat undetected extrapelvic nodal disease (107). A 3-year disease-free survival rate of 85% occurred in patients with positive pelvic nodes, and a survival rate of 51% occurred in patients with positive common iliac nodes; these rates are better than the survival rates of 50% and 23%, respectively, for historical control groups receiving radiotherapy to the pelvis alone.

The GOG reported the results of a randomized controlled trial on patients with cervical cancer treated by radical hysterectomy and found to have at least two of the following risk factors: capillary lymphatic space invasion, more than one-third stromal invasion, and large tumor burden (101). A total of 277 patients were entered into the study, with 140 patients randomized to no further therapy and 137 patients randomized to adjuvant pelvic radiotherapy. **Patients with these risk factors who were treated postoperatively with radiation therapy had a statistically significant (47%) decrease in recurrent disease.** After extensive follow-up, there is no statistically significant difference in mortality rates (128). The morbidity with combination therapy was acceptable, with a low rate of enteric and urinary complications. A second GOG study of patients with high-risk cervical cancer randomized patients to concurrent chemoradiation therapy or radiation therapy alone, as discussed below (100).

**Concurrent Chemoradiation**

Radiation therapy fails to achieve tumor control in 20% to 65% of patients with advanced cervical cancer. Chemotherapy, despite its relative lack of success in treating patients with cervical cancer, was evaluated as neoadjuvant treatment in combination with surgery. **Concomitant use of chemotherapy and radiation was studied extensively by the GOG and results of five randomized studies were reported.** The concept of chemoradiation encompasses the benefits of systemic chemotherapy with the benefits of regional radiation therapy. **The use of chemotherapy to sensitize cells to radiation therapy improved local–regional control.** These new results changed the way cervical cancer is treated in many medical centers.

An Intergroup trial involving the GOG, the Southwestern Oncology Group, and the Radiation Therapy Oncology Group evaluated postoperative chemoradiation therapy in patients with stage IA2, IB, or IIA cervical cancer.
who had positive pelvic lymph nodes, positive parametrial extension, or positive vaginal margins at the completion of radical hysterectomy (127). A total of 243 patients were assessed in this trial, with 127 receiving chemoradiation (cisplatin, 5-fluorouracil [5-FU], radiation therapy) and 116 receiving radiation. The results of this trial showed a statistically significant improvement in progression-free survival and overall survival at 43 months for the patients receiving concurrent chemoradiation. The 4-year survival rates for the patients receiving chemoradiation versus radiation alone were 81% and 71%, respectively. The toxicity levels in the two groups were acceptable, with a higher rate of hematologic toxicity in the concurrent chemoradiation arm. This study showed that in patients with these high-risk factors after radical hysterectomy for stage IA2, IB, and IIA disease, chemoradiation is the postoperative treatment of choice.

Concurrent chemoradiation was evaluated in patients with advanced cervical carcinoma. GOG protocol 85 was a prospective study that enrolled patients with stage IIb to IVA cervical cancer and compared concurrent chemoradiation (129). There were 177 patients treated with cisplatin, 5-FU, and radiation. These patients were compared with 191 patients treated with hydroxyurea and radiation. The median follow-up of patients who were alive at the time of the analysis was 8.7 years. Patients who received concurrent chemoradiation and were treated with cisplatin and 5-FU had a statistically significant improvement in progression-free interval and overall survival (129). Hematologic toxicity levels in the two groups were similar. This study showed that cisplatin-based concurrent chemoradiation was a superior treatment when compared with hydroxyurea and concurrent radiation.

GOG Protocol 120 was initiated to evaluate patients with negative para-aortic nodes and cervical carcinoma stage IIB to IVA treated with concurrent chemoradiation. The treatment arms in this study consisted of radiation plus weekly cisplatin; or cisplatin, 5-FU, and hydroxyurea; or hydroxyurea. There were 176 patients in the weekly cisplatin arm; 173 patients in the cisplatin, 5-FU, and hydroxyurea arm; and 177 patients in the hydroxyurea arm (130). The two treatment arms with cisplatin-based chemotherapy and radiation showed an improvement in progression-free interval and overall survival at a median follow-up of 35 months. The relative risks for progression of disease or death were 0.55 and 0.57, respectively, for patients treated with cisplatin-based chemotherapy and radiation, compared with the patients treated with hydroxyurea and radiation (130). This study confirmed the findings of GOG Protocol 85 and reaffirmed the finding that cisplatin-based concurrent chemoradiation is the treatment of choice for patients with advanced-stage cervical cancer.

A third GOG trial evaluated patients with stage IB to IVA cervical cancer. Of the patients enrolled in this study, 70% had stage IB or IIA disease (131). A total of 403 patients were enrolled and evaluated. The 5-year survival rates were 73% in patients treated with chemoradiation and 58% in patients treated with radiation therapy alone. The cumulative rates of disease-free survival at 5 years were 67% in patients treated with concurrent chemoradiation and 40% in patients treated with radiation therapy alone. Survival and
progression-free intervals for patients receiving concurrent chemoradiation were significantly improved (131). The results of this study suggested that chemoradiation is the treatment of choice for stage IIB to IVA disease and that those patients with stage IB2 and IIA disease may benefit from chemoradiation.

A GOG study of chemoradiation comparing concurrent cisplatin and radiation with radiation alone in patients with bulky IB cervical cancer included adjuvant hysterectomy after completion of the radiation (132). There were 183 patients assigned to the concurrent chemotherapy and radiation arm and 186 patients treated with radiation alone. The median duration of follow-up was 36 months, with disease recurrence detected in 37% of the patients treated with radiation alone, compared with 21% who were treated with concurrent chemoradiation (132). The 3-year survival rates were 83% in the group who received concurrent chemoradiation and 74% in the group who received radiation alone (132). The study also included adjuvant hysterectomy after completion of radiation treatment. Because the results did not show an improvement in survival by using adjuvant hysterectomy, the authors concluded that adjuvant hysterectomy would not be part of their recommendations. This study supports the results of previous studies and shows that patients with bulky stage IB and IIA cervical cancer treated with concurrent chemoradiation have survival rates superior to those treated with radiation alone. These two studies indicate that patients with bulky stage IB and IIA disease should have primary treatment consisting of chemoradiation, with the chemotherapy agent being weekly cisplatin.

Surgical Staging before Radiation
Surgical staging procedures designed to discover positive lymph nodes may be forgone with use of PET/CT imaging studies. The use of transperitoneal exploration was associated with a 16% to 33% mortality rate from radiotherapy-induced bowel complications and a 5-year survival rate of only 9% to 12% (133,134). To avoid these complications, extraperitoneal dissection of the para-aortic nodes is recommended, and the radiation dose should be reduced to 5,000 cGy or less (135,136). When this approach is used, postradiotherapy bowel complications occur in fewer than 5% of patients, and the 5-year survival rate is 15% to 26% in patients with positive para-aortic nodes (19,137,138). Survival appears to be related to the amount of disease in the para-aortic nodes and to the size of the primary tumor. In patients whose metastases to the para-aortic lymph nodes are microscopic and whose central tumor has not extended to the pelvic sidewall, the 5-year survival rate improves to 20% to 50% (139,140). Surgical staging techniques have improved to include laparoscopic assessment of the para-aortic and pelvic lymph nodes. Studies demonstrated benefit from surgical staging with improved survival and changes in treatment plans in 40% of patients (136,137). When PET/CT is compared with surgicopathological staging of para-aortic lymph nodes, some patients with histologically
positive para-aortic lymph nodes are missed with surgicopathological staging (141).
Management of Grossly Positive Para-aortic Lymph Nodes

The management of patients with macroscopic or grossly positive para-aortic lymph nodes discovered at the time of surgery or by imaging studies is controversial. It is likely that grossly positive nodes are beyond the ability of radiation therapy alone to sterilize. Therefore, to improve survival, additional therapy is required. In a representative study of the multiple reports in the literature, lymph node metastases were noted in 133 of 266 patients. Pelvic and para-aortic nodes were positive in 44 patients and positive para-aortic nodes were noted in only 2 patients. Five- and 10-year survival rates were similar for patients with macroscopically positive resectable nodes and microscopically positive nodes. Patients with unresectable nodal disease had a worse survival rate than those with resectable disease. All patients underwent extraperitoneal lymph node resections and subsequent radiotherapy. There was a 10% incidence of severe morbidity related to radiation use. Consistent with other reports in the literature, this study showed that extraperitoneal debulking lymphadenectomy confers a survival advantage similar to that enjoyed by patients with micrometastatic disease without additional morbidity (27).

Prophylactic Para-aortic Radiation Therapy

Prophylactic extended-field radiation therapy is an alternative to surgical staging of the para-aortic lymph node chain in women with advanced cervical cancer judged to be at high risk but without radiological or clinical evidence of para-aortic lymph node involvement. This treatment strategy was evaluated in 441 patients with stages I to III disease (142). High rates of gastrointestinal toxicity were noted in the treatment group. There was no difference in disease-free survival or overall survival between the control and treated groups, although treated patients had fewer para-aortic failures. A lack of difference in survival rates in this study may be related to high local and regional failure rates, suggesting that ideal patients for prophylactic radiotherapy would be those in whom there is a high likelihood of achieving pelvic control. A survival benefit was noted in a study by the Radiation Therapy Oncology Group, in which 367 patients with stages IB to IIB disease were randomized to pelvic radiotherapy versus pelvic and extended field radiotherapy (143). The extended field treatment arm suffered more grade 4 and 5 toxicity, confirming previous studies. Complicating the issue is another study from the Radiation Therapy Oncology Group that revealed that in locally advanced cervical cancer, pelvic radiation therapy with concurrent cisplatin chemotherapy was superior to extended-field radiation therapy (131). The appropriate role of prophylactic para-aortic radiation therapy is still under investigation.

Supraclavicular Lymph Node Biopsy

Although not standard practice, the performance of a supraclavicular lymph node biopsy was advocated in patients with positive para-aortic lymph nodes before the initiation of extended-field irradiation and in patients with a central recurrence before exploration for
possible exenteration. The incidence of metastatic disease in the supraclavicular lymph nodes in patients with positive para-aortic lymph nodes is 5% to 30% (144). Node enlargement and increased metabolic activity can be assessed with chest PET/CT scanning. Cytologic assessment by FNA can obviate the need for an excisional biopsy and should be performed if any enlarged nodes are present. If the scalene lymph nodes are positive, chemotherapy should be considered.

Complications of Radiation Therapy

Perforation of the uterus may occur with the insertion of the uterine tandem. This is particularly a problem for elderly patients and those who had a previous diagnostic conization procedure. When perforation is recognized, the tandem should be removed, and the patient should be observed for bleeding or signs of peritonitis. Survival may be decreased in patients who have uterine perforation, possibly because these patients have more extensive uterine disease (145). Fever may occur after insertion of the uterine tandem and ovoids. Fever most often results from infection of the necrotic tumor and occurs 2 to 6 hours after insertion of the intracavitary system. If uterine perforation was excluded by ultrasonography, intravenous broad-spectrum antibiotic coverage, usually with a cephalosporin, should be administered. If the fever does not decrease promptly or if the temperature is higher than 38.5°C, an aminoglycoside and a bacteroides species–specific antibiotic should administered. If fever persists or if the patient shows signs of septic shock or peritonitis, the intracavitary system must be removed. Antibiotics are continued until the patient recovers, and the intracavitary application is delayed for 1 to 2 weeks.

Acute Morbidity

The acute effects of radiotherapy are caused by ionizing radiation on the epithelium of the intestine and bladder and occur after administration of 2,000 to 3,000 cGy. Symptoms include diarrhea, abdominal cramps, nausea, frequent urination, and occasionally bleeding from the bladder or bowel mucosa. Bowel symptoms can be treated with a low-gluten, low-lactose, and low-protein diet. Antidiarrheal and antispasmodic agents may help. Bladder symptoms may be treated with antispasmodic medication. Severe symptoms may require a week of rest from radiotherapy.

Chronic Morbidity

The chronic effects of radiotherapy result from radiation-induced vasculitis and fibrosis and are more serious than the acute effects. These complications occur several months to years after radiotherapy is completed. The bowel and bladder fistula rate after pelvic radiation therapy for cervical cancer is 1.4% to 5.3%, respectively (59,61). Other serious toxicity (e.g., bowel bleeding, stricture, stenosis, or obstruction) occurs in 6.4% to 8.1% of patients (59,61).

Proctosigmoiditis
Bleeding from proctosigmoiditis should be treated with a low-residue diet, antidiarrheal medications, and steroid enemas. In extreme cases, a colostomy may be required to rest the bowel completely. Occasionally resection of the rectosigmoid must be performed.

Rectovaginal Fistula

Rectovaginal fistulas or rectal strictures occur in fewer than 2% of patients. The successful closure of fistulas with bulbocavernosus flaps or sigmoid colon transposition was reported (146,147). Occasionally, resection with anastomosis is feasible. Diversion resulting in colostomy may be the optimal therapy in patients who have poor vascular supply to the pelvis and a history of an anastomotic leak or breakdown from prior repairs.

Small Bowel Complications

Patients with previous abdominal surgery are more likely to have pelvic adhesions and thus sustain more radiotherapy complications in the small bowel. The terminal ileum may be particularly susceptible to chronic damage because of its relatively fixed position at the cecum. Patients with small bowel complications have a long history of crampy abdominal pain, intestinal rushes, and distention characteristic of partial small bowel obstruction. Often, low-grade fever and anemia accompany the symptoms. Patients who have no evidence of disease should be treated aggressively with total parenteral nutrition, nasogastric suction, and early surgical intervention after the anemia resolves and good nutritional status is attained. The type of procedure performed depends on individual circumstances (148). Small bowel fistulas that occur after radiotherapy rarely close spontaneously while total parenteral nutrition is maintained. Recurrent cancer should be excluded; aggressive fluid replacement, nasogastric suction, and wound care should be instituted. Fistulography and a barium enema should be performed to exclude a combined large and small bowel fistula. The fistula-containing loop of bowel may be either resected or isolated and left in situ. In the latter case, the fistula will act as its own mucous fistula.

Urinary Tract

Chronic urinary tract complications occur in 1% to 5% of patients and depend on the dose of radiation to the base of the bladder. Vesicovaginal fistulas are the most common complication and usually require supravesical urinary diversion. Occasionally, a small fistula can be repaired with either a bulbocavernosus flap or an omental pedicle. Ureteral strictures are usually a sign of recurrent cancer, and a cytologic sample should be obtained at the site of the obstruction using FNA guided by a CT scan. If the findings are negative, the patient should undergo exploratory surgery to evaluate the presence of recurrent disease. If radiation fibrosis is the cause, ureterolysis may be possible or indwelling ureteral stents may be passed through the open urinary bladder to relieve obstruction.
Chemotherapy

Neoadjuvant Chemotherapy
Randomized trials were initiated by the GOG and other large centers to determine the efficacy of neoadjuvant chemotherapy. In the era of effective chemoradiation therapy, there is no evidence that neoadjuvant chemotherapy offers superior results or a survival advantage over standard therapy.

Chemotherapy for Advanced Disease
Chemotherapy was studied in advanced cervical cancer with mixed results. Single-agent chemotherapy was the standard for advanced or recurrent disease. Active agents include cisplatin, carboplatin, paclitaxel, and ifosfamide, but response rates are only 10% to 20% with a median duration of only 4 to 6 months. A number of trials were performed to determine whether multiagent chemotherapy is superior. The GOG Protocol 149 studied patients with histologically confirmed, advanced stage (IVb), recurrent or persistent squamous cell cancer of the cervix and randomized these patients to one of two combination chemotherapy treatment arms. Of the 287 patients, 146 patients were randomized to the cisplatin and ifosfamide arm, and 141 patients received cisplatin, ifosfamide, and bleomycin. There were no differences in overall survival, progression-free survival, response rates, or overall toxicity between the two combination chemotherapy regimens (149). In another trial sponsored by the GOG, single-agent cisplatin was compared to cisplatin plus either dibromodulcitol or ifosfamide plus mesna. In this trial, the combination of cisplatin plus ifosfamide had a better response rate (31% vs. 18%) and median time to progression (4.6 months vs. 3.2 months) compared with single agent cisplatin. Toxicity was notably higher in the combination regimen, and there was no overall survival advantage demonstrated (150). The GOG published the results of a study comparing single-agent cisplatin to cisplatin plus paclitaxel in women with stage IVb squamous cell cancer of the cervix. Although the response rate (36% vs. 19%) and progression-free survival (4.8 months vs. 2.8 months) were greater for the combination regimen, there was only a 1-month increase in overall survival (151). Finally, the regimen of methotrexate, vinblastine, doxorubicin, and cisplatin (MVAC), which received considerable attention because of preliminary studies suggesting high response rates, was evaluated in POG Protocol 179. In this study, MVAC was compared to cisplatin alone, and cisplatin combined with topotecan. The MVAC arm was prematurely closed because of excessive toxicity, and the remaining cisplatin arms were compared. Although the combination of cisplatin and topotecan was superior to cisplatin alone, the improvement in overall survival was only 3 months. The combination arm had a higher complete response rate, overall response rate, progression-free survival, and overall survival (152). Doublet therapy with cisplatin and paclitaxel is considered standard therapy based on GOG 204, which analyzed four cisplatin-containing doublets (topotecan, paclitaxel, vinorelbine, and gemcitabine) for the best efficacy; although no major differences existed in overall survival for the four doublets, the...
cisplatin and paclitaxel doublet trended toward the best results (153). Overall, it appears that multiagent regimens offer an improved response rate and slightly higher overall survival but with increased toxicity. Other studies showed comparable survival and less toxicity with carboplatin and paclitaxel (154).

**Treatment of Cervical Cancer by Stage**

**Stage IA**

Until 1985, no FIGO recommendation existed concerning the size of lesion or the depth of invasion that should be considered microinvasive (stage Ia). This led to considerable confusion and controversy in the literature. Over the years, as many as 18 different definitions were used to describe microinvasion. In 1974, the Society of Gynecologic Oncologists recommended a definition that is accepted by FIGO: A microinvasive lesion is one in which neoplastic epithelium invades the stroma to a depth of less than 3 mm beneath the basement membrane and in which lymphatic or blood vascular involvement is not demonstrated. The purpose of defining microinvasion is to identify a group of patients who are not at risk for lymph node metastases or recurrence and who therefore may be treated with less than radical therapy.

Diagnosis must be determined on the basis of a cone biopsy of the cervix. The treatment decision rests with the gynecologist and should based on a review of the conization specimen with the pathologist. It is important that the pathologic condition be described in terms of (i) depth of invasion, (ii) width and breadth of the invasive area, (iii) presence or absence of lymph–vascular space invasion, and (iv) margin status. These variables are used to determine the degree of radicality of the operation and whether the regional lymph nodes should be treated (12).

**Stage IA1 ≤3 mm Invasion**

Lesions with invasion less than or equal to 3 mm have less than 1% incidence of pelvic node metastases. Within this group, it appears that the patients most at risk for nodal metastases or central pelvic recurrence are those with definitive evidence of tumor emboli in lymph vascular spaces (74,155). Therefore, patients with less than 3 mm invasion and no lymph–vascular space invasion may be treated with extrafascial hysterectomy without lymphadenectomy. Therapeutic conization appears to be adequate therapy for these patients if preservation of childbearing capability is desired. Surgical margins and postconization endocervical curettage must be free of disease. If there is lymph–vascular space invasion, a type I (extrafascial) or II (modified radical) hysterectomy with pelvic lymphadenectomy should be considered.

Treatment of microinvasive cervical adenocarcinoma is complicated by a lack of agreement on approaches. Recent reports show that patients with stage Ia1 cervical adenocarcinoma may be treated in a fashion similar to patients with this stage
and a squamous lesion (103–105). Some experts disagree with this interpretation because of the difficulty in establishing a pathologic diagnosis of microinvasion from a frankly invasive adenocarcinoma. Patients diagnosed with microinvasive cervical adenocarcinoma should have expert pathologic assessment before considering treatment with extrafascial hysterectomy or conization.

**Stage IA2 >3–5 mm Invasion**

Lesions with invasion of greater than 3 to 5 mm have a 3% to 8% incidence of pelvic node metastases; thus, pelvic lymphadenectomy is necessary for these lesions (155,156). The primary tumor may be treated with a modified radical hysterectomy (type II) or a radical trachelectomy if preservation of fertility is desired. If intermediate- or high-risk pathologic factors are identified in the surgical specimen, adjuvant radiation or chemoradiation therapy is recommended.

**Stages IB1, IB2, and IIA1 Invasive Cancer**

Stage Ib lesions are subdivided into stage IB1, which denotes lesions that are 4 cm or smaller in maximum diameter, and stage IB2, which denotes lesions that are greater than 4 cm. Stage IIA1 disease involves the upper two-thirds of the vagina, but total lesion size is 4 cm or less. These patients may be managed with either radical trachelectomy or a type III radical hysterectomy, with pelvic lymphadenectomy. Radical trachelectomy should be restricted to candidates with low-risk disease and a tumor size less than 2 cm. The paraaortic lymph node chain must be evaluated, especially if pelvic nodal disease is encountered. Adjuvant radiation therapy is recommended if intermediate risk factors are identified postoperatively. Adjuvant chemoradiation is indicated if high risk features are found.

Alternatively, primary chemoradiation therapy with curative intent is appropriate. A comparison of radical hysterectomy with radiation resulted in similar survival rates for the two treatment modalities. Several studies comparing patients treated by either radical hysterectomy or radiation therapy showed similar survival rates and outcomes for both groups (85,157). However, patients treated with type III radical hysterectomy who subsequently received postoperative radiation had a higher rate of intestinal and urinary morbidity compared with patients treated with either modality alone. Therefore, some clinicians advocate using radiation and avoiding surgery in these patients because many will require adjuvant postoperative radiation.

**Bulky Stages IB2 and IIA2 Invasive Cancer**

Patients with bulky IB2 and IIA2 disease may be treated with either primary chemoradiation or radical surgery. Because many of these patients will have intermediate or high risk factors postoperatively, strong consideration should be given to primary chemoradiation. If surgical therapy is desired, a type III radical hysterectomy with pelvic and para-aortic lymphadenectomy, followed
by adjuvant chemoradiation if intermediate or high risk factors are present, is appropriate therapy. This option has benefits of complete surgical staging and ovarian preservation, if desired. Disadvantages of primary surgery include increased morbidity if multimodality therapy is utilized (157).

Stages IIB to IIIB Invasive Cancer

Therapy for patients with stage IIB or greater cervical cancer traditionally was radiation therapy. Primary pelvic radiotherapy fails to control disease progression in 30% to 82% of patients with advanced cervical carcinoma (3). Two-thirds of these failures occur in the pelvis (158). A variety of agents were used in an attempt to increase the effectiveness of radiation therapy in patients with large primary tumors. Because chemoradiation was superior to radiation therapy alone, chemoradiation is the preferred treatment strategy for these patients, with cisplatin the chemotherapy agent of choice. Nodal involvement, particularly the para-aortic lymph nodes, is the most important factor related to survival (see section above on Concurrent Chemoradiation).

Stages IVA and IVB Cancer

Primary exenteration may be considered for patients with direct extension to the rectum or bladder, but it is rarely performed. For patients with extension to the bladder, the survival rate with radiation therapy is as high as 30%, with a urinary fistula rate of only 3.8% (159). The presence of tumor in the bladder may prohibit cure with radiation therapy alone; thus, consideration must be given to removal of the bladder on completion of external beam radiation treatment. This is particularly true if the disease persists at that time and the geometry is not conducive to brachytherapy. Rectal extension is less commonly observed but may require diversion of the fecal stream before chemoradiation to avoid septic episodes from fecal contamination. In certain clinical situations, such as with patients who have stage IVA disease and present with vesicovaginal or rectovaginal fistula, urinary or rectal diversion may be performed, followed by chemoradiation.

Patients with stage IVB cervical carcinoma are candidates for chemotherapy and palliative pelvic radiation therapy. Control of symptoms with the least morbidity is of primary concern in this patient population.

Patient Evaluation and Follow-up after Therapy

Patients who receive radiotherapy should be monitored closely to assess treatment response. Tumors may be expected to regress for up to 3 months after radiotherapy. During the pelvic examination, progressive shrinkage of the cervix and possible stenosis of the cervical os and surrounding upper vagina is expected and should be noted. During rectovaginal examination, careful palpation of the uterosacral and cardinal ligaments for nodularity is important. Cytologic assessment by FNA of suspicious areas should be performed to allow early diagnosis of persistent disease. In addition to the pelvic examination, the supraclavicular and inguinal lymph nodes should
be carefully examined, and cervical or vaginal assessment should be performed every 3 months for 2 years and then every 6 months for the next 3 years. Endocervical curettage may be performed in patients with large central tumors.

**Radiography of the chest may be performed yearly in patients who have advanced disease.** Metastasis to the lung was reported in 1.5% of cases. Solitary nodules are present in 25% of cases with metastasis. Resection of a solitary nodule in the absence of other persistent disease may yield some long-term survivors (160). Although intravenous pyelography (IVP) is not a part of routine postradiotherapy surveillance, it should be performed if a pelvic mass is detected or if urinary symptoms warrant evaluation. The finding of ureteral obstruction after radiotherapy in the absence of a palpable mass may indicate unresectable pelvic sidewall disease, but this finding should be confirmed, usually by FNA cytologic assessment (161).

**Patients who had radical hysterectomy and who are at high risk for recurrence may benefit from early recognition of recurrence because they might be saved with radiation therapy.** In these patients, a routine CT urogram 6 to 12 months after surgery may be beneficial. After radical hysterectomy, about 80% of recurrences are detected within 2 years (162). The larger the primary lesion, the shorter the median time is to recurrence (163).
Special Considerations

Cervical Cancer during Pregnancy

The incidence of invasive cervical cancer associated with pregnancy is 1.2 in 10,000 (164). A Pap test should be performed on all pregnant patients at the initial prenatal visit, and any grossly suspicious lesions should be biopsied. Diagnosis is often delayed during pregnancy because bleeding is attributed to pregnancy-related complications. If the result of the Pap test is positive for malignant cells, and invasive cancer cannot be diagnosed using colposcopy and biopsy, a diagnostic conization procedure may be necessary. Conization in the first trimester of pregnancy is associated with hemorrhagic and infectious complications, and an abortion rate as high as 33% (165,166). Because conization subjects the mother and fetus to complications, it should not be performed before the second trimester and only in patients with colposcopy findings consistent with cancer, biopsy-proven microinvasive cervical cancer, or strong cytologic evidence of invasive cancer. Inadequate colposcopic examination may be encountered during pregnancy in patients who had prior ablative therapy. Close follow-up throughout pregnancy may allow the cervix to evert and develop an ectropion, allowing satisfactory colposcopy in the second or third trimester. Patients with obvious cervical carcinoma may undergo cervical biopsy and clinical staging similar to that of nonpregnant patients.

After conization, there appears to be no harm in delaying definitive treatment until fetal maturity is achieved in patients with stage Ia cervical cancer (165,167,168). Patients with less than 3 mm of invasion and no lymphatic or vascular space involvement may be followed to term. Historically, these patients were allowed to deliver vaginally, and a hysterectomy was performed 6 weeks postpartum if further childbearing was not desired. However, in a multivariate analysis of 56 women with cervical cancer diagnosed during pregnancy and 27 women with cervical cancer diagnosed within 6 months of delivery, vaginal delivery was the most significant predictor of recurrence. In addition, most recurrences after vaginal delivery involved distant sites. The ideal delivery method for these patients is not known definitively; however, strong consideration should be given to performing a cesarean birth in women with cervical cancer of any stage (169). If vaginal delivery is chosen, close inspection of the episiotomy site is required during follow-up because of rare reports of metastatic cervical cancer at these locations (170).

Patients with 3 to 5 mm of invasion and those with lymph–vascular space invasion may be followed to term or delivered early after establishment of fetal pulmonary maturity (165,168). They may have cesarean delivery, immediately followed by modified radical hysterectomy and pelvic lymphadenectomy. Patients with more than 5 mm invasion should be treated as having frankly invasive carcinoma of the cervix. Treatment depends on the gestational age of the pregnancy and the wishes of the patient. Modern neonatal care affords a 75% survival rate for infants delivered at 28 weeks of gestation and 90% for those delivered at 32 weeks of
gestation. Fetal pulmonary maturity can be determined by amniocentesis, and prompt treatment can be instituted when pulmonary maturity is documented. Although timing is controversial, it is probably unwise to delay therapy for longer than 4 weeks (167,168). The recommended treatment is classic cesarean delivery followed by radical hysterectomy with pelvic lymphadenectomy. There should be a thorough discussion of the risks and options with both parents before any treatment is undertaken.

Patients with stages II to IV cervical cancer should be treated with radiotherapy. If the fetus is viable, it is delivered by classic cesarean birth, and therapy is begun postoperatively. If the pregnancy is in the first trimester, external radiation therapy can be started with the expectation that spontaneous abortion will occur before the delivery of 4,000 cGy. In the second trimester, a delay of therapy may be entertained to improve the chances of fetal survival. If the patient wishes to delay therapy, it is important to ensure fetal pulmonary maturity before delivery is undertaken. Neoadjuvant chemotherapy has been administered to women during pregnancy with cervical cancer after 13 weeks gestation, without clear short-term harm to the fetus, although longer clinical follow-up is necessary (171).

The clinical stage is the most important prognostic factor for cervical cancer during pregnancy. Overall survival for these patients is slightly better because an increased proportion of these patients have stage I disease. For patients with advanced disease, there is evidence that pregnancy impairs the prognosis (165,168). The diagnosis of cancer in the postpartum period is associated with a more advanced clinical stage and a corresponding decrease in survival (169).

Cancer of the Cervical Stump

Cancer of the cervical stump was more common many decades ago when supracervical hysterectomy was popular; because this operation is being performed more frequently, this situation may become increasingly familiar. Early-stage disease is treated surgically, with very little change in technique from that used when the uterus is intact (172). Radical parametrectomy with upper vaginectomy and pelvic lymphadenectomy is the standard procedure. Advanced-stage disease may present a therapeutic problem for the radiotherapist if the length of the cervical canal is less than 2 cm. This length is necessary to allow satisfactory placement of the uterine tandem. If the uterine tandem cannot be placed, radiation therapy can be completed with vaginal ovoids or with an external treatment plan in which lateral ports are used to augment the standard anterior and posterior ports. Such a technique will reduce the dosage to the bowel and bladder and thus reduce the incidence of complications.

Pelvic Mass

The origin of a pelvic mass must be clarified before treatment is initiated. A CT urogram can exclude a pelvic kidney, and a barium enema helps to identify diverticular disease or carcinoma of the colon. An abdominal x-ray film may show calcifications
typically associated with benign ovarian teratomas or uterine leiomyomas. Pelvic ultrasonography differentiates between solid and cystic masses and indicates uterine or adnexal origin. Solid masses of uterine origin are most often leiomyomas and do not need further investigation.

Pyometra and Hematometra

An enlarged fluid-filled uterine cavity may be a pyometra or a hematometra. The hematometra can be drained by dilation of the cervical canal and will not interfere with treatment. The pyometra also should be drained, and the patient should be given antibiotics to cover bacteroides species, anaerobic staphylococcus and streptococcus species, and aerobic coliform bacterial infection. Placement of a large mushroom catheter through the cervix was advocated, but the catheter itself may become obstructed, leading to further occlusion of the drainage. Repeated dilation of the cervix with aspiration of pus every 2 to 3 days is more effective.

If the disease is stage I, a radical hysterectomy and pelvic lymphadenectomy may be performed. However, a pyometra is usually found in patients with advanced disease, and thus radiotherapy is required. External-beam therapy can begin after the pyometra is healed. Patients often have a significant amount of pus in the uterus or a tubo-ovarian abscess without signs of infection; therefore, a normal temperature and a normal white blood cell count do not necessarily exclude infection. Repeat physical examination or pelvic ultrasonography is necessary to ensure adequate drainage.

Cervical Carcinoma after Extrafascial Hysterectomy

When invasive cervical cancer is found after simple hysterectomy, further treatment is predicated on the extent of disease. Microinvasive disease in patients at low risk for lymph node metastasis does not require further treatment. Invasive disease may be treated with radiotherapy or reoperation involving a pelvic lymphadenectomy and radical excision of parametrial tissue, cardinal ligaments, and the vaginal stump (173).

Reoperation

Reoperation is indicated for a young patient who has a small lesion and in whom preservation of ovarian function is desirable. It is not indicated for patients who have positive margins or obvious residual disease (173). Survival rates after radical reoperation are similar to those after radical hysterectomy for stage I disease.

Concurrent cisplatin-based chemoradiation is recommended for gross residual disease, positive imaging, disease in the lymph nodes or parametrium, or a positive surgical margin; individualized brachytherapy is clearly indicated for a positive vaginal margin (174).
Radiation Therapy

Survival after radiotherapy depends on the volume of disease, the status of the surgical margins, and the length of delay from surgery to radiotherapy. Patients with microscopic disease have a 95% to 100% 5-year survival rate; the 5-year survival rate is 82% to 84% in those with macroscopic disease and free margins, 38% to 87% in those with microscopically positive margins, and 20% to 47% in those with obvious residual cancer (175–177). A delay in treatment of more than 6 months is associated with a 20% survival rate (177).

Acute Hemorrhage

Occasionally, a large lesion can produce life-threatening hemorrhage. A biopsy of the lesion should be performed to verify neoplasia, and a vaginal pack soaked in Monsel’s solution (ferric subsulfate) should be packed tightly against the cervix. After proper evaluation, external radiation therapy can be started with the expectation that control of bleeding may require 8 to 10 daily treatments at 180 to 200 cGy per day. Broad-spectrum antibiotics should be used to reduce the incidence of infection. If the patient becomes febrile, the pack should be removed. Rapid replacement of the pack may be necessary, and a fresh pack should be immediately available. This approach to management of hemorrhage in patients previously untreated is preferable to exploration and vascular ligation. Vascular embolization under fluoroscopic control may be required in severe cases, and this procedure may obviate a laparotomy. However, vascular occlusion ultimately may lead to decreased blood flow and oxygenation of the tumor, compromising the effectiveness of subsequent radiotherapy.

Ureteral Obstruction

Treatment of bilateral ureteral obstruction and uremia in previously untreated patients should be determined on an individual basis. Transvesical or percutaneous ureteral catheters should be placed in patients with no evidence of distant disease, and radiotherapy with curative intent should be instituted. Patients with metastatic disease beyond curative treatment fields should be presented with the options of ureteral stenting, palliative radiotherapy, and chemotherapy. With aggressive management, a median survival rate of 17 months may be achieved for these patients (178).

Barrel-Shaped Cervix

The expansion of the upper endocervix and lower uterine segment by tumor is referred to as a barrel-shaped cervix. Patients with tumors larger than 6 cm in diameter have a 17.5% central failure rate when treated with radiotherapy alone because the tumor at the periphery of the lower uterine segment is too far from the standard intracavitary source to receive an adequate tumoricidal dose (179). Attempts were made to overcome this problem radiotherapeutically by
means of interstitial implants into the tumor with a perineal template, but high central failure rates were reported with this technique (180).

**One approach is to use a combination of radiotherapy and surgery for treatment of patients with a barrel-shaped cervix.** An extrafascial hysterectomy is performed 2 to 3 months after the completion of radiation therapy in an effort to resect a small, centrally persistent tumor. The dose of external radiotherapy is reduced to 4,000 cGy, and a single intracavitary treatment is given, which is followed by an extrafascial hysterectomy (181,182). This method appears to result in a lower rate of central failure (2%), although it is not clear that the overall survival rate is improved. **There is disagreement concerning the need for extrafascial hysterectomy**, and the GOG is undertaking a randomized study to compare adjuvant hysterectomy with radiotherapy alone in patients who have no evidence of occult metastases in the para-aortic nodes (see stages IB and IIA discussion).

The narrow upper vagina of older patients may preclude the use of an intracavitary source of radiation. These patients must receive their entire course of therapy from external sources, leading to a higher central failure rate and more significant bowel and bladder morbidity. If stage I disease is present in such a patient, a radical hysterectomy with pelvic lymphadenectomy is preferable, if the patient’s medical condition allows this approach. There may be a role for IMRT in the management of such tumors.
Recurrent Cervical Cancer

Treatment of recurrent cervical cancer depends on the mode of primary therapy and the site of recurrence. Patients who were treated initially with surgery should be considered for radiation therapy, and those who had radiation therapy should be considered for surgical treatment. Chemotherapy is palliative only and is reserved for patients who are not considered curable by either surgery or radiation therapy.

Radiotherapy for recurrence after surgery consists primarily of external treatment. Vaginal ovoids may be placed in patients with isolated vaginal cuff recurrences. Patients with a regional recurrence may require interstitial implantation with a Syed type of template in addition to external therapy. A 25% survival rate can be expected in patients treated with radiation for a postsurgical recurrence (162).

Radiation Retreatment

Retreatment of recurrent pelvic disease by means of radiotherapy with curative intent is confined to patients who had suboptimal or incomplete primary therapy. This may allow the radiotherapist to deliver curative doses of radiation to the tumor. The proximity of the bladder and rectum to the cancer and the relative sensitivity of these organs to radiation injury are the major deterrents to retreatment with radiation. The insertion of multiple interstitial radiation sources into locally recurrent cancer through a perineal template may help overcome these dosimetric considerations (173,183). The fistula rates are high, and those consequences must be considered before interstitial therapy is initiated. For patients considered curable with interstitial implant therapy, pelvic exenteration is a better treatment choice. Palliative radiotherapy can be given to patients with localized metastatic lesions that are deemed incurable. Painful bony metastases, central nervous system lesions, and severe urologic or vena caval obstructions are specific indications.

Surgical Therapy

Surgical therapy for postirradiation recurrence is limited to patients with central pelvic disease. A few carefully selected patients with small-volume disease limited to the cervix may be treated with an extrafascial or radical hysterectomy. However, the difficulty of assessing tumor volume and the 30% to 50% rate of serious urinary complications in these previously irradiated patients have led most gynecologic oncologists to recommend pelvic exenteration as a last chance for cure (184,185).

Exenteration

There are three types of exenterative procedures: (i) an anterior exenteration (removal of the bladder, vagina, cervix, and uterus), (ii) a posterior exenteration (removal of the rectum, vagina, cervix, and uterus), and (iii) a total exenteration (removal of both bladder and rectum with the vagina,
cervix, and uterus (Fig. 36.9). A total exenteration that includes a large perineal phase includes the entire rectum and leaves the patient with a permanent colostomy and a urinary conduit (infralevator). In selected patients, a total exenteration may take place above the levator muscle (supralevator), leaving a rectal stump that may be anastomosed to the sigmoid, thus avoiding a permanent colostomy.

Preoperative Evaluation and Patient Selection

It is imperative to search for metastatic disease before undergoing an exenteration. The presence of metastatic disease in this setting is considered a contraindication to exenterative procedures. Physical examination includes careful palpation of the peripheral lymph nodes with FNA cytologic sampling of any nodes that appear suspicious. A random biopsy of nonsuspicious supraclavicular lymph nodes is advocated by some clinicians but is not routinely practiced (145,186). A PET/CT scan of the chest and abdomen and pelvis CT helps in the detection of liver metastases and enlarged nodes. Cytologic study of any abnormality should be undertaken with CT-guided FNA. If a positive cytologic diagnosis is obtained, it will obviate the need for exploratory laparotomy.

Extension of the tumor to the pelvic sidewall is a contraindication to exenteration; however, this may be difficult for even the most experienced examiner to determine because of radiation fibrosis. If any question of resectability arises, exploratory laparotomy and parametrial biopsies should be offered (187–190). The clinical triad of unilateral leg edema, sciatic pain, and ureteral obstruction is nearly always pathognomonic of unresectable disease on the pelvic sidewall. Preoperatively, the patient should be prepared for a major operation. Total parenteral nutrition may be necessary to place the patient in an anabolic state for optimal healing. A bowel preparation, preoperative antibiotic administration, and prophylaxis for deep venous thrombosis with low-dose heparin or pneumatic calf compression should be undertaken (191). Surgical mortality increases with age, and the operation should rarely be considered in a patient who is older than 70 years. Other medical illnesses should be taken into account. When life expectancy is limited, exenterative surgery is unwise.

Anterior Exenteration

Candidates for anterior exenteration are those in whom the disease is limited to the cervix and anterior portion of the upper vagina. Proctoscopic examination should be performed because a positive finding would mandate a total exenteration. However, a negative proctoscopic examination finding does not exclude disease in the rectal muscularis, and findings at laparotomy still must be considered. The presence of disease in the posterior vaginal mucosa directly over the rectum mandates removal of the underlying rectum.

Posterior Exenteration
A posterior exenteration is rarely performed for recurrent cervical cancer. It is indicated, however, for the patient with an isolated posterior vaginal recurrence in which dissection of the ureters through the cardinal ligaments will not be necessary.

**Figure 36.9 Pelvic exenteration specimen.**

**Total Exenteration**

Total exenteration with a large perineal phase is indicated when the disease extends to the lower part of the vagina (Fig. 36.9). Because distal vaginal lymphatics may empty into the nodal basins of the inguinal region, these nodes should be carefully evaluated preoperatively. A supravelvator total exenteration with low rectal anastomosis is indicated in the patient whose disease is confined to the upper vagina and cervix (192,193). Samples from margins of the rectal edge should be obtained for frozen-section evaluation because occult metastases to the muscularis may occur.

The development of techniques to establish continent urinary diversion help improve a woman’s physical appearance after exenteration (194–196). When both a rectal anastomosis and a continent diversion are performed, the patient will not have a permanent external appliance. Associated psychological trauma in such cases may be avoided. **Every effort should be made to create a neovagina simultaneously with the exenteration** (197). This procedure helps in the reconstruction of the pelvic floor after extirpation of the pelvic viscera. Regardless of whether a neovagina is constructed, it is desirable to mobilize the omentum on the left gastroepiploic artery to create a new pelvic floor.

Surgical mortality from exenterative procedures has steadily decreased to less than 10%. Common causes of postoperative death are sepsis, pulmonary thromboembolism, and hemorrhage. Fistulas of the gastrointestinal and genitourinary tract are serious surgical complications, with a 30% to 40% mortality rate despite attempts at surgical repair. The
The risk for fistula formation is decreased if nonirradiated segments of bowel are used for formation of the urinary conduit (191). **The 5-year survival rate is 33% to 60% for patients undergoing anterior exenteration and 20% to 46% for those undergoing total exenteration (187–197).** Survival rates are worse for patients with recurrent disease (larger than 3 cm), invasion into the bladder, positive pelvic lymph nodes, and recurrence diagnosed within 1 year after radiotherapy (190). The 5-year survival rate of patients with positive pelvic lymph nodes is less than 5%; thus, the performance of an extensive lymphadenectomy in the irradiated field is not warranted. Discontinuation of the procedure is advisable if any nodes are positive for metastatic cancer. Patients who have any disease in the peritoneal cavity have no chance of survival.

**Laterally Extended Endopelvic Resection**

Locally recurrent cervical cancer in a previously irradiated field is associated with a dismal prognosis. Exenterative therapy traditionally was reserved for the highly select patient with centrally recurrent disease, a selection criteria that excludes most patients with recurrence. A technique called the laterally extended endopelvic resection (LEER) procedure was described, which offers a surgical treatment option for patients with recurrent disease involving the pelvic sidewall. The LEER procedure involves extending the lateral resection plane of the traditional pelvic exenteration to include resection of the internal iliac vessels; the endopelvic portion of the obturator internus muscle; and the coccygeus, iliococcygeus, and pubococcygeus muscles. Extension of the surgical plane allows for resection of lateral tumors with a negative margin. Experience with it is limited to one center, which reports as high as a 62% recurrence-free survival, but as high as 70% moderate to severe morbidity (198).

**Chemotherapy for Recurrent Cervical Cancer**

Recurrent cervical cancer is not considered curable with chemotherapy. The delivery of chemotherapy to recurrent tumor in a prior radiated field may be compromised because of altered blood supply caused by radiation. Topotecan and cisplatin had response rates of 15% to 20%, with a median duration of 6 to 9 months (199). Many other agents showed activity against cervical cancer and may be used in attempt to help control symptoms. Several clinical trials with various drugs (e.g., paclitaxel, topotecan, cisplatin, and carboplatin) showed response rates of up to 45%. Most responses are partial; complete responses are unusual and limited to patients with chest metastases in whom the dose of drug delivered to the disease is stronger than that delivered to the fibrotic postirradiated pelvis (200,201). Doublet therapy with cisplatin and paclitaxel is considered standard therapy based on GOG 204, which analyzed four cisplatin-containing doublets for the best efficacy; although no major differences existed in overall survival for the four doublets, the cisplatin and paclitaxel doublet trended toward the best results (153). Other studies showed comparable survival and less toxicity with carboplatin and paclitaxel (154).
Palliative Therapy

Palliative therapy for patients with incurable disease consists of radiation or chemotherapy or both. **Palliative radiation therapy is intended to relieve symptoms of pain or bleeding associated with advanced disease and may be administered as either external beam therapy (teletherapy) or brachytherapy.** Special care should be given to previously irradiated sites because additional radiation therapy may be associated with unacceptable morbidity. Single or multiagent palliative chemotherapy may be used with variable response rates. Symptomatic recurrent disease within previously irradiated fields may not respond well to palliative chemotherapy.
Primary vaginal cancer is a relatively uncommon tumor, representing only 2% to 3% of malignant neoplasms of the female genital tract. In the United States it is estimated that there were 2,160 new cases in 2009, and 770 deaths from the disease (1). Squamous histology accounts for 80% (202). Primary vaginal cancer should be differentiated from cancers metastatic to the vagina, which constitute the majority of cancers found in the vagina (84%) (203).
Staging

The FIGO staging of vaginal cancer dictates that a tumor extending to the vagina from the cervix be regarded as a cancer of the cervix, whereas a tumor involving both the vulva and the vagina should be classified as a cancer of the vulva.

The FIGO staging for vaginal carcinoma is shown in Table 36.6. Staging is performed by clinical examination and, if indicated, cystoscopy, proctoscopy, and chest and skeletal radiography. Information derived from lymphangiography, CT, MRI, or PET cannot be used to change the FIGO stage; however, it can be used for planning treatment. Less than 30% of vaginal cancers present at stage I (204–206).

Surgical staging and resection of enlarged lymph nodes may be indicated in selected patients. FIGO staging does not include a category for microinvasive disease. Because vaginal cancer is rare and treatment is by radiotherapy, there is very little information concerning the spread of disease in relation to depth of invasion, lymph–vascular space invasion, and size of the lesion.
Etiology

The association of cervical cancer with HPV suggests that vaginal cancer may have a similar association (207). A study of 341 cases revealed that in younger patients the disease seemed to be related to HPV infection, while in older patients there was no association (206). In addition, as many as 30% of women with vaginal cancer have a history of cervical cancer treated within the previous 5 years (208–210). As with cervical cancer, there appears to be a premalignant phase called vaginal intraepithelial neoplasia (VAIN) (see Chapter 19). The exact incidence of progression to invasive vaginal cancer from VAIN is not known; however, there are documented cases of invasive disease occurring despite adequate treatment of VAIN (211,212).

By convention, any new vaginal carcinoma developing at least 5 years after cervical cancer is considered a new primary lesion. There are three possible mechanisms for the occurrence of vaginal cancer after cervical neoplasia:

- Residual disease in the vaginal epithelium after treatment of the cervical neoplasia
- New primary disease arising in a patient with increased susceptibility to lower genital tract carcinogenesis (the role of HPV in this setting is suspected)
- Increased susceptibility to carcinogenesis caused by radiation therapy
Screening

**Routine screening of all patients for vaginal cancer is inappropriate.** For women who had a cervical or vulvar neoplasm, the Pap test is an important part of routine follow-up with each physician visit, because these patients are at an increased lifetime risk for developing vaginal cancer. It is recommended that Pap test surveillance for vaginal cancer be performed yearly after the patient has completed surveillance for cancer of the cervix or vulva. **For women who had a hysterectomy for benign disease and have no antecedent history of CIN 2–3, performance of Pap testing is unnecessary. If the patient has a history of cervical dysplasia or cervical cancer, yearly screening is recommended.** When adjusted for age and prior cervical disease, the incidence of vaginal cancer is not increased in women who had hysterectomy for benign disease (213). Because primary vaginal tumors tend to be multicentric, the entire vaginal mucosa should be considered at risk. Therefore, in addition to screening cytology, careful bimanual examination of the entire vagina and vulva is recommended for women at high risk.
Symptoms

Painless vaginal bleeding and discharge are the most common symptoms of vaginal cancer. With more advanced tumors, urinary retention, bladder spasm, hematuria, and frequency of urination may occur. In a large series, 14% were asymptomatic and diagnosis was made by routine examination or abnormal cytology (206). Tumors developing on the posterior vaginal wall may produce rectal symptoms, such as tenesmus, constipation, or blood in the stool.
Diagnosis

The diagnostic workup includes a complete history and physical examination, careful speculum examination and palpation of the vagina, and bimanual pelvic and rectal examinations. **It is important to rotate the speculum to obtain a careful view of the entire vagina because posterior wall lesions frequently occur and may be overlooked.**

In early squamous cell lesions, the diagnosis is often suggested by an abnormal Pap test result; however, this is not true for clear cell adenocarcinomas, which are characterized by submucosal growth. In these cases, the diagnosis is suggested by cytologic findings in only 33% of cases. Visually suspicious areas in the vagina should be evaluated with a targeted biopsy using the same instruments as those used for cervical biopsies. Careful palpation of the vagina may be helpful in detecting submucosal irregularities. **The most common site of vaginal cancer is in the upper one-third of the vagina on the posterior wall.** The developing tumor may be missed during initial inspection because of obscured visualization caused by the blades of the speculum (214). Colposcopy is valuable in evaluating patients with abnormal Pap test results, unexplained vaginal bleeding, or ulcerated erythematous patches in the upper vagina. A colposcopically targeted biopsy may not allow a definitive diagnosis, and a partial vaginectomy may be necessary to determine invasion. Occult invasive carcinoma may be detected by such an excision, particularly in patients who have a history of prior hysterectomy in whom the vaginal vault closure may bury some of the vaginal epithelium at risk for cancer (215).
Pathology

Cancer of the vagina spreads most often by direct extension into the pelvic soft tissues and adjacent organs. Metastases to the pelvic and para-aortic lymph nodes may occur in advanced disease. Lesions in the lower one-third of the vagina may spread directly to the inguinal femoral lymph nodes and the pelvic nodes (216). Hematogenous dissemination to the lungs, liver, or bone may occur as a late phenomenon.

Squamous cell carcinomas are the most common form of vaginal cancer, occurring in 80% to 90% of cases. These tumors most commonly occur in the upper one-third, posterior wall of the vagina. The mean age of patients with squamous cell cancer is 60 years (217,218). Malignant melanoma is the second most common cancer of the vagina, accounting for 2.8% to 5% of all vaginal neoplasms (219–221). Other histologic subtypes include adenocarcinoma and sarcoma.

Primary adenocarcinoma of the vagina is rare, constituting 9% of primary tumors of the vagina. The most common adenocarcinoma of the vagina is metastatic, originating from the colon, endometrium, ovary, or, rarely, pancreas and stomach. In general, adenocarcinomas affect a younger population of women, regardless of whether they were exposed to diethylstilbestrol (DES) in utero (222). Adenocarcinomas may arise in wolffian rest elements, periurethral glands, and foci of endometriosis (223). In women exposed to DES in utero, adenocarcinoma may develop in vaginal adenosis.

**Figure 36.10 Vaginal clear cell carcinoma.** Note the formation of tubules with hobnail cells lining the lumen. These cells are characterized by nuclear protrusion into the apical cytoplasm.

DES was used in the United States from 1940 until 1971 to maintain high-risk pregnancies in women with a history of spontaneous abortions. In 1970, seven young women were reported with clear cell adenocarcinoma of the vagina (Fig. 36.10); later, an association
between this cancer and maternal ingestion of DES during pregnancy was identified (224). Subsequently, more than 500 cases of clear cell cancer of the vagina and cervix were reported to the Registry for Research on Hormonal Transplacental Carcinogenesis.

**The estimated risk for developing clear cell adenocarcinoma for an exposed offspring is 1 in 1,000 or less. The mean age of diagnosis is 19 years (225).** Clear cell adenocarcinoma in women with a history of in utero exposure to DES typically presents in the exocervix or anterior, upper one-third of the vagina. These tumors vary greatly in size and are most frequently exophytic and superficially invasive. Stage is the most important prognostic factor. Other statistically significant factors include a tubulocystic growth pattern, size less than 3 cm², and less than 3 mm of stromal invasion. Because the use of DES in pregnant women was discontinued in 1971, most of these tumors probably have been discovered. It is uncertain, however, what will happen to this cohort of women as they move into their fifth, sixth, and seventh decades of life. Continued surveillance of these women is indicated.

**Ninety-seven percent of cases of vaginal clear cell adenocarcinoma are associated with adenosis.** Adenosis is characterized by the presence of persistent müllerian-type glandular epithelium. Although adenosis is the most common histologic abnormality in women exposed to DES in utero, adenosis can be found in women without a history of exposure. Adenosis typically appears as red, grapelike clusters in the vagina.

**Malignant melanoma of the vagina is rare and lethal, occurring most often in white women. The average age of these patients is 58 years (226).** Most lesions are deeply invasive, corresponding to a Clark level IV when compared with the staging for vulvar melanomas. The most common location of these tumors is in the lower one-third of the vagina (227). Melanomas have a wide variety of size, color, and growth patterns (225,228). Radical excision (vaginectomy, hysterectomy, and pelvic lymphadenectomy) is the mainstay of treatment. The goal of treatment is to avoid local (vaginal) recurrence, which is the most common site of recurrence (226,227). The need to dissect regional lymph nodes is uncertain. Because the disease is deeply invasive, hematogenous spread is the most common lethal recurrence. There is no difference in overall survival of patients with local as opposed to radical excision (226). The survival rate is approximately 10% at 5 years.

**The most common benign and malignant mesenchymal tumors of the vagina in adult women are smooth muscle tumors (229).** Vaginal sarcomas are usually fibrosarcomas or leiomyosarcomas and are extremely rare. Radical local excision, followed by adjuvant chemotherapy or radiation therapy, is the indicated treatment.

*Figure 36.11 Embryonal rhabdomyosarcoma of the vagina (botryoid sarcoma).* This lesion consists of primitive mesenchymal cells and rhabdomyoblasts, which have abundant eosinophilic cytoplasm. With further differentiation, cross striations may become evident.
The most common malignant mesenchymal tumor of the vagina in children and infants is botryoid rhabdomyosarcoma (Fig. 36.11). Botryoid sarcoma is usually found in the vagina during infancy and early childhood, in the cervix during the reproductive years, and in the corpus uteri during postmenopausal years. Preoperative chemotherapy with vincristine, actinomycin D, and cyclophosphamide, followed by conservative surgery or radiation, has improved survival.
Treatment selection is based on the clinical examination, CT scan results, chest radiography results, age, and condition of the patient. PET scans may give more accurate information about disease spread than MRI or CT scan alone (230). Most tumors are treated by radiation therapy. Surgery is limited to selected cases. These are as follows:

**Women with stage I disease involving the upper posterior vagina may be treated by radical vaginectomy and pelvic lymphadenectomy.** If the uterus is in situ, it is removed as a radical hysterectomy specimen. When margins are clear and lymph nodes are negative, no additional therapy is necessary.

**Patients with stage IV disease with either rectovaginal or vesicovaginal fistula** may be candidates for primary pelvic exenteration with pelvic and para-aortic lymphadenectomy (225). Low rectal anastomosis, continent urinary diversion, and vaginal reconstruction are indicated and are more successful in these nonirradiated patients than in patients who received prior radiation therapy.

**Women with central pelvic recurrence after radiation therapy are candidates for pelvic exenteration similar to that used for cervical cancer.** Surgical staging with resection of enlarged lymph nodes followed by radiation therapy may improve the control of pelvic disease.

**Radiation therapy is the treatment of choice for all patients except those described previously.** Small superficial lesions may be treated with intracavitary radiation alone (225). Larger, thicker lesions should be treated first with external teletherapy to decrease tumor volume and to treat the regional pelvic nodes, followed by intracavitary and interstitial therapy to deliver a high dose to the primary tumor (218,226). If the uterus is intact and the lesion involves the upper vagina, an intrauterine tandem and ovoids can be used. If the uterus was previously removed, a vaginal cylinder may be used for superficial irradiation. When brachytherapy is used, high- and low-dose rate techniques were described. If the lesion is more than 0.5 cm thick, interstitial radiation techniques can improve the dose distribution to the primary tumor. Surgical exploration or laparoscopy at the time of insertion of Syed interstitial implants defines more precisely the placement of the needles and ensures that needles do not pass into adherent loops of bowel. Extended-field radiation may be used for vaginal cancer in a manner similar to its use for cervical carcinoma, although there is no experience reported with the use of this technique in the treatment of vaginal cancer. Likewise, there is little reported experience with combination chemoradiation treatment (231). Although there will never be enough patients for a proper randomized control trial, concurrent use of 5-FU and cisplatin was highly successful in anal and cervical cancer and thus should be considered for treatment of vaginal cancer.
Sequelae

The proximity of the rectum, bladder, and urethra leads to a major complication rate of 10% to 15% for both surgery and radiation treatment. For large tumors, the risk of bladder or bowel fistula is significant. Radiation cystitis and proctitis are common, as are rectal strictures or ulcerations. Radiation necrosis of the vagina occasionally occurs, requiring debridement, and often leads to fistula formation. Vaginal fibrosis, stenosis, and stricture are common after radiation therapy. Use of vaginal dilators and resumption of regular sexual relations should be encouraged, along with the use of topical estrogen to maintain adequate vaginal function.
Survival

The overall 5-year survival rate for patients with vaginal cancer is 52% (Table 36.7). This reflects the difficulties of treatment and the fact the disease presents at late stage. For patients with stage I disease, the 5-year survival rate is 74%. Most recurrences are in the pelvis, either from enlarged regional nodes or from large central tumors. Radiation techniques, including interstitial implants with Syed applicator and combination chemoradiation, are the mainstay of therapy. Careful evaluation of patients who receive radiation therapy to detect central recurrence may allow some patients to be saved by pelvic exenteration. Because of the rarity of vaginal cancer, these patients should be treated in a center that is familiar with the complexity of treatment and modalities of therapy.

References

The peak incidence of invasive epithelial ovarian cancer is at about 60 years of age. About 30% of ovarian neoplasms in postmenopausal women are malignant, whereas only about 7% of ovarian epithelial tumors in premenopausal patients are frankly malignant. The average age of patients with borderline tumors is approximately 46 years.

Ovarian cancer is associated with low parity and infertility. Because parity is inversely related to the risk of ovarian cancer, having at least one child is protective for the disease, with a risk reduction of 0.3 to 0.4.

Oral contraceptive use reduces the risk of epithelial ovarian cancer. Women who use oral contraceptives for 5 or more years reduce their relative risk to 0.5 (i.e., there is a 50% reduction in the likelihood of development of ovarian cancer).

Given the false-positive results for both CA125 and transvaginal ultrasonography, particularly in premenopausal women, and the absence of evidence from randomized trials that these tests reduce the mortality of ovarian cancer, these tests should not be used routinely to screen women at risk for ovarian cancer.

Most epithelial ovarian cancers are sporadic, but at least 5% to 10% result from inherited susceptibility and are hereditary. Hereditary ovarian cancers, particularly those caused by BRCA1 mutations, occur in women approximately 10 years younger than those with nonhereditary tumors.

Most hereditary ovarian cancers result from germline mutations in the BRCA1 and BRCA2 genes. The mutations are inherited in an autosomal dominant fashion, and therefore a full pedigree analysis (i.e., both maternal and paternal sides of the family history for both breast and ovarian cancer) must be
carefully evaluated in all patients with epithelial ovarian cancer, and those with fallopian tube cancer and peritoneal cancer. The value of prophylactic salpingo-oophorectomy in these patients is well documented and is the most effective way to reduce risk of these cancers.

The importance of thorough surgical staging cannot be overemphasized, because subsequent treatment and prognosis will be determined by the stage of disease. Patients with advanced-stage disease should undergo debulking or cytoreductive surgery to remove as much of the tumor and its metastases as possible, if the patient is medically fit for major surgery. The performance of a debulking operation as early as possible in the course of the patient’s treatment is considered the standard of care for most patients. Most patients have a primary debulking surgery, while a smaller proportion of patients not suitable for initial surgery receive two to three cycles of primary chemotherapy followed by interval debulking surgery.

Combination chemotherapy with carboplatin and paclitaxel is recommended for patients with high-risk, low-stage disease. For advanced-stage epithelial ovarian cancer, the choice of intravenous versus intraperitoneal platinum and taxane chemotherapy should be individualized.

In the first two decades of life, almost 70% of ovarian tumors are of germ cell origin, and one-third of these are malignant. In contrast to the relatively slow-growing epithelial ovarian tumors, germ cell malignancies grow rapidly. The most common types of malignant germ cell tumors are dysgerminomas, immature teratomas, and endodermal sinus tumors. Preservation of fertility should be standard in most patients. The most effective chemotherapy is bleomycin, etoposide, and cisplatin (BEP).

Stromal tumors include granulosa cell tumors, which are low-grade malignancies. In premenopausal women, they can be treated conservatively. Adjuvant chemotherapy is of unproven value.

Metastatic tumors to the ovaries are most frequently from the breast and gastrointestinal tract.

Fallopian tube carcinomas and peritoneal cancers are treated the same as ovarian cancer, with staging and cytoreductive surgery followed by platinum and taxane chemotherapy.

Of all the gynecologic cancers, ovarian malignancies represent the greatest clinical challenge because they have a high mortality. Epithelial cancers are the most common ovarian malignancy, and over two-thirds of patients have advanced disease at diagnosis. Ovarian cancer represents a major surgical challenge, and optimal therapy includes surgical debulking followed by platinum-based combination chemotherapy. It has the highest fatality-to-case ratio of all the gynecologic malignancies. There are nearly 22,000 new cases annually in the United States, and 15,460 women can be expected to succumb to their illness (1). Ovarian cancer is the seventh most common cancer in women in the United States, accounting for 3% of all malignancies and 6% of deaths from cancer in
women and almost one-third of invasive malignancies of the female genital organs. Ovarian cancer is the fifth most common cause of death from malignancy in women. A woman’s risk at birth of having ovarian cancer at some point in her lifetime is 1% to 1.5% and that of dying from ovarian cancer is almost 0.5% (2).
Epithelial Ovarian Cancer

Approximately 90% of ovarian cancers are derived from the coelomic epithelium or mesothelium (2). The cells are a product of the primitive mesoderm, which can undergo metaplasia. A classification of the histologic types of epithelial tumors of the ovary is presented in Table 37.1. Neoplastic transformation can occur when the cells are genetically predisposed to oncogenesis or exposed to an oncogenic agent or both (3).

From Seroy SF, Scully RE, Sobin LH. International histological classification of
Pathology

Invasive Cancer
Seventy-five percent to 80% of epithelial cancers are of the serous histologic type. Less common types are endometrioid (10%), clear cell (5%), mucinous (5%), transitional (Brenner), and undifferentiated carcinomas, with each of the last two types representing less than 1% of epithelial lesions (2). Each of the major tumor types is named on the basis of a histologic pattern that resembles epithelium in the lower genital tract (3). For example, serous tumors have an appearance similar to that of the glandular epithelial lining of the fallopian tube, endometrioid tumors resemble proliferative endometrium, and clear cell tumors resemble secretory or gestational endometrium. Mucinous tumors may contain cells that resemble endocervical glands, but more commonly these cells resemble the gastrointestinal epithelium. Transitional (Brenner) tumors are so named because of a resemblance to the epithelium in Walthard rests and bladder urothelium.

Although it was believed that epithelial ovarian cancers arise from either the surface epithelium of the ovary or from inclusion cysts within the ovary, there is growing evidence to suggest that many, if not most, high-grade serous carcinomas of the ovary arise from the fimbrial end of the fallopian tube rather than from the ovary (4,5). It is suggested that serous epithelial ovarian cancers be separated into two distinct groups—type I and type II serous tumors—as they differ considerably in the cell of origin, molecular pathogenesis, and their biological behavior (6). Type I tumors include serous borderline tumors and low-grade serous carcinoma; they are genetically stable and are characterized by mutations in KRAS and BRAF. Type II serous tumors are rapidly growing, highly aggressive neoplasms that lack well-defined precursor lesions; most are advanced stage at, or soon after, their inception and many appear to arise in the fimbrial end of the fallopian tube (7). The type II tumors are genetically unstable and harbor p53 mutations.

Borderline Tumors
An important group of tumors to distinguish is the tumor of low malignant potential, also called the borderline tumor. Borderline tumors are lesions that tend to remain confined to the ovary for long periods, occur predominantly in premenopausal women, and are associated with a very good prognosis (2,3,8–12). They are encountered most frequently in women between the ages of 30 and 50 years, whereas invasive carcinomas occur more often in women between the ages of 50 and 70 years (2).

Although uncommon, implants may occur with serous borderline tumors. Such implants are divided into noninvasive and invasive forms. The latter group has a higher likelihood of developing into progressive, proliferative disease in the peritoneal cavity, which can lead to intestinal obstruction and death (2,6).
Classification of Epithelial Ovarian Tumors

**Serous Tumors**

Serous tumors are so classified because they resemble tubal secretory cells. **Psammoma bodies** are frequently found in these neoplasms, and they are made up of concentric rings of calcification. Several hypotheses pertaining to the origin and development of psammoma bodies are proposed, including apoptosis of tumor cells and osteoinductive cytokines produced by macrophages (6). In the wall of the mesothelial invaginations, papillary ingrowths are common, representing the early stages of development of a papillary serous cystadenoma. There are many variations in the proliferation of these mesothelial inclusions. Several foci may be lined with flattened inactive epithelium; in adjacent cavities, papillary excrescences are present, often resulting from local irritants (2).

**Borderline Serous Tumors**

Approximately 10% of all ovarian serous tumors fall into the category of a tumor of low malignant potential or borderline tumor (Fig. 37.1), and 50% occur before the age of 40 years. The criteria for the diagnosis of serous borderline tumors are as follows (11):

- Epithelial hyperplasia in the form of pseudostratification, tufting, cribriform, and micropapillary architecture
- Mild nuclear atypia and mild increased mitotic activity
- Detached cell clusters
- Absence of destructive stromal invasion (i.e., without tissue destruction)

Serous borderline tumors that are composed of an exuberant micropapillary architecture are designated as serous borderline tumors with micropapillary features (Fig. 37.2); these tumors are more frequently bilateral, exophytic, and high-stage than the usual serous borderline tumor.

**Figure 37.1 Serous borderline tumor of the ovary.** Complex papillary fronds with hierarchical branching are lined with pseudostratified columnar cells. The epithelium and the stroma are clearly separated by a basement membrane, indicating no stromal invasion.
Figure 37.2 Serous borderline tumor with micropapillary features. The papillae have a non-hierarchical branching pattern and are lined by a monomorphous population of cells.
It should be emphasized that up to 40% of serous borderline tumors are associated with spread beyond the ovary, but high-stage disease does not necessarily warrant a diagnosis of carcinoma. The diagnosis of a serous borderline tumor versus serous carcinoma is based on the histologic features of the primary tumor (11). Up to 10% of women with ovarian serous borderline tumors and extraovarian implants may have invasive implants, and these can behave more aggressively (13). The 5-year overall survival for women with invasive implants is about 50% if stringent criteria are applied (10,13–15). Most implants are noninvasive (10,16). In the noninvasive implants, papillary proliferations of atypical cells involve the peritoneal surface and form smooth invaginations (10). In contrast, the invasive implants resemble well-differentiated serous carcinoma and are characterized by atypical cells forming irregular glands with sharp borders. Implants are usually confined to the abdominal cavity and may be seen in the pelvis, omentum, and adjacent tissues, including lymph nodes, but spread outside the abdominal cavity is rare. Death can occur as the result of intestinal obstruction (16–19).

**Borderline serous tumors may harbor foci of stromal microinvasion** (18). Most patients are young and International Federation of Gynecology and Obstetrics (FIGO) stage I. Stromal microinvasion is increased about ninefold in pregnant women with serous borderline tumors. The presence of stromal microinvasion is associated with lymphovascular space invasion in the primary ovarian tumor (and likely represents a form of true stromal invasion), but it is not associated with an aggressive clinical course, and patients with this finding should be managed in the same way as patients without stromal microinvasion.

**Serous Carcinomas**

**In malignant serous tumors, stromal invasion is present** (2). The grade of tumor is important and needs to be documented. In low-grade serous adenocarcinomas, papillary and glandular structures predominate (Fig. 37.3); high-grade neoplasms are characterized by solid sheets of cells, nuclear pleomorphism, and high mitotic activity (Fig. 37.4). Laminated, calcified psammoma bodies are found in 80% of serous carcinomas. **Serous psammocarcinoma is a rare variant of serous carcinoma characterized by massive psammoma body formation and low-grade cytological features.** At least 75% of the epithelial nests are associated with psammoma body formation. Patients with serous psammocarcinoma have a protracted clinical course and a relatively favorable prognosis; their clinical course more closely resembles that of high-stage, progressive serous borderline tumor than serous carcinoma.

Figure 37.3 Low-grade serous adenocarcinoma of the ovary. Clusters and papillae of malignant cells are in direct contact with fibrous stroma indicative of stromal invasion.
Mucinous Tumors
These cystic ovarian tumors have loculi lined with mucin-secreting epithelium. The lining epithelial cells contain intracytoplasmic mucin and resemble those of endocervix, gastric pylorus, or intestine. They represent about 8% to 10% of epithelial ovarian tumors. They may reach enormous size, filling the entire abdominal cavity (2).

Borderline Mucinous Tumors
The mucinous tumor of low malignant potential is often difficult to diagnose. Although it is common to find a rather uniform pattern from section to section in the serous borderline tumor, this is not true in the mucinous tumors. Well-differentiated mucinous epithelium may be seen immediately adjacent to a poorly differentiated focus. It is important to take multiple sections from many areas in the mucinous tumor to identify the most malignant alteration (2).

Mucinous Carcinomas
Bilateral tumors occur in 8% to 10% of cases. The mucinous lesions are confined to the ovary in 95% to 98% of cases (Fig. 37.5). Because most ovarian mucinous carcinomas contain intestinal-type cells, they cannot be distinguished from metastatic carcinoma of the gastrointestinal tract on the basis of histology alone (2,6). Primary ovarian neoplasms rarely metastasize to the mucosa of the bowel, although they commonly involve the serosa, whereas gastrointestinal lesions frequently involve the ovary by direct extension or lymphatic spread (2).

Figure 37.4 High-grade serous adenocarcinoma. Papillae lined by sheets of cytologically malignant cells invade stroma, often with associated necrosis.
Figure 37.5 Mucinous adenocarcinoma of the ovary. Irregular glandular spaces are lined with a layer of tall columnar cells with abundant mucinous cytoplasm, resembling intestinal epithelium at the left. At the right, there is destructive invasion into the ovarian stroma.
Pseudomyxoma Peritonei

**Pseudomyxoma peritonei** is a clinical term used to describe the finding of abundant mucoid or gelatinous material in the pelvis and abdominal cavity surrounded by fibrous tissue. It is most commonly secondary to a well-differentiated appendiceal mucinous neoplasm or other gastrointestinal primary; rarely, mucinous tumors arising in an ovarian mature teratoma are associated with pseudomyxoma peritonei.

Endometrioid Tumors

**Endometrioid lesions constitute 6% to 8% of epithelial tumors.** Endometrioid neoplasia includes all the benign demonstrations of endometriosis. In 1925, Sampson suggested that certain cases of adenocarcinoma of the ovary probably arose in areas of endometriosis (19). The adenocarcinomas are similar to those seen in the uterine corpus. The malignant potential of endometriosis is very low, although a transition from benign to malignant epithelium may be demonstrated.

Borderline Endometrioid Tumors

The endometrioid tumor of low malignant potential has a wide morphologic spectrum. Tumors may resemble an endometrial polyp or complex endometrial hyperplasia with glandular crowding. When there are back-to-back, architecturally complex glands with no intervening stroma, the tumor is classified as a well-differentiated endometrioid carcinoma. Some borderline endometrioid tumors have a prominent fibromatous component. In such cases, the term adenofibroma is used to describe them (2).

Endometrioid Carcinomas

Endometrioid tumors are characterized by a markedly complex glandular pattern with all the potential variations of epithelia found in the uterus (Fig. 37.6).

**Figure 37.6** Endometrioid cancer. Round to tubular glands lined by stratified columnar cells with confluent growth pattern.
Multifocal Disease

The endometrioid tumors afford the greatest opportunity to evaluate multifocal disease. **Endometrioid carcinoma of the ovary is associated in 15% to 20% of the cases with carcinoma of the endometrium. Identification of multifocal disease is important because patients with disease metastatic from the uterus to the ovaries have a 30% to 40% 5-year survival, whereas those with synchronous multifocal disease have a 75% to 80% 5-year survival** (20). When the histologic appearance of endometrial and ovarian tumors is different, the two tumors most likely represent two separate primary lesions. When they appear similar, the endometrial tumor can be considered a separate primary tumor if it is well differentiated and only superficially invasive.

**Clear Cell Carcinomas**

Several basic histologic patterns are present in the clear cell adenocarcinoma (i.e., tubulocystic, papillary, reticular, and solid). The tumors are made up of clear and hobnail cells that project their nuclei into the apical cytoplasm. The clear cells have abundant clear or vacuolated cytoplasm, hyperchromatic irregular nuclei, and nucleoli of various sizes (Fig. 37.7). **Focal areas of endometriosis are common and mixed clear cell and endometrioid carcinoma may occur** (20). The clear cell carcinoma seen in the ovary is histologically identical to that seen in the uterus or vagina of the young patient who has been exposed to diethylstilbestrol (DES) in utero. Nuclei of clear cell carcinoma range from grade 1 to grade 3, but pure grade 1 tumors are extremely rare. **Almost invariably high-grade (grade 3) nuclei are identified. Hence, clear cell carcinoma is not graded.**

**Figure 37.7 Clear cell carcinoma of the ovary.** Note the solid variant of clear cell carcinoma with sheets of cells that have clear cytoplasm (“hobnail” cells).
Transitional (Brenner) Tumors

Borderline Brenner Tumors
In the past, proliferative Brenner tumors were subclassified as proliferating tumors (those tumors that resemble low-grade papillary urothelial carcinoma of the urinary bladder) and borderline tumors (those tumors that resemble high-grade papillary urothelial carcinoma), but both groups of tumors are now classified as borderline Brenner tumors (21). Complete surgical removal usually results in cure.

Malignant Brenner Tumors
These rare tumors are defined as benign or borderline Brenner tumors coexisting with invasive transitional cell carcinoma.

Transitional Cell Carcinoma
The designation transitional cell carcinoma refers to a primary ovarian carcinoma resembling transitional cell carcinoma of the urinary bladder without a recognizable Brenner tumor. It is reported that those ovarian carcinomas that contain more than 50% of transitional cell carcinoma are more sensitive to chemotherapy and have a more favorable prognosis than other poorly differentiated ovarian carcinomas of comparable stage (22,23). Transitional cell tumors differ from malignant Brenner tumors in that they are more frequently diagnosed in an advanced stage and are associated with a poorer survival rate (24).

Peritoneal Carcinomas
Peritoneal tumors are histologically indistinguishable from ovarian serous tumors. In the case of borderline serous peritoneal tumors and serous peritoneal carcinomas, the ovaries are normal or minimally involved, and the tumors affect predominantly the uterosacral ligaments, pelvic peritoneum, or omentum. The overall prognosis for borderline serous peritoneal tumors is excellent and comparable to that of ovarian borderline serous tumors (25–27). In the review of 38 cases of peritoneal borderline serous tumors from the literature, 32 women had no persistent disease, 4 were well after resection of recurrence, 1 developed an invasive serous carcinoma, and 1 died from the effects of the tumor (25).

Carcinoma that appears predominantly as peritoneal carcinomatosis without appreciable ovarian or fallopian tube enlargement is called peritoneal carcinoma or müllerian carcinoma when tumors spread from the breast, gastrointestinal tract, and other organs of nonmüllerian origin are excluded. Most are peritoneal serous carcinomas, which have the appearance of a moderately to poorly differentiated serous ovarian carcinoma. Peritoneal endometrioid carcinoma is less common.

Peritoneal carcinoma should be considered clinically the same as ovarian and
Fallopian tube cancers. In patients for whom exploratory surgery is performed, there may be microscopic or small macroscopic cancer on the surface of the ovary and extensive disease in the upper abdomen, particularly in the omentum (28).

Mesotheliomas

Peritoneal malignant mesotheliomas may be epithelial, sarcomatous, or biphasic (2,29). Deciduoid peritoneal mesothelioma is an unusual variant that resembles exuberant, ectopic decidual reaction of the peritoneum. Asbestos exposure is not correlated with peritoneal mesotheliomas in women. These lesions typically appear as multiple intraperitoneal masses, often coating the entire peritoneum and can develop after hysterectomy and bilateral salpingo-oophorectomy for benign disease. Malignant mesotheliomas should be distinguished from benign multicystic peritoneal mesothelioma (multilocular peritoneal inclusion cyst), and ovarian tumor implants and primary peritoneal müllerian neoplasms.
Clinical Features

More than 80% of epithelial ovarian cancers are found in postmenopausal women (Fig. 37.8). The peak incidence of invasive epithelial ovarian cancer is at 56 to 60 years of age (2,3,30). The age-specific incidence of ovarian epithelial cancer rises precipitously from 20 to 80 years of age and subsequently declines (30). These cancers are relatively uncommon in women younger than age 45. Fewer than 1% of epithelial ovarian cancers occur before the age of 21 years, two-thirds of ovarian malignancies in such patients being germ cell tumors (2,30,31). About 30% of ovarian neoplasms in postmenopausal women are malignant, whereas only about 7% of ovarian epithelial tumors in premenopausal patients are frankly malignant (2,3).

Figure 37.8 Ovarian cancer incidence: distribution by age. (From Nagy K. The side effects of managed care on the drug industry. J Natl Cancer Inst 1995;87:1280, with permission.)

The average age of patients with borderline tumors is approximately 46 years (2,3,9). Eighty percent to 90% of ovarian cancers, including borderline forms, occur after the age of 40 years, whereas 30% to 40% of malignancies occur after the age of 65 years. The chance that a primary epithelial tumor will be of borderline or invasive malignancy in a patient younger than 40 years is approximately 1 in 10, but after that age it rises to 1 in 3 (2,3). Less than 1% of epithelial ovarian cancers occur before the age of 20 years, with two-thirds of ovarian malignancies in such patients being germ cell tumors (31).
Etiology

Ovarian cancer is associated with low parity and infertility (32). Although there are a variety of epidemiologic variables correlated with ovarian cancer, such as talc use, galactose consumption, and tubal ligation (see Chapter 4), none is so strongly correlated as prior reproductive history and duration of the reproductive career (32,33). Early menarche and late menopause increase the risk of ovarian cancer (33). These factors and the relationship of parity and infertility to the risk of ovarian cancer led to the hypothesis that suppression of ovulation may be an important factor. Theoretically, the surface epithelium undergoes repetitive disruption and repair. It is thought that this process might lead to a higher probability of spontaneous mutations that can unmask germline mutations or otherwise lead to the oncogenic phenotype (see Chapter 6).
Prevention

Because parity is inversely related to the risk of ovarian cancer, having at least one child is protective for the disease, with a risk reduction of 0.3 to 0.4. Oral contraceptive use reduces the risk of epithelial ovarian cancer (32). Women who use oral contraceptives for 5 or more years reduce their relative risk to 0.5 (i.e., there is a 50% reduction in the likelihood of development of ovarian cancer). Women who had two children and used oral contraceptives for 5 or more years have a relative risk of ovarian cancer as low as 0.3, or a 70% reduction (34). The oral contraceptive pill is the only documented method of chemoprevention for ovarian cancer, and it should be recommended to women for this purpose. When counseling patients regarding birth control options, this important benefit of oral contraceptive use should be emphasized. This is important for women with a strong family history of ovarian cancer.

The performance of a prophylactic salpingo-oophorectomy significantly reduces, but does not totally eliminate, the risk of nonuterine pelvic cancers; because the entire peritoneum is at risk, peritoneal carcinomas can occur in 2% to 3% of women even after prophylactic bilateral salpingo-oophorectomy (25,28).

A thorough discussion of the risks and benefits of oophorectomy should be undertaken in premenopausal women who are undergoing a hysterectomy for benign disease, who do not carry germline mutations, and do not have a family history that suggests that they are at higher than average risk for ovarian cancer (35). The ovaries may provide protection from cardiovascular disease and osteoporosis, and long-term mortality may not be decreased by the performance of prophylactic oophorectomy in women at population risk of ovarian cancer (36).
Screening

The value of tumor markers and ultrasonography to screen for epithelial ovarian cancer is not established by prospective studies. Screening results with transabdominal ultrasonography are encouraging in postmenopausal women, but specificity is limited (37–39). Advances in transvaginal ultrasonography showed a very high (>95%) sensitivity for the detection of early-stage ovarian cancer, although this test alone might require performance of as many as 10 to 15 laparotomy procedures for each case of ovarian cancer detected (37,38). Routine annual pelvic examinations have disappointing results in the early detection of ovarian cancer (40). Transvaginal color flow Doppler to assess the vascularity of the ovarian vessels is a useful adjunct to ultrasonography, but it is not useful in screening (41,42).

CA125 is useful for monitoring epithelial ovarian cancer patients during their chemotherapy, but the role of CA125 is still being defined in a screening setting (43–49). Regarding the sensitivity of the test, elevated CA125 levels are seen in 50% of patients with stage I disease (43,48). Data suggest that the specificity of CA125 is improved when the test is combined with transvaginal ultrasonography or when the CA125 levels are followed over time (49,50). These data encouraged the development of prospective screening studies in Sweden and the United Kingdom (45,47). In these studies, patients with elevated CA125 levels (>30 U/mL) underwent abdominal ultrasonography, and 14 ovarian cancers were discovered among 27,000 women screened. About four laparotomies were performed for each case of cancer detected (47).

A randomized trial of nearly 22,000 women aged 45 years or older was performed in the United Kingdom (50). The patients were assigned to either a control group of routine pelvic examination (n = 9,977) or to a screening group (n = 10,958). The screening consisted of three annual screens that involved measurement of serum CA125 levels, pelvic ultrasonography if the CA125 was 30 U/mL or higher, and referral for gynecologic examination if the ovarian volume was 8.8 mL or greater on the ultrasonography. Of the 468 women in the screened group with an elevated CA125, 29 were referred for surgery, 6 cancers were discovered, and 23 had false-positive screening results, yielding a positive predictive value of 20.7%. During a 7-year follow-up period, cancer developed in 10 additional women in the screened group, as it did in 20 women in the control group. Although the median survival of women in whom cancer developed in the screened group was 72.9 months, compared with 41.8 months in the control group (p = .0112), the number of deaths did not differ significantly between the control and screened groups (18/10,977 vs. 9/10,958; relative risk 2.0 [0.78 to 5.13]). These data show that a multimodal approach to ovarian cancer screening is feasible, but a larger trial is necessary to determine whether this approach affects mortality. Such a three-arm randomized trial is ongoing in the United Kingdom, and the anticipated accrual is approximately 50,000 women per study arm and 100,000 women in the control arm. Based on the risk of ovarian cancer (ROC) algorithm for CA125 levels, patients in the third group will be referred for transvaginal ultrasonography and/or surgery (51). Women will
be screened for 3 years and studied for 7 years. The aims of this trial are to determine the feasibility of screening for ovarian cancer and whether ovarian cancers can be diagnosed at an earlier stage and the impact of early detection on survival.

Another approach is the use of proteomic patterns to identify ovarian cancer using surface-enhanced laser desorption ionization time-of-flight (SELDI-TOF) technology (52). In a study using this technology, the sensitivity for predicting ovarian cancer was 100%, with a specificity of 95% and a positive predictive value of 94%. The assay correctly identified all 18 women with stage I tumors. This technology is in the early phases of development and validation, and its efficacy has yet to be demonstrated in large population-based studies (53).

Given the false-positive and false-negative results for both CA125 and transvaginal ultrasonography and the absence of good data to show that screening detects ovarian cancers at an earlier stage, these tests are not recommended and should not be used routinely to screen women with a population risk or high risk for ovarian cancer (54–56). In the future, new markers or technologies may improve the specificity of ovarian cancer screening, but proof of this will require a large, prospective study (47,48). Screening in women who have a familial risk may have a better yield, but to date there is no evidence to demonstrate a benefit of screening even in high-risk women, and this is being actively investigated (55,57). The findings of two prospective studies of annual transvaginal ultrasound and CA125 screening in 888 BRCA1 and BRCA2 mutation carriers in the Netherlands and 279 mutation carriers in the United Kingdom are not encouraging and suggest a very limited benefit of screening in high-risk women (55,56). Despite annual gynecologic screening Hermsen et al. reported that a high proportion of ovarian cancers in BRCA1-2 carriers were interval cancers and the large majority of all cancers diagnosed were at advanced stages; similar results were reported by Woodward et al. (55,56).
Genetic Risk for Epithelial Ovarian Cancer

The lifetime risk of ovarian carcinoma for women in the United States is about 1.4% (1–3). The risk of ovarian cancer is higher than that in the general population in women with certain family histories (51–60). Most epithelial ovarian cancer is sporadic, with familial or hereditary causes accounting for 5% to 10% of invasive epithelial ovarian cancer (59).

Hereditary Ovarian Cancer

BRCA1 and BRCA2

Most hereditary ovarian cancer is associated with mutations in the BRCA1 gene, located on chromosome 17 (58–69). A small proportion of inherited disease is associated with germline mutations in another gene, BRCA2, located on chromosome 13 (60). Discovered through linkage analyses, these two high-penetrance genes are associated with the genetic predisposition to both ovarian and breast cancers. There are almost certainly other low- to moderate-penetrance genes that predispose to ovarian and breast cancer, and this is an area of intense research interest (1).

It was thought that there were two distinct syndromes associated with a genetic risk, site-specific hereditary ovarian cancer and hereditary breast-ovarian cancer syndrome. It is now believed that these groups represent a continuum of mutations with different degrees of penetrance within a given family (62,70). There is a higher-than-expected risk of ovarian and endometrial cancer in Lynch syndrome, known as the hereditary nonpolyposis colorectal cancer syndrome (HNPCC syndrome) (71).

The mutations are inherited in an autosomal dominant fashion, and therefore a full pedigree analysis (i.e., both maternal and paternal sides of the family) must be carefully evaluated (62). There are numerous distinct mutations that were identified on each of these genes, and the mutations have different degrees of penetrance that may account for the preponderance of either breast cancer, ovarian cancer, or both, in any given family. Based on analysis of women who have a mutation in the BRCA1 gene and are from high-risk families, the lifetime risk of ovarian cancer may be as high as 28% to 44%, and the risk was calculated to be as high as 27% for those women with a BRCA2 mutation (59,60,66–69). The risk of breast cancer in women with a BRCA1 or BRCA2 mutation may be as high as 56% to 87%.

Hereditary ovarian cancers occur in women approximately 10 years younger than those with nonhereditary tumors (i.e., closer to age 50 compared to age 60 for those with sporadic cancer) (59). A woman with a first- or second-degree relative who had premenopausal ovarian cancer may have a higher probability of carrying an affected gene. Breast and ovarian cancer may exist in a family in which there is a combination of epithelial ovarian and breast cancers, affecting a mixture of first- and second-degree relatives. Women with this syndrome tend to have these tumors at a young age, and the
breast cancers may be bilateral. If two first-degree relatives are affected, this pedigree is consistent with an autosomal dominant mode of inheritance (50,58). Most BRCA1 ovarian cancers are high-grade serous carcinomas (Fig. 37.9).

**Figure 37.9** BRCA1-associated ovarian carcinoma is typically a high-grade serous adenocarcinoma with numerous mitotic figures and marked nuclear pleomorphism. A brisk lymphocytic infiltrate with tumor infiltrating lymphocytes is not uncommon in these tumors.
Founder Effect

There is a higher carrier rate of BRCA1 and BRCA2 mutations in women of Ashkenazi Jewish descent, in Icelandic women, and in many other ethnic groups (64,65,67–69). There are three specific founder mutations carried by the Ashkenazi population, 185delAG and 5382insC on BRCA1, and 6174delT on BRCA2. **Individuals of Ashkenazi Jewish descent have a 1 in 40, or 2.5%, chance of having a mutation in BRCA1 or BRCA2, and thus there is a greater risk in this population.** The increased risk is a result of the founder effect, in which a higher rate of specific mutations occurs in an ethnic group from a defined geographic area. These founder mutations generated considerable interest, because they facilitate studies of prevalence and penetrance and can be used to quantify the degree of homogeneity within a population.

Pedigree Analysis

The risk of carrying a germline mutation that predisposes to ovarian cancer depends on the number of first- or second-degree relatives (or both) with a history of epithelial ovarian carcinoma or breast cancer (or both) and on the number of malignancies that occurs at an earlier age. The degree of risk is difficult to determine precisely unless a full pedigree analysis is performed.

In families with two first-degree relatives (i.e., mother, sister, or daughter) with documented premenopausal epithelial ovarian cancer, the risk that a female first-degree relative has an affected gene could be as high as 35% to 40% (60).

In families with a single first-degree relative and a single second-degree relative (i.e., grandmother, aunt, first cousin, or granddaughter) with epithelial ovarian cancer, the risk that a woman has an affected gene may be increased. The risk may be two- to 10-fold higher than in those without a familial history of the disease (60).

In families with a single postmenopausal first-degree relative with epithelial ovarian carcinoma, a woman may not have an increased risk of having an affected gene because the case is most likely to be sporadic. If the ovarian cancer occurs in a premenopausal relative, this could be significant, and a full pedigree analysis should be undertaken.

Women with a primary history of breast cancer have twice the expected incidence of subsequent ovarian cancer (59).

Lynch Syndrome or Hereditary Nonpolyposis Colon Cancer

Lynch syndrome (HNPCC), which includes multiple adenocarcinomas, involves a combination of colon cancer and endometrial or ovarian cancer and other malignancies of the gastrointestinal and genitourinary systems (71). **The mutations that are associated with this syndrome are MSH2, MLH1, PMS1, and PMS2.** The risk that a woman who is a member of one of these families will develop epithelial ovarian cancer depends on the frequency of this disease in first- and second-degree relatives, although these women appear to have at least three times the relative risk of the general population. A full pedigree analysis of such families should be
Management of Women at High Risk for Ovarian Cancer

The management of a woman with a strong family history of epithelial ovarian cancer must be individualized and depends on her age, her reproductive plans, and the extent of risk. In all of these syndromes, women at risk benefit from a thorough pedigree analysis. A geneticist should evaluate the family pedigree for at least three generations. Decisions about management are best made after careful study and, whenever possible, verification of the histologic diagnosis of the family members' ovarian cancer.

The value of testing for BRCA1 and BRCA2 is established, and there are guidelines for testing (62,70,72). The importance of genetic counseling cannot be overemphasized because the decision is complex. The American Society of Clinical Oncology offered guidelines that emphasize careful evaluation by geneticists, careful maintenance of medical records, and an understanding in a genetic screening clinic of how to effectively counsel and manage these patients. Concerns remain over the use of the information, the impact on insurability, the interpretation of the results, and how the information will be used within a specific family (e.g., to counsel children).

Although there are some conflicting data, the behavior of breast cancers arising in women with germline mutations in BRCA1 or BRCA2 is comparable to the behavior of sporadic tumors (61,73). Women with breast cancer who carry these mutations are at a greatly increased risk of ovarian cancer and a second breast cancer: the lifetime risk of ovarian cancer is 54% for women who have a BRCA1 mutation and 23% for those with a BRCA2 mutation, and for the two groups together, there is an 82% lifetime risk of breast cancer (73).

Despite recommendation by the National Institutes of Health Consensus Conference on Ovarian Cancer, the value of screening with transvaginal ultrasonography, CA125 levels, or other procedures is not established in women at high risk (74). Bourne and coworkers showed that, using this approach, tumors can be detected approximately 10 times more often than in the general population, and they recommend screening in high-risk women, but other groups have not confirmed these findings, and bilateral salpingo-oophorectomy remains the most effective way to reduce risk (57,75).

Data derived from a multicenter consortium of genetic screening centers indicate that the use of the oral contraceptive pill is associated with a lower risk for development of ovarian cancer in women who have a mutation in either BRCA1 or BRCA2 (76). The risk reduction is significant: in women who take oral contraceptives for 5 or more years, the relative risk of ovarian cancer is 0.4, or a 60% reduction in the incidence of the disease.

Prophylactic Salpingo-oophorectomy in High-Risk Women
The value of prophylactic salpingo-oophorectomy in these patients is documented (77–83). Women at high risk for ovarian cancer who undergo prophylactic salpingo-oophorectomy have a risk of harboring occult neoplasia: in one series of 98 such operations, 3 (3.1%) patients had a low-stage ovarian malignancy (80). The protection against ovarian cancer is excellent: the performance of a prophylactic salpingo-oophorectomy reduced the risk of BRCA-related gynecologic cancer by 96% (80). In a series of 42 such operations, 4 patients (9.5%) had a malignancy, 1 of which was noted at surgery and 3 that were microscopic; all were smaller than 5 mm (78). Although the risk of ovarian cancer is significantly diminished, there remains the small risk of peritoneal carcinoma, a tumor for which women who have mutations in BRCA1 and BRCA2 may have a higher predisposition. In these series, the subsequent development of peritoneal carcinoma was 0.8% and 1%, respectively (78,79). The risk of developing subsequent breast cancer was reduced by 50% to 80%.

The role of hysterectomy is more controversial. Most studies show no increase in the rate of uterine and cervical tumors, but there are rare reports of an increase of papillary serous tumors of the endometrium (83). Women on tamoxifen are at higher risk for benign endometrial lesions (e.g., polyps) and endometrial cancer. It is reasonable to consider the performance of a prophylactic hysterectomy in conjunction with salpingo-oophorectomy, but this decision should be individualized.

The survival of women who have a BRCA1 or BRCA2 mutation and develop ovarian cancer is longer than that for those who do not have a mutation. In one study, the median survival for mutation carriers was 53.4 months compared with 37.8 months for those with sporadic ovarian cancer from the same institution (84).

Recommendations

Current recommendations for management of women at high risk for ovarian cancer are summarized as follows (72,82):

Women who appear to be at high risk for ovarian or breast cancer should undergo genetic counseling and, if the risk appears to be substantial (i.e., a calculated risk of at least 10% in having a mutation in BRCA1 or BRCA2), may be offered genetic testing for BRCA1 and BRCA2.

Women who wish to preserve their reproductive capacity can undergo screening by transvaginal ultrasonography every 6 months, although the efficacy of this approach is not established.

Oral contraceptives should be recommended to young women before they embark on an attempt to have a family.

Women who do not wish to maintain their fertility or who have completed their families should be recommended to undergo prophylactic bilateral salpingo-oophorectomy after the age of 35, but by age 40 years. The risk of ovarian cancers under the age of 40 is very low but the decision regarding the age of surgery should be based on the age of onset of ovarian cancers in the family. Most BRCA2-related
ovarian cancers tend to occur after the age of 50, whereas BRCA1-related cancers occur at an earlier age. The risk should be clearly documented, preferably established by BRCA1 and BRCA2 testing, before salpingo-oophorectomy is performed. These women should be counseled that this operation does not offer absolute protection, because peritoneal carcinomas can occur after bilateral salpingo-oophorectomy (25,28,83).

In women who have a strong family history of breast or ovarian cancer, annual breast screening should be performed beginning at age 30 years using a combination of magnetic resonance imaging (MRI), mammograms, and ultrasound. Ideally, these women should be followed in clinics that manage women at high risk for cancer.

Women with a documented HNPCC syndrome should be treated as mentioned above, and they should undergo periodic colonoscopy, endometrial biopsy, or prophylactic hysterectomy after the completion of childbearing (71).
Symptoms

The majority of women with epithelial ovarian cancer have vague and nonspecific symptoms (3,85–87). In early-stage disease, if the patient is premenopausal, she may experience irregular menses. If a pelvic mass is compressing the bladder or rectum, she may report urinary frequency or constipation (85–87). Occasionally, she may perceive lower abdominal distention, pressure, or pain, such as dyspareunia. Acute symptoms, such as pain secondary to rupture or torsion, are unusual.

In advanced-stage disease, patients have symptoms related to the presence of ascites, omental metastases, or bowel metastases. The symptoms include abdominal distention, bloating, constipation, nausea, anorexia, or early satiety. Premenopausal women may report irregular or heavy menses, whereas vaginal bleeding may occur in postmenopausal women (86).

Traditionally, ovarian cancer was considered a “silent killer” that did not produce symptoms until far advanced. Some patients with ovarian cancers confined to the ovary are asymptomatic, but the majority will have nonspecific symptoms that do not necessarily suggest an origin in the ovary (86,88–90). In one survey of 1,725 with ovarian cancer, 95% recalled symptoms before diagnosis, including 89% with stage I and II disease and 97% with stages III and IV disease (86). Some 70% had abdominal or gastrointestinal symptoms, 58% pain, 34% urinary symptoms, and 26% pelvic discomfort. At least some of these symptoms could have reflected pressure on the pelvic viscera from the enlarging ovary. Goff et al. developed an ovarian cancer symptom index and reported that symptoms associated with ovarian cancer, when present for less than 1 year and occurring longer than 12 days a month, were pelvic/abdominal pain, urinary frequency/urgency, increased abdominal size or bloating, and difficulty eating or feeling full (88). The index had a sensitivity of 56.7% for early ovarian cancer and 79.5% for advanced stage disease. A population-based study from Australia found that there did not appear to be a significant difference in the duration of symptoms or the nature of symptoms in patients with early as opposed to advanced stage ovarian cancer, reinforcing the concept that they are biologically different entities and arguing against the widely held misconception that early stage ovarian cancers are at an early stage because they were diagnosed earlier than patients with more advanced stage cancers (89).
Signs

The most important sign of epithelial ovarian cancer is the presence of a pelvic mass on physical examination. A solid, irregular, fixed pelvic mass is highly suggestive of an ovarian malignancy. If an upper abdominal mass or ascites is present, the diagnosis of ovarian cancer is almost certain. Because the patient usually reports abdominal symptoms, she may not have a pelvic examination, and a tumor may be missed.

In patients who are at least 1 year past menopause, the ovaries should be atrophic and not palpable. It was proposed that any palpable pelvic mass in these patients should be considered potentially malignant, a situation that was referred to as the postmenopausal palpable ovary syndrome (91). This concept was challenged, because subsequent authors reported that only about 3% of palpable masses measuring less than 5 cm in postmenopausal women are malignant (57).
Diagnosis

Ovarian epithelial cancers must be differentiated from benign neoplasms and functional cysts of the ovaries. A variety of benign conditions of the reproductive tract, such as pelvic inflammatory disease, endometriosis, and pedunculated uterine leiomyomas, can simulate ovarian cancer. Nongynecologic causes of a pelvic tumor, such as an inflammatory (e.g., diverticular) disease or neoplastic colonic mass, must be excluded (3). A pelvic kidney can simulate ovarian cancer.

Serum CA125 levels are useful in distinguishing malignant from benign pelvic masses (92). For a postmenopausal patient with an adnexal mass and a very high serum CA125 level (>200 U/mL), there is a 96% positive predictive value for malignancy. For premenopausal patients, the specificity of the test is low because the CA125 level tends to be elevated in common benign conditions.

For the premenopausal patient, a period of observation is reasonable provided the adnexal mass does not have characteristics that suggest malignancy (i.e., it is mobile, mostly cystic, unilateral, and of regular contour). An interval of no more than 2 months is allowed, during which hormonal suppression with an oral contraceptive may be used. If the lesion is not neoplastic, it should regress, as measured by pelvic examination and pelvic ultrasonography. If the mass does not regress or if it increases in size, it must be presumed to be neoplastic and must be removed surgically.

The size of the lesion is important. If a cystic mass is greater than 8 cm in diameter, the probability is high that the lesion is neoplastic, unless the patient is taking clomiphene citrate or other agents to induce ovulation (37–40). Premenopausal patients whose lesions are clinically suspicious (i.e., large, predominantly solid, relatively fixed, or irregularly shaped) should undergo laparotomy, as should postmenopausal patients with complex adnexal masses of any size.

Ultrasonographic signs of malignancy include an adnexal pelvic mass with areas of complexity, such as irregular borders, multiple echogenic patterns within the mass, and dense multiple irregular septae. Bilateral tumors are more likely to be malignant, although the individual characteristics of the lesions are of greater significance. Transvaginal ultrasonography may have a somewhat better resolution than transabdominal ultrasonography for adnexal neoplasms (93–96). Doppler color flow imaging may enhance the specificity of ultrasonography for demonstrating findings consistent with malignancy (97–99).

In postmenopausal women with unilocular cysts measuring 8 to 10 cm or less and normal serial CA125 levels, expectant management is acceptable, and this approach may decrease the number of surgical interventions (100–102).

The diagnosis of an ovarian cancer requires an exploratory laparotomy. The preoperative evaluation of the patient with an adnexal mass is outlined in Figure 14.19 (see Chapter 14).

Before the planned exploration, the patient should undergo routine hematologic and
biochemical assessments. A preoperative evaluation in a patient undergoing laparotomy should include a radiograph of the chest. Abdominal and pelvic computed tomography (CT) or MRI are of limited value for a patient with a definite pelvic mass (103–105). A CT or MRI should be performed for patients with ascites and no pelvic mass to look for liver or pancreatic tumors. The findings only rarely preclude laparotomy (103). The value of PET scanning is still being evaluated (105–107). If the hepatic enzyme values are normal, the likelihood of liver disease is low. Liver-spleen scans, bone scans, and brain scans are unnecessary unless symptoms or signs suggest metastases to these sites.

The preoperative evaluation should exclude other primary cancers metastatic to the ovary. A barium enema or colonoscopy is indicated in selected patients with symptoms and signs suspicious for colon cancer. This study should be performed for any patient who has evidence of occult blood in the stool or of intestinal obstruction. An upper gastrointestinal radiographic series or gastroscopy is indicated if there are upper gastrointestinal symptoms such as nausea, vomiting, or hematemesis (3,108). Bilateral mammography is indicated if there is any breast mass, because breast cancer metastatic to the ovaries can simulate primary ovarian cancer.

A Papanicolaou (Pap) test should be performed, although its value for the detection of ovarian cancer is very limited. Patients who have irregular menses or postmenopausal vaginal bleeding should have endometrial biopsy and endocervical curettage to exclude the presence of uterine or endocervical cancer metastatic to the ovary.

Differential Diagnosis

Ovarian epithelial cancers must be differentiated from benign neoplasms and functional cysts of the ovaries (100–102). A variety of benign conditions of the reproductive tract, such as pelvic inflammatory disease, endometriosis, and pedunculated uterine leiomyomata, can simulate ovarian cancer. Nongynecologic causes of a pelvic tumor, such as an inflammatory or neoplastic colonic mass, must be excluded. A pelvic kidney can simulate ovarian cancer.
Patterns of Spread

Ovarian epithelial cancers spread primarily by exfoliation of cells into the peritoneal cavity, by lymphatic dissemination, and by hematogenous spread.

Transcoelomic

The most common and earliest mode of dissemination of ovarian epithelial cancer is by exfoliation of cells that implant along the surfaces of the peritoneal cavity. The cells tend to follow the circulatory path of the peritoneal fluid. The fluid moves with the forces of respiration from the pelvis, up the paracolic gutters, especially on the right, along the intestinal mesenteries, to the right hemidiaphragm. Metastases are typically seen on the posterior cul-de-sac, paracolic gutters, right hemidiaphragm, liver capsule, the peritoneal surfaces of the intestines and their mesenteries, and the omentum. The disease seldom invades the intestinal lumen but progressively agglutinates loops of bowel, leading to a functional intestinal obstruction. This condition is known as carcinomatous ileus (3).

Lymphatic

Lymphatic dissemination to the pelvic and para-aortic lymph nodes is common, particularly in advanced-stage disease (109–111). Spread through the lymphatic channels of the diaphragm and through the retroperitoneal lymph nodes can lead to dissemination above the diaphragm, especially to the supraclavicular lymph nodes (109). Burghardt et al. reported that 78% of patients with stage III disease have metastases to the pelvic lymph nodes (111). In another series, the rate of para-aortic lymph nodes positive for metastasis was 18% in stage I, 20% in stage II, 42% in stage III, and 67% in stage IV (109).

Hematogenous

Hematogenous dissemination at the time of diagnosis is uncommon. Spread to vital organ parenchyma, such as the lungs and liver, occurs in only about 2% to 3% of patients. Most patients with disease above the diaphragm when diagnosed have a right pleural effusion (3). Systemic metastases appear more frequently in patients who survived for some years. Dauplat et al. reported that distant metastasis consistent with stage IV disease ultimately occurred in 38% of the patients whose disease was originally intraperitoneal (112).
The outcome of treatment can be evaluated in the context of prognostic factors, which can be grouped into pathologic, biologic, and clinical factors (113).

**Pathologic Factors**

The morphology and histologic pattern, including the architecture and grade of the lesion, are important prognostic variables (3). Histologic type was not believed to have prognostic significance, but several papers contained suggestions that clear cell carcinomas are associated with a prognosis worse than that of other histologic types (113,114).

Histologic grade, as determined either by the pattern of differentiation or by the extent of cellular anaplasia and the proportion of undifferentiated cells, seems to be of prognostic significance (115–118). Studies of the reproducibility of grading ovarian cancers show a high degree of intraobserver and interobserver variation (119,120). Because there is significant heterogeneity of tumors and observational bias, the value of histologic grade as an independent prognostic factor is not established. Baak et al. have presented a standard grading system based on morphometric analysis, and the system seems to correlate with prognosis, especially in its ability to distinguish low-grade or borderline patterns from other tumors (121).

**Clinical Factors**

In addition to stage, the extent of residual disease after primary surgery, the volume of ascites, patient age, and performance status are all independent prognostic variables (122–131). Among patients with stage I disease, Dembo et al. showed, in a multivariate analysis, that tumor grade and dense adherence to the pelvic peritoneum had a significant adverse impact on prognosis, whereas intraoperative tumor spillage or rupture did not (128). Sjövall et al. confirmed that ovarian cancers that undergo intraoperative rupture or spillage do not worsen prognosis, whereas tumors that are ruptured preoperatively do have a poorer prognosis (129). A multivariate analysis of these and several other studies was performed by Vergote et al., who found that for early-stage disease, poor prognostic variables were tumor grade, capsular penetration, surface excrescences, and malignant ascites, but not iatrogenic rupture (131).
**Initial Surgery for Ovarian Cancer**

**Staging**

Ovarian epithelial malignancies are staged according to the FIGO system listed in Table 37.2 (30). The FIGO staging is based on findings at surgical exploration. A preoperative evaluation should exclude the presence of extraperitoneal metastases.

**Table 37.2 FIGO Staging for Primary Carcinoma of the Ovary**

equals stage IV.

These categories are based on findings at clinical examination or surgical exploration or both. The histologic characteristics are to be considered in the staging, as are results of cytologic testing as far as effusions are concerned. It is desirable that a biopsy be performed on suspicious areas outside the pelvis.

FIGO, International Federation of Obstetrics and Gynecology.

To evaluate the impact on prognosis of the different criteria for allotting cases to stage IC or IIC, it would be of value to know if rupture of the capsule was (i) spontaneous or (ii) caused by the surgeon and if the source of malignant cells detected was (i) peritoneal washings or (ii) ascites.

The importance of thorough surgical staging cannot be overemphasized, because subsequent treatment will be determined by the stage of disease. For patients in whom exploratory laparotomy does not reveal any macroscopic evidence of disease on inspection and palpation of the entire intra-abdominal space, a careful search for microscopic spread must be undertaken. In earlier series in which patients did not undergo careful surgical staging, the overall 5-year survival for patients with apparent stage I epithelial ovarian cancer was only about 60% (132). Since then, survival rates of 90% to 100% are reported for patients who were properly staged and were found to have stage IA or IB disease (133,134).

Technique for Surgical Staging

In patients whose preoperative evaluation suggests a probable malignancy, a midline or paramedian abdominal incision is recommended to allow adequate access to the upper abdomen (3,132). When a malignancy is unexpectedly discovered in a patient who has a lower transverse incision, the rectus muscles can be either divided or detached from the symphysis pubis to allow better access to the upper abdomen. If this is not sufficient, the incision can be extended on one side to create a “J” incision (3).

The ovarian tumor should be removed intact, if possible, and a frozen histologic section should be obtained. If ovarian malignancy is present and the tumor is apparently confined to the ovaries or the pelvis, thorough surgical staging should be performed. Staging involves the following steps (3,132):

Any free fluid, especially in the pelvic cul-de-sac, should be submitted for cytologic evaluation.

If no free fluid is present, peritoneal washings should be performed by instilling and recovering 50 to 100 mL of saline from the pelvic cul-de-sac, each paracolic gutter, and beneath each hemidiaphragm. Obtaining the
specimens from under the diaphragms can be facilitated with the use of a rubber catheter attached to the end of a bulb syringe.

**A systematic exploration of all the intra-abdominal surfaces and viscera is performed,** proceeding in a clockwise fashion from the cecum cephalad along the paracolic gutter and the ascending colon to the right kidney, the liver and gallbladder, the right hemidiaphragm, the entrance to the lesser sac at the para-aortic area, across the transverse colon to the left hemidiaphragm, down the left gutter and the descending colon to the rectosigmoid colon. The small intestine and its mesentery from the Treitz ligament to the cecum should be inspected.

**Any suspicious areas or adhesions on the peritoneal surfaces should be biopsied.** If there is no evidence of disease, multiple intraperitoneal biopsies should be performed. Tissue from the peritoneum of the pelvic cul-de-sac, both paracolic gutters, the peritoneum over the bladder, and the intestinal mesenteries should be taken for biopsy.

**The diaphragm should be sampled, either by biopsy or by scraping with a tongue depressor, and a sample obtained for cytologic assessment.** Biopsies of any irregularities on the surface of the diaphragm can be facilitated by use of the laparoscope and the associated biopsy instrument.

**The omentum should be resected from the transverse colon, a procedure called an infracolic omentectomy.** The procedure is initiated on the underside of the greater omentum, where the peritoneum is incised just a few millimeters away from the transverse colon. The branches of the gastroepiploic vessels are clamped, ligated, and divided, along with all the small branching vessels that feed the infracolic omentum. If the gastrocolic ligament is palpably normal, it does not need to be resected.

**The retroperitoneal spaces should be explored to evaluate the pelvic and para-aortic lymph nodes.** The retroperitoneal dissection is performed by incision of the peritoneum over the psoas muscles. This may be performed on the ipsilateral side only for unilateral tumors. Any enlarged lymph nodes should be resected and submitted for frozen section. If no metastases are present, a formal pelvic lymphadenectomy should be performed. The para-aortic area should be explored.

**Results**

Metastases in apparent stage I and II epithelial ovarian cancer occur in as many as 3 in 10 patients whose tumors appear to be confined to the pelvis but who have occult metastatic disease in the upper abdomen or the retroperitoneal lymph nodes (110,133–140). In a literature review, occult metastases in such patients were found in biopsies of the diaphragm in 7.3%, biopsies of the omentum in 8.6%, the pelvic lymph nodes in 5.9%, the aortic lymph nodes in 18.1%, and in 26.4% of peritoneal washings (132).

The importance of careful initial surgical staging is emphasized by the findings of a cooperative national study in which 100 patients with apparent stage I and II disease were referred for subsequent therapy and underwent additional surgical staging (133). In
This series, 28% of the patients initially believed to have stage I disease were upstaged and 43% of those believed to have stage II disease had more advanced lesions. A total of 31% of the patients were upstaged as a result of additional surgery, and 77% were reclassified as having actual stage III disease. Histologic grade was a significant predictor of occult metastasis. Sixteen percent of the patients with grade 1 lesions were upstaged, compared with 34% with grade 2 disease and 46% with grade 3 disease.

Borderline Tumors

The principal treatment of borderline (low malignant potential) ovarian tumors is surgical resection of the primary tumor. There is no evidence that either subsequent chemotherapy or radiation therapy improves survival. When a frozen section determines that the histology is borderline, premenopausal patients who desire preservation of ovarian function may undergo a conservative operation, a unilateral oophorectomy [3,141]. In a study of patients who underwent unilateral ovarian cystectomy only for apparent stage I borderline serous tumors, Lim-Tan et al. found that this conservative operation was safe, with only 8% of the patients developing recurrences 2 to 18 years later, all with curable disease confined to the ovaries [141]. Recurrence was associated with positive margins of the removed ovarian cyst. Thus, hormonal function and fertility can be maintained [3,141]. For patients who had an oophorectomy or cystectomy and a borderline tumor is documented later in the permanent pathology, no additional immediate surgery is necessary.

Stage I

After a comprehensive staging laparotomy, only a minority of women will have local disease (FIGO stage I). There are over 20,000 women diagnosed yearly with epithelial ovarian cancer in the United States, and nearly 4,000 of these have disease confined to the ovaries [1,142]. The prognosis for these patients depends on the clinical–pathologic features, as outlined below. Because of this emphasis on the importance of surgical staging, the rate of lymph node sampling increased in the United States, with a study showing that for women with stages I and II disease, the percentage having lymph nodes sampled increased from 38% to 59% from 1991 to 1996 [143].

The primary surgical treatment for stage I epithelial ovarian cancer is surgical, and patients should undergo total abdominal hysterectomy, bilateral salpingo-oophorectomy, and surgical staging [132,133]. In certain circumstances, a unilateral salpingo-oophorectomy may be performed. Based on the findings at surgery and the pathologic evaluation, patients with stage I ovarian cancer can be grouped into low-risk and high-risk categories (Table 37.3).

**Stage I Low Risk**

**Fertility Preservation in Early-Stage Ovarian Cancer**

For patients who underwent a thorough staging laparotomy and who have no evidence of spread beyond the ovary, abdominal hysterectomy and bilateral salpingo-oophorectomy are appropriate therapy. The uterus and the contralateral ovary can be preserved in women with stage IA, grade 1 to 2 disease who desire to preserve fertility. The conditions of the women should be monitored carefully with routine periodic pelvic examinations and determinations of serum CA125 levels. Generally, the other ovary and the uterus are removed at the completion of childbearing.

Guthrie et al. studied the outcome of 656 patients with early-stage epithelial ovarian cancer (140). No untreated patients who had stage IA, grade 1 cancer died of their disease; thus, adjuvant radiation and chemotherapy are unnecessary. Furthermore, the Gynecologic Oncology Group (GOG) carried out a prospective, randomized trial of observation versus melphalan for patients with stage IA and IB, grade 1 or 2 disease (114). Five-year survival for each group was 94% and 96%, respectively, confirming that no further treatment is needed for such patients.

**Stage I High Risk**

Patients who have more poorly differentiated disease or who have malignant cells, either in ascites fluid or in peritoneal washings, must undergo complete surgical staging (3). The surgery should include the performance of a hysterectomy and bilateral salpingo-oophorectomy in addition to the staging laparotomy. Although the optimal supportive therapy for these patients is not known, most patients are treated with chemotherapy, as outlined below.

**Advanced-Stage Ovarian Cancer**

The surgical management of all patients with advanced-stage disease is...
approached in a similar manner, with modifications made in response to the overall status and general health of the patient and the extent of residual disease present at the time treatment is initiated. A treatment scheme is outlined in Figure 37.10. Most patients subsequently receive combination chemotherapy for an empiric number of cycles.

Cytoreductive Surgery for Advanced-Stage Disease

If the patient is medically stable, she should undergo cytoreductive surgery to remove as much of the tumor and its metastases as possible (144–171). The operation to remove the primary tumor and the associated metastatic disease is referred to as **debulking** or cytoreductive surgery. The operation typically includes the performance of a total abdominal hysterectomy and bilateral salpingo-oophorectomy, along with a complete omentectomy and resection of any metastatic lesions from the peritoneal surfaces or from the intestines. The pelvic tumor often directly involves the rectosigmoid colon, the terminal ileum, and the cecum (Fig. 37.11). In a minority of patients, most or all of the disease is confined to the pelvic viscera and the omentum, so that removal of these organs will result in extirpation of all gross tumor, a situation that is associated with a reasonable chance of prolonged progression-free survival.

**Figure 37.10** Treatment scheme for patients with advanced-stage ovarian cancer. *In selected cases of Stage IIIc/IV disease, neoadjuvant chemotherapy may be given, and then an interval cytoreductive surgery is performed after 3 cycles. †Chemotherapy depends on whether platinum-sensitive or platinum-resistant. (Modified from Berek JS, Hacker NF. Berek & Hacker's Gynecologic Oncology. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010:460, with permission.)
Figure 37.11 Extensive ovarian carcinoma involving the bladder, rectosigmoid, and ileocecal area. (Redrawn from Heintz APM, Berek JS. Cytoreductive surgery for ovarian carcinoma. In: Piver MS, ed. Ovarian malignancies. Edinburgh, UK: Churchill Livingstone, 1987:134, with permission.)
The removal of bulky tumor masses may reduce the volume of ascites present. Often, ascites will disappear after removal of the primary tumor and a large omental “cake.” Removal of the omental cake may alleviate the nausea and early satiety that many patients experience. Removal of intestinal metastases may restore adequate intestinal function and improve the overall nutritional status of the patient, thereby facilitating the patient’s ability to tolerate subsequent chemotherapy.

A large, bulky tumor may contain areas that are poorly vascularized, and these areas will be exposed to suboptimal concentrations of chemotherapeutic agents. Similarly, these areas are poorly oxygenated, so that radiation therapy, which requires adequate oxygenation to achieve maximal cell kill, will be less effective. Surgical removal of these bulky tumors may eliminate areas that could be relatively resistant to radiation and chemotherapeutic treatment.

Larger tumor masses tend to be composed of a higher proportion of cells that are either nondividing or in the “resting” phase (i.e., G₀ cells, which are essentially resistant to the therapy). A low growth fraction is characteristic of bulky tumor masses, and cytoreductive surgery can result in smaller residual masses with a relatively higher growth fraction.

**Goals of Cytoreductive Surgery**

The principal goal of cytoreductive surgery is removal of all of the primary cancer and, if possible, all metastatic disease. If resection of all metastases is not feasible, the goal is to reduce the tumor burden by resection of all individual tumors to an optimal status. Griffiths initially proposed that all metastatic nodules should be reduced to less than 1.5 cm in maximal diameter and showed that survival was significantly longer in
Hacker and Berek demonstrated that patients whose largest residual lesions were less than 5 mm had a superior survival rate, which was substantiated by Van Lindert et al. (145–148). The median survival of patients in this category was 40 months, compared with 18 months for patients whose lesions were less than 1.5 cm and 6 months for patients with nodules greater than 1.5 cm. **Patients whose disease is completely resected to no macroscopic (microscopic only) residual disease have the best overall survival (149)** (Fig. 37.12). Approximately 30% to 40% of patients in this category will be free of disease at 5 years.

**Figure 37.12 Survival of patients with stage IIIC epithelial ovarian cancer based on the maximal size of residual tumor after exploratory laparotomy and tumor resection.** (From Heintz APM, Odicino F, Maisonneuve P, et al. Carcinoma of the ovary. Twenty-sixth annual report of the results of treatment of gynaecological cancer. Int J Gynecol Oncol 2006;95(suppl 1):S161–S192, with permission.)

The resectability of the metastatic tumor is usually determined by the location of the disease. Optimal cytoreduction is difficult to achieve in the presence of extensive disease on the diaphragm, in the parenchyma of the liver, along the base of the small bowel mesentery, in the lesser omentum, or in the porta hepatis.

The ability of cytoreductive surgery to influence survival is limited by the extent of metastases before cytoreduction, presumably because of the presence of phenotypically resistant clones of cells in large metastatic masses. A patient whose metastatic tumor is very large (i.e., >10 cm before cytoreductive surgery) has a shorter survival than those with smaller areas of disease (147,149). Extensive carcinomatosis, the presence of ascites, and poor tumor grade, even with lesions that measure less than 5 mm, may shorten the survival (150–153).

**Exploration**
The supine position on the operating table may be sufficient for surgical exploration of most patients. For patients with extensive pelvic disease and for whom a low resection of the colon may be necessary, the low lithotomy position should be used. Debulking operations should be performed through a vertical incision to gain adequate access to the upper abdomen and to the pelvis.

After the peritoneal cavity is opened, ascites fluid, if present, should be evacuated. In some centers, fluid is submitted for in vitro research studies, such as molecular analyses. In cases of massive ascites, careful attention must be given to hemodynamic monitoring, especially for patients with borderline cardiovascular function.

The peritoneal cavity and retroperitoneum are thoroughly inspected and palpated to assess the extent of the primary tumor and the metastatic disease. All abdominal viscera must be palpated to exclude the possibility that the ovarian disease is metastatic, particularly from the stomach, colon, or pancreas. If optimal status is not considered achievable, extensive bowel and urologic resections are not indicated, except to overcome a bowel obstruction. Removal of the primary tumor and omental cake is usually both feasible and desirable.

**Figure 37.13** The resection of the pelvic tumor may include removal of the uterus, tubes, and ovaries, as well as portions of the lower intestinal tract. The arrows represent the plane of resection. (From Berek JS, Hacker NF. Berek & Hacker’s Gynecologic Oncology. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010:465, with permission.)

**Pelvic Tumor Resection**

The essential principle of pelvic tumor removal is the retroperitoneal approach.
To accomplish this, the retroperitoneum is entered laterally, along the surface of the psoas muscles, which avoids the iliac vessels and the ureters. If the uterus is present, the procedure is initiated by bilateral division of the round ligaments. The peritoneal incision is extended cephalad, lateral to the ovarian vessels within the infundibulopelvic ligament, and caudally toward the bladder. With careful dissection, the retroperitoneal space is explored, and the ureter and pelvic vessels are identified. The pararectal and paravesicular spaces are identified and developed, as described in Chapter 36.

The peritoneum overlying the bladder is dissected to connect the peritoneal incisions anteriorly. The vesicouterine plane is identified, and with careful sharp dissection the bladder is mobilized from the anterior surface of the cervix. The ovarian vessels are isolated, doubly ligated, and divided.

**Hysterectomy is then performed.** The ureters must be carefully displayed to avoid injury. During this procedure, the uterine vessels can be identified. Ligation of the uterine vessels and the remainder of the tissues within the cardinal ligaments completes the hysterectomy and resection of the contiguous tumor.

Figure 37.14 Separation of the omentum from stomach and transverse colon. Arrow, the direction of the initial surgical approach. (From Heintz APM, Berek JS. Cytoreductive surgery for ovarian carcinoma. In: Piver MS, ed. Ovarian malignancies. Edinburgh, UK: Churchill Livingstone, 1987:134, with permission.)

Because epithelial ovarian cancers tend not to invade the lumina of the colon or bladder, it is usually feasible to resect pelvic tumors without having to resect portions of the lower colon or the urinary tract (154,155). Resection of a small portion of the bladder may be required and, if so, a cystotomy should be performed to assist in resection of the disease (155).

**Intestinal Resection**

Resection of focal areas of disease involving the small or large intestine should
be performed if that would permit the removal of all or most of the abdominal metastases and leave the patient with optimal disease at the end of the cytoreduction. Apart from the rectosigmoid colon, the most frequent sites of intestinal metastasis are the terminal ileum, the cecum, and the transverse colon. Resection of one or more of these segments of bowel may be necessary (154, 156).

If the disease surrounds the rectosigmoid colon and its mesentery, that portion of the colon may have to be removed in order to clear the pelvic disease (Fig. 37.13) (154). When the pararectal space is identified in such patients, the proximal site of colonic involvement is identified, the colon and its mesentery are divided, and the rectosigmoid is removed along with the uterus en bloc. A reanastomosis of the colon is performed.

Omentectomy

Advanced epithelial ovarian cancer often completely replaces the omentum, forming an “omental cake.” This disease may be adherent to the parietal peritoneum of the anterior abdominal wall, making entry into the abdominal cavity difficult. After freeing the omentum from any adhesions to parietal peritoneum, adherent loops of small intestine are freed by sharp dissection. The omentum is lifted and pulled gently in the cranial direction, exposing the attachment of the infracolic omentum to the transverse colon. The peritoneum is incised to open the appropriate plane, which is developed by sharp dissection along the serosa of the transverse colon. Small vessels are ligated with hemoclips. The omentum is separated from the greater curvature of the stomach by ligation of the right and left gastroepiploic arteries and ligation of the short gastric arteries (Fig. 37.14).

The disease in the gastrocolic ligament can extend to the hilus of the spleen and splenic flexure of the colon on the left and to the capsule of the liver and the hepatic flexure of the colon on the right. Usually, the disease does not invade the parenchyma of the liver or spleen, and a plane can be found between the tumor and these organs. It will occasionally be necessary to perform splenectomy to remove all the omental disease (157).

Resection of Other Metastases

Other large masses of tumor located on the parietal peritoneum should be removed, particularly if they are isolated masses and their removal will permit optimal cytoreduction. Resection of extensive disease from the surfaces of the diaphragm is neither practical nor feasible, although solitary metastases may be resected, the diaphragm sutured, and a chest tube placed for a few days (157, 158). The use of the Cavitron Ultrasonic Surgical Aspirator (CUSA) and the argon beam coagulator may facilitate resection of small tumor nodules, especially those on flat surfaces (159, 160).

Feasibility and Outcome
There was no randomized prospective study performed to define the value of primary cytoreductive surgery, but all retrospective studies indicate that the diameter of the largest residual tumor nodule before the initiation of chemotherapy is significantly related to progression-free survival in patients with advanced ovarian cancer (163). Quality of life may be significantly enhanced by removal of bulky tumor masses from the pelvis and upper abdomen (166).

An analysis of the retrospective data indicates that, when performed by gynecologic oncologists, successful operations are feasible in 70% to 90% of patients (152,153). Major morbidity is approximately 5% and operative mortality is 1% (156,161,162). Intestinal resection in these patients does not appear to increase the overall morbidity caused by the operation (156).

In a meta-analysis of 81 studies of women who underwent cytoreductive surgery for advanced ovarian cancer, Bristow et al. documented that the extent of debulking correlated with incremental benefits in survival (i.e., the greater the percentage of tumor reduction, the longer the survival). Each 10% increase in cytoreduction equaled a 5.5% increase in median survival (163). Women whose cytoreduction was greater than 75% of their tumor burden had a median survival of 33.9 months compared with 22.7 months for women whose tumors were cytoreduced less than 75% (p < 0.001). The performance of a pelvic and para-aortic lymphadenectomy in patients with stage III disease does not prolong survival, based on the results of a large prospective, randomized trial (164).

A prospective randomized study of “interval” cytoreductive surgery was carried out by the European Organisation for the Research and Treatment of Cancer (EORTC). Interval surgery was performed after three cycles of platinum-combination chemotherapy in patients whose primary attempt at cytoreduction was suboptimal. The initial surgery for most of these patients was not an aggressive attempt to debunk their tumors. Patients in the surgical arm of the study demonstrated a survival benefit when compared with those who did not undergo interval debulking (165). The risk of mortality was reduced by more than 40% in the group that was randomized to the debulking arm of the study. Based on these data, the performance of a debulking operation as early as possible in the course of the patient’s treatment should be considered the standard of care (166).

A prospective phase III study of interval cytoreductive surgery was conducted by the GOG; the patients entered on the trial had a maximal attempt at tumor resection at their initial surgery (167). The randomized findings showed no difference between the patients who had an additional attempt at debulking after three cycles of chemotherapy compared with those who did not. The median survival of the 216 women who underwent interval cytoreduction was 32 months compared with 33 months for the 209 women who did not undergo surgical cytoreduction.

There is evidence that the survival of women with advanced ovarian cancer is improved when the surgeon is specifically trained to perform cytoreductive surgery and when there
is centralization of care (168–171). Whenever feasible, patients with advanced ovarian malignancy should be referred to a subspecialty unit for primary surgery, and every effort should be made to attain as complete a cytoreduction as possible.
Chemotherapy

Stage I Epithelial Ovarian Cancer

Early Stage, Low Risk

Guthrie et al. studied the outcome of 656 patients with early-stage epithelial ovarian cancer (140). Patients who had stage IA, grade 1 cancer and did not receive radiation or chemotherapy did not die of their disease; indicating that adjuvant therapy is unnecessary. The GOG carried out a prospective, randomized trial of observation versus melphalan for patients with stage IA and IB, grades 1 and 2 disease (114). Five-year survival for each group was 94% and 96%, respectively, confirming that adjuvant treatment did not improve survival. Therefore, no adjuvant chemotherapy is recommended for these patients.

Early Stage, High Risk

In patients whose disease is high risk (e.g., more poorly differentiated or in whom there are malignant cells either in ascites fluid or in peritoneal washings), additional therapy is indicated. Most investigators recommend chemotherapy for these patients (172–185). Chemotherapy for patients with early-stage high-risk epithelial ovarian cancer can be either single agent or multiagent. Some researchers question the wisdom of overly aggressive chemotherapy in women with early-stage disease, suggesting that the evidence for a durable impact on survival is marginal (174,175,181). The risk of leukemia with alkylating agents and platinum make the administration of adjuvant therapy hazardous unless there is a significant benefit (186,187).

Because cisplatin, carboplatin, cyclophosphamide, and paclitaxel (Taxol) are active single agents against epithelial ovarian cancer, these drugs are administered in various combinations. There are some series in which cisplatin or cyclophosphamide (PC) or both have been used to treat patients with stage I disease (176–181). In a GOG trial of three cycles of cisplatin and cyclophosphamide versus intraperitoneal chromic phosphate (32P) in patients with stage IB and IC disease, the progression-free survival of women receiving the platinum-based chemotherapy was 31% higher than those receiving the radiocolloid (178). Similar results were reported by a multicenter trial performed in Italy by the Gruppo Italiano Collaborativo Oncologica Ginecologica (GICOOG) for progression-free survival, although there was no overall survival advantage (179).

Two large parallel randomized phase III clinical trials were conducted on women with early-stage disease: the International Collaborative Ovarian Neoplasm Trial 1 (ICON1) and the Adjuvant Chemotherapy Trial in Ovarian Neoplasia (ACTION) (188,189).

In the ICON1 trial, 477 patients from 84 centers in Europe were entered. Patients of all stages were eligible for the trial if, in the opinion of the investigator, it was unclear
whether adjuvant therapy would be of benefit. Most patients were considered to have stage I and IIA disease, but optimal surgical staging was not required, and it is likely that a significant number of these women had stage III disease. Adjuvant platinum-based chemotherapy was given to 241 patients, and no adjuvant chemotherapy was given to 236 patients. The 5-year survival was 73% in the group who received adjuvant chemotherapy compared with 62% in the control group (hazard ratio [HR] = 0.65, \( p = 0.01 \)) (189).

In the ACTION trial, 440 patients from 40 European centers were randomized; 224 patients received adjuvant platinum-based chemotherapy, and 224 patients did not (188). Patients with As I and IIa, grades 2 and 3 were eligible. Only about one-third of the total group was optimally staged (151 patients). In the observation arm, optimal staging was associated with a better survival (HR = 2.31, \( p = 0.03 \)), and in the suboptimally staged patients, adjuvant chemotherapy was associated with an improvement in survival (HR = 1.78, \( p = 0.009 \)). In optimally staged patients, no benefit of adjuvant chemotherapy was seen. In the ACTION trial, the benefit from adjuvant chemotherapy was limited to the patients with suboptimal staging, suggesting that patients benefit only if they had a likelihood of occult microscopic dissemination.

When the data from the two trials were combined and analyzed, a total of 465 patients were randomized to receive platinum-based adjuvant chemotherapy and 460 to observation until disease progression (190). After a median follow-up of more than 4 years, the overall survival was 82% in the chemotherapy arm and 74% in the observation arm (HR = 0.67, \( p = 0.001 \)). Recurrence-free survival was better in the chemotherapy arm: 76% versus 65% (HR = 0.64, \( p = 0.001 \)). The results of this analysis must be interpreted with caution, because most of the patients did not undergo thorough surgical staging, but the findings suggest that platinum-based chemotherapy should be given to patients who were not optimally staged.

Carboplatin is widely used instead of cisplatin, as it is equivalent in efficacy and much better tolerated with significantly fewer side effects (191). A randomized phase III trial of three versus six cycles of adjuvant carboplatin and paclitaxel in 457 patients with early stage epithelial ovarian carcinoma was conducted by the GOG (192). An unexpectedly large number of patients (126 patients, 29%) had incomplete or inadequately documented surgical staging in this study. The recurrence rate for six cycles was 24% lower (HR = 0.76; confidence interval [CI], 0.5–1.13; \( p = 0.18 \)) versus three cycles, but this was not statistically significant. The estimates of probability of recurrence at 5 years were 20.1% for six cycles and 25.4% for three cycles. The authors concluded that three cycles of adjuvant carboplatin and paclitaxel was a reasonable option for women with high-risk early stage ovarian cancer. The current GOG trial includes patients with high-risk stage I and stage II disease, and offers three cycles of carboplatin and paclitaxel followed by a randomization to either observation versus 26 weeks of weekly low-dose (40 mg/m\(^2\)) paclitaxel. High-risk stage I is defined as stage IA or IB, grade 3, stage IC, or clear cell carcinomas.
The recommendations for therapy follow:

- Patients with high-grade, high-risk stage I epithelial ovarian cancer should be given adjuvant chemotherapy. The type depends on the patient’s overall health and medical comorbidities.

- Treatment with carboplatin and paclitaxel chemotherapy for three to six cycles is used in these patients, whereas single agent carboplatin may be preferable for older women and patients with other medical comorbidities.

**Advanced-Stage Epithelial Ovarian Cancer**

Systemic multiagent chemotherapy is the standard treatment for metastatic epithelial ovarian cancer (193–217). After the introduction of cisplatin in the latter half of the 1970s, platinum-based combination chemotherapy became the most frequently used treatment regimen in the United States. Paclitaxel became available in the 1980s, and this drug was incorporated into the combination chemotherapy in the 1990s (192–196). Comparative trials of paclitaxel, cisplatin, and carboplatin are summarized below.

In a meta-analysis performed on studies of patients with advanced-stage disease, those patients given cisplatin-containing combination chemotherapy were compared with those treated with regimens that did not include cisplatin (197). Survival differences between the groups were seen from 2 to 5 years, with the cisplatin group having a slight survival advantage, but this difference disappeared by 8 years.

*A major advance in the treatment of advanced-stage disease was the incorporation of paclitaxel into the chemotherapeutic regimens in the late 1990s. A series of randomized, prospective clinical trials with paclitaxel-containing arms defined carboplatin and paclitaxel as the standard treatment protocol in advanced epithelial ovarian cancer, although there are data to support intraperitoneal chemotherapy in selected patients (194,195,201,202).*

Reporting the GOG data (Protocol 111), McGuire et al. showed that the combination of cisplatin (75 mg/m²) and paclitaxel (135 mg/m²) was superior to cisplatin (75 mg/m²) and cyclophosphamide (600 mg/m²), each given for six cycles (194). In suboptimally resected patients, the paclitaxel-containing arm produced a 36% reduction in mortality. These data were verified in a trial conducted jointly by the EORTC, the Nordic Ovarian Cancer Study Group (NOCOVA), and the National Cancer Institute of Canada (NCIC), in which patients with both optimal and suboptimal disease were treated (195). In this study, the paclitaxel-containing arm produced a significant improvement in both progression-free interval and overall survival in both optimal and suboptimal groups.

*Based on these two studies, paclitaxel is included in the primary treatment of all women with advanced-stage epithelial ovarian cancer, unless there are contraindications to paclitaxel, such as preexisting peripheral neuropathy.*

A three-arm comparison of paclitaxel (T) versus cisplatin (P) versus PT in suboptimal stage III and IV patients (Protocol 132) showed equivalency in the three groups, but
Crossover from one drug to the other was permitted (196). The study showed that the combination regimen was better tolerated than the sequential administration of the agents in suboptimally resected patients.

The second-generation platinum analogue, carboplatin, was developed to have less toxicity than its parent compound, cisplatin. In early trials, carboplatin had lower overall toxicity (204). Fewer gastrointestinal side effects, especially nausea and vomiting, were observed than with cisplatin, and there was less nephrotoxicity, neurotoxicity, and ototoxicity. Carboplatin is associated with a higher degree of myelosuppression (206).

The dose of carboplatin is calculated by using the area under the curve (AUC) and the glomerular filtration rate (GFR) according to the Calvert formula (207). The target AUC is 5 to 6 for previously untreated patients with ovarian cancer.

**Carboplatin and Paclitaxel**

Two randomized, prospective clinical studies compared the combination of paclitaxel and carboplatin to paclitaxel and cisplatin (201,202). In both studies, the efficacy and survivals were similar, but the toxicity was more acceptable with the carboplatin-containing regimen. In the first trial, GOG Protocol 158, the randomization was carboplatin AUC = 7.5 and paclitaxel 175 mg/m² over 3 hours versus cisplatin 75 mg/m² and paclitaxel 135 mg/m² over 24 hours (Fig. 37.15). The disease progression-free survival of the carboplatin-containing arm was 22 months versus 21.7 months for the control arm (201). The gastrointestinal and neurotoxicity of the carboplatin arm were appreciably lower than that of the cisplatin arm. A similar result was obtained in a large randomized trial in Germany, in which the dose of carboplatin was AUC = 6 and paclitaxel was 185 mg/m² over 3 hours compared with the same dose of paclitaxel and cisplatin 75 mg/m² (202). Based on these data, the preferred regimen in patients with advanced-stage disease is the paclitaxel plus carboplatin combination (203).

The ICON3 trial was a study of 2,074 women with all stages of ovarian cancer, including 20% who had stage I or II disease (208). Carboplatin plus paclitaxel was compared with two non-paclitaxel regimens, carboplatin (70%), or cyclophosphamide, Adriamycin, and cisplatin (CAP) (30%). The regimens were chosen before randomization and based on the clinical preference of the treating physician. One-third of patients who received carboplatin or CAP subsequently received second-line paclitaxel, and this additional chemotherapy was often given before clinical progression. With a median follow-up of 51 months, the carboplatin plus paclitaxel and the control groups had a similar progression-free survival (0.93) and overall survival (0.98). The median survival for the paclitaxel plus carboplatin and control groups was 36.1 and 35.4 months, respectively. The median duration of progression-free survival was 17.3 and 16.1 months, respectively. The researchers
concluded that single agent carboplatin and CAP were as effective as paclitaxel and carboplatin for first-line chemotherapy. Because carboplatin as a single agent had a lower toxicity than the other regimens and the median survival (33 months) was similar in the prior trial (ICON2) that compared carboplatin and CAP as first-line treatment, the researchers suggested that carboplatin alone was the preferred therapy (209). The design of the study limited the interpretation of the results and was criticized, because patients with FIGO stages I to IV disease were included, the extent of primary surgery was variable, and the majority (85%) of patients who relapsed after single-agent carboplatin or CAP received paclitaxel. The results of this study did not change the practice in the United Kingdom where the study was predominantly carried out.

Carboplatin and Docetaxel

Docetaxel has a different toxicity profile from paclitaxel. The SCOT-ROC (Scottish Gynaecological Cancer Trials Group) study randomly assigned 1,077 women with stages Ic to IV epithelial ovarian cancer to carboplatin with either paclitaxel or docetaxel (210). The efficacy of docetaxel appeared to be similar to paclitaxel: The median progression-free survival was 15.1 months versus 15.4 months, and the docetaxel group had fewer neurologic effects, arthralgias, myalgias, and extremity weakness than the paclitaxel group. The docetaxel plus carboplatin regimen was associated with significantly more myelosuppression and its consequences (i.e., serious infections and prolonged grade 3 to 4 neutropenia). Additional study is necessary to determine whether docetaxel should supplant paclitaxel in the primary treatment of epithelial ovarian cancer.

Five-Arm Trial

An Intergroup, international trial—GOG 182/Southwest Oncology Group (SWOG) 182/ICON5—compared the standard combination of carboplatin and paclitaxel with these drugs in combination with gemcitabine, topotecan, or liposomal doxorubicin in sequential doublets or triplets (211). The study showed that the addition of any these three drugs to the standard chemotherapy with carboplatin and paclitaxel did not improve progression-free survival or overall survival.

Intraperitoneal Chemotherapy

A randomized, prospective GOG study (Protocol 104) of intraperitoneal cisplatin versus intravenous cisplatin (100 mg/m²), each given with 750 mg/m² cyclophosphamide, was performed jointly by the SWOG and the GOG in patients with minimal residual disease (212). The intraperitoneal cisplatin arm had a somewhat longer overall median survival than the intravenous arm, 49 versus 41 months (p = 0.03). In the patients with minimal residual disease (<0.5 cm maximal residual), paradoxically, there was no difference between the two treatments, 51 versus 46 months (p = 0.08).

In a follow-up GOG study (Protocol 114), the dose-intense arm was initiated by giving a
moderately high dose of carboplatin (dose AUC = 9) for two induction cycles, followed by intraperitoneal cisplatin 100 mg/m² and intravenous paclitaxel 135 mg/m² over 24 hours, versus intravenous cisplatin 75 mg/m² and intravenous paclitaxel 135 mg/m² (213). The dose-intense arm results were slightly better—the disease progression-free median survival was 27.6 months compared with 22.5 months for the control arm (p = 0.02). There was no difference in overall survival (52.9 months versus 47.6 months, p = 0.056). Based on this study, it was unclear whether dose intensification with intraperitoneal cisplatin has a sustained long-term impact on the survival of these patients.

A third randomized prospective GOG study (Protocol 172) compared intraperitoneal cisplatin and paclitaxel versus intravenous cisplatin and paclitaxel (214). The combination of cisplatin 75 mg/m² and paclitaxel 135 mg/m² given intravenously every 3 weeks was compared with paclitaxel 135 mg/m² intravenous day 1, followed by cisplatin 100 mg/m² intraperitoneal day 2, and paclitaxel 60 mg/m² intraperitoneal day 8 every 3 weeks, each given for six cycles. Although 83% of the patients randomized to intravenous chemotherapy completed all six cycles of therapy, only 42% of those treated with intraperitoneal chemotherapy completed the six cycles, principally because of catheter-related complications. For patients in either group who could not complete the therapy because of cisplatin-related toxicity, the chemotherapy was switched to intravenous carboplatin. Comparing the intravenous and intraperitoneal arms, the median duration of progression-free survival was 18.3 and 23.8 months, respectively (p = 0.05). The median duration of overall survival in the intravenous-therapy and intraperitoneal-therapy groups was 49.7 and 65.6 months, respectively (p = 0.03) (214). Quality of life was significantly worse in the intraperitoneal-therapy group before cycle four and 3 to 6 weeks after treatment but not 1 year after treatment. A summary of the intraperitoneal catheter-related issues in this trial was presented (215).

Based on these randomized trials, the intraperitoneal route of administration for cisplatin and paclitaxel chemotherapy in the primary treatment of optimally resected stage III ovarian cancer is an acceptable therapeutic alternative to intravenous chemotherapy with carboplatin and paclitaxel (216). There are no reports of randomized direct comparisons of this intraperitoneal regimen to intravenous carboplatin and paclitaxel or to intraperitoneal carboplatin and paclitaxel. Intraperitoneal therapy can be used in patients with optimally resected tumors who have a good performance status and are in overall good health. Because intraperitoneal chemotherapy is more cumbersome and has a higher morbidity than intravenous therapy, the use of this technique of drug delivery should be individualized after thorough discussion with the patient.

Dose-Dense Intravenous Chemotherapy
The Japanese GOG randomized 637 patients with ovarian cancer to receive carboplatin AUC 6 and paclitaxel 180 mg/m² every 3 weeks or the same dose of carboplatin and 80 mg/m² paclitaxel every week for at least six cycles (217). The median progression-free
survival was 28 months in the dose-dense arm and 17 months in the control group, and they reported relatively little difference in toxicity between the two arms and that grade 3 to 4 neurotoxicity in particular was very low. In the 417 patients who had stage III disease, about half had less than 1 cm maximum residual disease, similar to the patients in GOG 172. There is no subgroup analysis to determine whether these optimally debulked patients fared better with dose-dense paclitaxel, but the hazard ratio for recurrence was 0.69 for stage III as a group. These findings are very encouraging but need to be validated in another study. **There is good evidence that weekly paclitaxel is more effective than paclitaxel every 3 weeks in breast cancer and the Japanese GOG study suggests that the same may apply to ovarian cancer.** This important question is being studied in GOG and other studies comparing intravenous dose-dense treatment with intraperitoneal chemotherapy.

**Neoadjuvant Chemotherapy**

Some authors suggested that selected patients with suboptimal stage III and stage IV disease and those with large volume ascites and pleural effusions should have chemotherapy prior to debulking surgery. A series performed by Schwartz et al. suggested that these patients treated with neoadjuvant or cytoreductive chemotherapy had survival that was comparable to those patients treated in the same institution with debulking surgery followed by conventional chemotherapy (218). It is accepted that two or three cycles of chemotherapy before cytoreductive surgery may be helpful in patients with massive ascites and large pleural effusions. The chemotherapy may “dry up” the effusions, improve the patient’s performance status, and decrease postoperative morbidity, particularly chest morbidity (219,220).

The EORTC completed a large randomized trial in 718 patients with advanced ovarian cancer comparing initial surgery followed by six cycles of carboplatin and paclitaxel with three cycles of neoadjuvant chemotherapy followed by surgical debulking and another three cycles of chemotherapy. The study found that the progression-free survival was identical in both arms (12 months) and similarly the overall survival (30 months) was the same in both arms (221). The morbidity of surgery was significantly less in patients receiving neoadjuvant chemotherapy, suggesting that in selected patients with very advanced (stages IIIC and IV) ovarian cancer two to three cycles of neoadjuvant chemotherapy prior to surgical debulking is a reasonable option.

**Chemotherapy and Bevacizumab**

Inhibition of angiogenesis with drugs such as bevacizumab demonstrated activity and benefit in women with recurrent ovarian cancer. There is evidence in other tumor types such as breast cancer and colon cancer that the addition of bevacizumab to chemotherapy increases response rates, progression-free survival, and survival in some studies (222–224). Two large randomized trials (GOG 218 and ICON7) investigating the impact of the addition of bevacizumab to standard carboplatin and paclitaxel in patients with advanced ovarian cancer were completed (225,226). GOG 218 is a phase III three-
arm randomized double-blind placebo-controlled trial. Patients in arm one received six cycles of carboplatin and paclitaxel and placebo starting with the second cycle and continuing for 16 additional cycles after the completion of chemotherapy. Patients in arm two received six cycles of chemotherapy with bevacizumab starting with cycle two and administered with chemotherapy followed by 16 cycles of placebo, and in arm three patients received bevacizumab starting with cycle two of chemotherapy and then received 16 additional cycles after the completion of chemotherapy. This study was designed to investigate the benefit of bevacizumab in combination with chemotherapy and as a maintenance therapy. The bevacizumab was administered at a does of 15 mg/kg, starting with the second cycle of chemotherapy, to decrease the risk of gastrointestinal perforation, which is a rare complication of this agent in the setting of its use in colorectal cancer. The results of GOG 218 reported a modest improvement of 3.8 months in progression-free survival in patients randomized to receive bevacizumab in combination with carboplatin and paclitaxel every 3 weeks and then as a maintenance therapy every 3 weeks for an additional 16 cycles for a total of 15 months' treatment (225). The toxicity of bevacizumab was acceptable and the risk of bowel perforation very low (below 2%). The study did not find any improvement in overall survival, but follow-up is required. The ICON7 study is similar to the GOG study, although it is a two-arm study of carboplatin and paclitaxel plus or minus bevacizumab 7.5 mg/kg administered every 3 weeks with chemotherapy for six cycles and then as maintenance therapy for 12 additional cycles. The ICON7 results were presented and reported a statistically significant, yet modest, 1.7-month improvement in median progression-free survival in the experimental arm (226). The results of these studies support a role of bevacizumab in combination with chemotherapy in patients with advanced ovarian cancer. However, the cost of bevacizumab is very high and the improvement in progressive-free survival is short.

**Chemotherapeutic Recommendation in Advanced Epithelial Ovarian Cancer**

For the treatment of advanced-stage epithelial ovarian cancer, the following is recommended (Table 37.4):

**Table 37.4 Combination Chemotherapy for Advanced Epithelial Ovarian Cancer: Recommended Regimens**
Combination chemotherapy or intravenous carboplatin and paclitaxel or intraperitoneal cisplatin and paclitaxel (using the GOG 172 protocol) are the treatments of choice for patients with advanced disease. The advantages and disadvantages of the intravenous versus intraperitoneal routes of administration of these drugs should be discussed with the patient.

The recommended doses and schedule for intravenous chemotherapy are: carboplatin (starting dose AUC = 5–6), and paclitaxel (175 mg/m²), every 3 weeks for six to eight cycles, or the dose-dense regimen of carboplatin AUC 6 every 3 weeks for six cycles and weekly paclitaxel 80 mg/m² (217).

The recommended doses and schedule for intraperitoneal chemotherapy are paclitaxel 135 mg/m² intravenous on day 1, followed by cisplatin 75 to 100 mg/m² intraperitoneal on day 2, followed by paclitaxel 60 mg/m² intraperitoneal on day 8, every 3 weeks for six cycles, as tolerated. (Many centers modified the dose of cisplatin to 75 mg/m² rather than 100 mg/m² to reduce toxicity. Others substitute carboplatin (AUC 6) for cisplatin in the regimen.) The impact on outcome of these pragmatic modifications is unknown.

Bevacizumab 7.5–15 mg/kg can be added to any of these intravenous or intraperitoneal chemotherapy regimens.

In patients who cannot tolerate combination chemotherapy, single-agent, intravenously administered carboplatin (AUC 5–6) can be given.

In patients who have a hypersensitivity to paclitaxel or carboplatin, an alternative active drug can be substituted (e.g., docetaxel, nanoparticle paclitaxel, cisplatin). In the case of
The treatment of all patients with advanced-stage disease is approached in a similar manner, with modifications based on the overall status and general health of the patient and the extent of residual disease present at the time treatment is initiated.

Maintenance of Complete Clinical Response to First-Line Chemotherapy

Because as many as 80% of women with advanced-stage disease who completely respond to their first-line chemotherapy will ultimately relapse, several trials were conducted that administer a drug to these patients immediately following their primary treatment in an effort to decrease the relapse rate.

Paclitaxel

In a study conducted by the GOG and SWOG, 277 women with advanced ovarian cancer who had a complete clinical remission to first-line chemotherapy were randomized to receive 3 or 12 cycles of additional single-agent paclitaxel (175 or 135 mg/m² every 28 days) (227). Patients were excluded if they developed grade 2 or 3 neurotoxicity during their initial chemotherapy. Because of cumulative toxicity, the mean number of actual cycles of paclitaxel received by the group assigned to receive 12 cycles was 9. The treatment-related grade 2 to 3 neuropathy was more common with longer treatment, 24% versus 14% of patients, respectively. The study closed after a median follow-up of only 8.5 months, and an interim analysis showed a significant 7-month prolongation in median progression-free survival (28 versus 21 months) with 9 versus 3 months of consolidation paclitaxel. There was no difference in median overall survival and this study has not changed practice. The rate of disease progression increased significantly after maintenance therapy was discontinued, which suggested that long-term survival was not likely to be improved. It is improbable that a survival benefit will appear with longer follow-up, because patients assigned to three cycles were given the option of receiving an additional nine courses of paclitaxel after the study was discontinued (228). Another placebo-controlled, randomized trial using two formulations of paclitaxel is being conducted by the GOG.

Topotecan

Four additional treatment courses of topotecan were administered to patients following six cycles of carboplatin and paclitaxel in two randomized trials, one conducted in Italy and the other in Germany (229,230). In the larger trial conducted in Germany, 1,059 evaluable patients were randomly assigned to six cycles of paclitaxel (175 mg/m² over 3 hours) and carboplatin (AUC 5) with (537 patients) or without (522 patients) four additional cycles of topotecan (1.25 mg/m² intravenous days 1 to 5 every 3 weeks) (230). In the Italian trial, 273 women were randomly assigned to receive four additional cycles (137 patients) of topotecan at a dose of 1 mg/m² on days 1 to 5 every 3 weeks or no further chemotherapy (136 patients) (229). Preliminary reports suggest no

carboplatin hypersensitivity, desensitization could be attempted.
significant differences in either progression-free or overall survival in patients who received four to six cycles of consolidation topotecan.

Cisplatin

In a randomized clinical trial of intraperitoneal cisplatin for consolidation versus observation, there was no difference in survival between the treatment arms (231).

Biologic Therapies

As noted above, the use of the monoclonal antibody (MonAb) bevacizumab with first-line carboplatin and paclitaxel chemotherapy followed by maintenance bevacizumab for a year was associated with a modest improvement in progression-free survival, (225,226). Patients and their physicians may consider maintenance therapy with bevacizumab as delivered in GOG 218 and ICON7. There are a number of ongoing trials addressing the role of oral angiogenesis inhibitors as maintenance therapy after completion of first-line therapy in women with advanced ovarian cancer.

Studies MonAbs directed toward CA125 (OvaRex) and toward the HMFG (human milk fat globulin) tumor–associated antigens were conducted (232–234). In a randomized, placebo-controlled trial of intravenous oregovomab (anti-CA125 MonAb) as maintenance therapy, Berek et al. reported that oregovomab did not demonstrate a survival advantage as a maintenance therapy (233). A randomized trial of an intraperitoneally administered yttrium-labeled antimucin (HMFG) MonAb versus placebo was not associated with an improved overall survival after a negative second-look laparoscopy (234).

Treatment Assessment

Many patients who undergo optimal cytoreductive surgery and subsequent chemotherapy for epithelial ovarian cancer have no evidence of disease at the completion of treatment. Tumor markers and radiologic assessments are too insensitive to exclude the presence of subclinical disease. Historically, a second-look surgery was performed to evaluate these patients, but was abandoned, as there is no evidence of a meaningful benefit to patients (132,235–244).

Tumor Markers

The level of CA125, a surface glycoprotein associated with müllerian epithelial tissues, is elevated in about 80% of patients with epithelial ovarian cancers, particularly those with nonmucinous tumors (245–247). The levels frequently become undetectable after the initial surgical resection and one or two cycles of chemotherapy. Carcinoembryonic antigen (CEA) levels are often elevated in patients with ovarian cancer, and the test is too nonspecific and insensitive to be used in the management of these patients, apart from patients with a mucinous cancer of the ovary (48).

Levels of CA125 were correlated with findings at second-look operations. Elevated levels
are useful in predicting the presence of disease, but negative levels are an insensitive
determinant of the absence of disease. In a prospective study, the predictive value of a
positive test was 100%; if the level of CA125 was elevated (>35 U/mL), disease was
always detectable in patients at the second-look procedure (245). The predictive value of
a negative test was only 56%; if the level was less than 35 U/mL, disease was present in
44% of the patients at the time of the second-look surgery. A literature review
suggests that an elevated CA125 level predicts persistent disease at second-
look surgery in 97% of the cases, but the CA125 level is not sensitive enough
to exclude subclinical disease in many patients (246).

Serum CA125 levels can be used during chemotherapy to follow those patients
whose levels were positive at the initiation of therapy (245). The change in
level correlates with response. Those patients with persistently elevated levels after
three cycles of treatment probably have persistent disease. When levels rise after
treatment, almost invariably treatment has failed, and continuation of the current
regimen is futile. A retrospective study determined that a doubling of the CA125 level
from its nadir in those patients with a persistently elevated level accurately predicts
disease progression (247).

Radiologic Assessment

Radiologic tests assess response in patients with measurable lesions at the
start of therapy. In patients who have no or minimal residual disease following
cytoreductive surgery, the value of these tests is limited, but they may be useful
in follow-up, especially to document the site of recurrence. Ascites can be readily
detected, but quite large omental metastases can be missed on CT scan in patients with
recurrent disease (248). If liver enzyme levels are abnormal, the liver can be evaluated
with a CT scan or ultrasonography. A positive CT scan and fine-needle aspiration (FNA)
cytology indicating tumor persistence could document persistent or recurrent disease, but
the false-negative rate of a CT scan is about 45% (249). Positron-emission
tomography (PET) alone, or with CT imaging, may help detect relapse,
although the relative value of adding PET is not established. There appears to
be a higher false-positive rate with PET compared with CT (106,107). MRI can be
used as an alternative to CT in patients with allergies to the contrast medium (105).

Second-Line Therapy

Secondary Cytoreductive Surgery

Secondary cytoreduction may be defined as an attempt at cytoreductive
surgery at some stage following completion of first-line chemotherapy
(250–253). Patients with progressive disease on chemotherapy are not suitable
candidates for secondary cytoreduction, but patients with recurrent disease are
occasionally candidates for surgical excision of their disease. Tumor resection under
these circumstances should be restricted to those who have a disease-free
interval of at least 12, but preferably 24, months or those in whom it is expected that all macroscopic disease can be resected, regardless of the disease-free interval (250–258). Complete resection is possible when there are only one or two isolated recurrences in patients without diffuse carcinomatosis (258).

## Chemotherapy for Persistent-Recurrent Ovarian Cancer

The majority of women who relapse will be offered more chemotherapy with the likelihood of benefit related to the initial response and the duration of response. The goals of treatment include improving control of disease-related symptoms, maintaining or improving quality of life, delaying time to progression, and possibly prolonging survival, particularly in women with platinum-sensitive recurrences. Many active chemotherapy agents (platinum, paclitaxel, topotecan, liposomal doxorubicin, docetaxel, gemcitabine, and etoposide) and targeted agents (bevacizumab) are available, and the choice of treatment is based on many factors including likelihood of benefit, potential toxicity, and patient convenience.

Women who relapse later than 6 months after primary chemotherapy are classified as platinum-sensitive and usually receive further platinum-based chemotherapy with response rates ranging from 27% to 65% and a median survival of 12 to 24 months (259–263). Patients who relapse within 6 months of completing first-line chemotherapy are classified as platinum-resistant and have a median survival of 6 to 9 months and a 10% to 30% likelihood of responding to chemotherapy. Patients who progress while on treatment are classified as having platinum-refractory disease. Objective response rates to chemotherapy in patients with platinum-refractory ovarian cancer are low—less than 20% (264).

The potential adverse effects associated with chemotherapy in trials in women with recurrent ovarian cancer are well documented and should not be underestimated. The three most commonly used drugs are paclitaxel, topotecan, and liposomal doxorubicin (265–291). The reported adverse effects associated with paclitaxel were alopecia in 62% to 100%, neurotoxicity (any grade) in 5% to 42% of patients, and severe leukopenia in 4% to 24% of patients. Topotecan is associated with significantly greater myelosuppression than liposomal doxorubicin or paclitaxel and is observed in 49% to 76% of patients. Liposomal doxorubicin is associated with palmer-planter erythrodysesthesia (PPE) of any grade in over 50% of patients and is severe in 23%. Severe stomatitis is reported in up to 10% of patients (265–268).

## Platinum-Sensitive Disease

The use of combination platinum plus paclitaxel chemotherapy versus a single-agent platinum was tested in two multinational randomized phase III trials and a randomized phase II study (292,293). In a report of the ICON4 and AGO-OVAR-2.2 (AGO Studiengruppe Ovarialkarzinom) trials, 802 women with platinum-sensitive ovarian
cancer, who relapsed after being treatment free for at least 6 to 12 months were randomized to platinum-based chemotherapy (72% carboplatin or cisplatin alone; 17% CAP; 4% carboplatin plus cisplatin; and 3% cisplatin plus doxorubicin) or paclitaxel plus platinum-based chemotherapy (80% paclitaxel plus carboplatin; 10% paclitaxel plus cisplatin; 5% paclitaxel plus both carboplatin and cisplatin; and 4% paclitaxel alone) (292). The AGO-OVAR-2.2 trial did not accrue its planned number of patients. In both trials, a significant proportion of the patients did not receive paclitaxel as part of their initial chemotherapeutic regimen. Combining the trials for analysis, there was a significant survival advantage for the paclitaxel-containing therapy (HR = 0.82) with a median follow-up of 42 months. The absolute 2-year survival advantage was 7% (57% versus 50%), and there was a 5-month improvement in median survival (29 versus 24 months). Progression-free survival was better with the paclitaxel regimen (HR = 0.76); there was a 10% difference in 1-year progression-free survival (50% versus 40%) and a 3-month prolongation in median progression-free survival (13 versus 10 months). The toxicities were comparable, except for a significantly higher incidence of neurologic toxicity and alopecia in the paclitaxel group, while myelosuppression was significantly greater with the non-paclitaxel-containing regimens. These data support the slight advantage of a second-line regimen containing both paclitaxel and a platinum agent compared with platinum-based therapy alone in patients who have not received paclitaxel in their primary chemotherapeutic regimen.

There were two randomized trials comparing carboplatin alone to carboplatin and gemcitabine or liposomal doxorubicin (294,295). There was a higher response rate with the combination therapy and a longer progression-free survival, but the studies were not powered to look at overall survival. In the Gynecologic Oncology Intergroup (GCIG) study comparing carboplatin and gemcitabine with carboplatin alone, the response rate was 47.2% for the combination and 30.9% for carboplatin, with the progression-free survival being 8.6 months and 5.8 months, respectively (294). A large GCIG study (CALYPSO) compared carboplatin and liposomal doxorubicin (CD) with carboplatin and paclitaxel (CP) in 976 patients (296). The progression-free survival for the CD arm was statistically superior to CP arm with a median progression-free survival of 11.3 months versus 9.4 months, respectively. Overall survival data are not yet available. The CD arm was better tolerated with less severe toxicities, and this combination is now widely used (296).

Platinum-Resistant and Refractory Disease

Patients with platinum-refractory and resistant ovarian cancer are treated with chemotherapy and may have a number of lines of therapy depending on response and performance status. In platinum-refractory patients (i.e., those progressing on treatment), response rates to second-line chemotherapy are less than 10% and the median survival is short, around 3 to 5 months (260–264). The management of women who are platinum-resistant (i.e., progressing within 6 months of
The completion of chemotherapy is difficult and “non-cross-resistant agents” are selected, but there does not appear to be one best treatment. Single-agent therapy is typically used because combination regimens are associated with more toxicity without any apparent additional benefit. High response rates of 48% to 64% were reported with dose-dense weekly carboplatin (AUC4) plus paclitaxel (90 mg/m²), and this deserves more study (297). There are a variety of potentially active drugs: paclitaxel, docetaxel, topotecan, liposomal doxorubicin, gemcitabine, oral etoposide, tamoxifen, and bevacizumab are the most frequently used. Other agents include vinorelbine and newer drugs such as trabectedin.

The results of a study comparing topotecan with liposomal doxorubicin demonstrate the low response rates and poor prognosis among women with platinum-resistant ovarian cancer (265). There were two randomized trials comparing liposomal doxorubicin with either topotecan or paclitaxel. In a study of 237 women who relapsed after receiving one platinum-containing regimen, 117 of whom (49.4%) had platinum-refractory disease, liposomal doxorubicin 50 mg/m² over 1 hour every 4 weeks was compared with topotecan 1.5 mg/m²/day for 5 days every 3 weeks (265). The two treatments had a similar overall response rate (20% versus 17%), time to progression (22 versus 20 weeks), and median overall survival (66 versus 56 weeks). The myelotoxicity was significantly lower in the liposomal doxorubicin-treated patients than with those receiving topotecan. In a second study comparing liposomal doxorubicin with single-agent paclitaxel in 214 platinum-treated patients who had not received prior taxanes, the overall response rates for liposomal doxorubicin and paclitaxel were 18% versus 22%, respectively, and median survival durations were 46 and 56 weeks, respectively, and these were not significantly different (266). In practice, most patients are treated with a starting dose of 40 mg/m² of liposomal doxorubicin every 4 weeks, because of the toxicity associated with the higher dose and the need to dose reduce when 50 mg/m² is used. In a subset analysis of platinum-resistant patients, the median time to progression ranged from 9.1 to 13.6 weeks for topotecan and liposomal doxorubicin, respectively. The median survival (p = 0.455) was 35.6 weeks for pegylated liposomal doxorubicin and 41.3 weeks for topotecan. Objective response rates were recorded in 6.5% of patients who received topotecan and in 12.3% of those who received pegylated liposomal doxorubicin (p = 0.118). It is not known whether the treatment improved symptoms control or quality of life because this was not specifically addressed.

In another randomized trial in 195 patients with platinum-resistant ovarian cancer, patients were randomized to receive either liposomal doxorubicin (PLD) or gemcitabine (298). In the gemcitabine and PLD groups, median progression-free survival was 3.6 versus 3.1 months; median overall survival was 12.7 versus 13.5 months; overall response rate was 6.1% versus 8.3%; and in the subset of patients with measurable disease, overall response rate was 9.2% versus 11.7%, respectively. None of the efficacy end points showed a statistically significant difference between treatment groups. The PLD group experienced significantly more hand-foot syndrome and mucositis; the gemcitabine group experienced significantly more constipation, nausea or vomiting.
Some researchers attempted to treat patients with non-platinum drugs to prolong the platinum-free interval, hoping that would allow the tumor to become platinum-sensitive during the interval use of non-cross-resistant agents. The rationale for this approach is the belief that the platinum-free interval is equivalent to the treatment-free interval, and before the availability of other active drugs, these two terms were synonymous. **There are no data to support the hypothesis that the interposition of another drug can produce an increased platinum sensitivity as a result of a longer interval since the last platinum treatment.**

**Taxanes**

Single-agent paclitaxel shows objective responses in 20% to 30% in phase II trials of women with platinum-resistant ovarian cancer ([269–274]). The main toxicities are fatigue and peripheral neuropathy. **Weekly paclitaxel is active, and the toxicity, especially myelosuppression, is less than with the every 3-week regimens.** In a study of 53 women with platinum-resistant ovarian cancer, weekly paclitaxel (80 mg/m² over 1 hour) had an objective response of 25% in patients with measurable disease, and 27% of patients without measurable disease had a 75% decline in serum CA125 levels ([269]).

Docetaxel has some activity in these patients ([299–301]). The GOG studied 60 women with platinum-resistant ovarian or primary peritoneal cancer ([301]). Although there was a 22% objective response rate, the median response duration was only 2.5 months, and therapy was complicated by severe neutropenia in three-quarters of the patients.

**Topotecan**

Topotecan is an active second-line treatment for patients with platinum-sensitive and platinum-resistant disease ([277–291]). In a study of 139 women receiving topotecan 1.5 mg/m² daily for 5 days, response rates were 19% and 13% in patients with platinum-sensitive and platinum-resistant disease, respectively ([287]). **The predominant toxicity of topotecan is hematologic, especially neutropenia.** With the 5-day dosing schedule, approximately 70% to 80% of patients have severe neutropenia, and 25% have febrile neutropenia with or without infection. In some studies, regimens of 5 days produce better response rates than regimens of shorter duration, but in others, reducing the dose to 1.0 mg/m² per day for 3 days is associated with similar response rates but lower toxicity ([280,290]). In a study of 31 patients, one-half of whom were platinum refractory, topotecan 2 mg/m² per day for 3 days every 21 days had a 32% response rate ([285]). Continuous infusion topotecan (0.4 mg/m² per day for 14 to 21 days) had a 27% to 35% objective response rate in platinum-refractory patients ([284]) . **Weekly topotecan administered at a dose of 4 mg/m² per week for 3 weeks with a week off every month produced a response rate similar to the 5-day regimen with considerably less toxicity,** and this is the preferred dose schedule in the recurrent setting ([290]).
**Oral topotecan**, not available in the United States, results in similar response rates with less hematologic toxicity (286). The intravenous and oral formulations of topotecan were compared in a randomized trial of 266 women as a third-line regimen after an initial platinum-based regimen (291). Compared with intravenous topotecan (1.5 mg/m² daily for 5 days every 3 weeks), oral topotecan (2.3 mg/m² per day for 5 days every 3 weeks) produced a similar response rate (13% versus 20%), less severe myelosuppression, and only a slightly shorter median survival (51 versus 58 weeks).

**Liposomal Doxorubicin**

Liposomal doxorubicin (Doxil in the United States and Caelyx in Europe), as noted above, has activity in platinum- and taxane-refractory disease (265–268,295). One of the most important side effects of liposomal doxorubicin is the hand-foot syndrome, also known as palmar-plantar erythrodysesthesia or acral erythema, which occurs in 20% of patients who receive 50 mg/m² every 4 weeks (266). Most oncologists administer 40 mg/m² and escalate only if there are no side effects. Liposomal doxorubicin has a low rate of alopecia. In a study of 89 patients with platinum-refractory disease, including 82 paclitaxel-resistant patients, liposomal doxorubicin (50 mg/m² every 3 weeks) produced a response in 17% (1 complete and 14 partial responses) (268). In another study, an objective response of 26% was reported, although there were no responses in women who progressed during first-line therapy (265).

**Gemcitabine**

Gemcitabine is associated with response rates of 20% to 50%, with 15% to 30% in patients who are platinum-resistant (302–306). The principal toxicities are myelosuppression and gastrointestinal. The drug is used in doublet combinations with cisplatin or carboplatin with acceptable responses and toxicities, and in the triplet combination with carboplatin and paclitaxel (304).

**Oral Etoposide**

The most common toxicities with oral etoposide are myelosuppression and gastrointestinal: grade 4 neutropenia is observed in about one-fourth of patients, and 10% to 15% have severe nausea and vomiting (307,308). A study of oral etoposide given for a prolonged treatment (50 mg/m² daily for 21 days every 4 weeks) had a 27% response rate in 41 women with platinum-resistant disease, 3 of whom had durable complete responses (308). In 25 patients with platinum and taxane-resistant disease, 8 objective responses (32%) were reported.

**Hormonal Therapy**

Tamoxifen is associated with CA125 response rates of 15% to 20% in small studies of patients with recurrent ovarian cancer (309–315). Aromatase inhibitors (e.g., letrozole, anastrozole, and exemestane), which have activity in metastatic breast cancer, are being studied in relapsed ovarian cancer (316). One of the principal
advantages of this class of agents is its very low toxicity (317).
Targeted Therapies

Knowledge of molecular pathways within normal and malignant cells is leading to the development of cancer treatment agents with specific molecular targets. There is great potential in targeting angiogenesis, in particular vascular endothelial growth factor (VEGF), which plays a major role in the biology of epithelial ovarian cancer (318). There are three main approaches to target angiogenesis: the first is to target VEGF itself, the second to target the VEGF receptor, and the third is to inhibit tyrosine kinase activation and downstream signaling with small molecules that work at the intracellular level.

Bevacizumab is the first targeted agent to show significant single agent activity in ovarian cancer. It is a humanized monoclonal antibody that targets angiogenesis by binding to VEGF-A, thereby blocking the interaction of VEGF with its receptor. There are a number of phase II studies reported using bevacizumab in patients with platinum-sensitive and platinum-resistant ovarian cancer with response rates ranging from 16% to 22% in both platinum-sensitive and -refractory patients (319). Up to 40% of patients had stabilization of disease for at least 6 months. A study of low-dose metronomic chemotherapy with 50 mg of cyclophosphamide daily and bevacizumab 10 mg/kg intravenously every 2 weeks showed significant activity in a study of 70 patients with recurrent ovarian cancer (320). The primary end point was progression-free survival at 6 months. The probability of being alive and progression free at 6 months was 56%. A partial response was achieved in 17 patients (24%). Median time to progression and survival were 7.2 and 16.9 months, respectively. This comes with toxicity. The side effects of bevacizumab are well recognized and include hypertension, fatigue, proteinuria, gastrointestinal perforation or fistula, and uncommonly, vascular thrombosis and central nervous system ischemia, pulmonary hypertension, and bleeding and wound healing complications. The most common side effects are hypertension that is grade 3 in 7% of patients and is usually treatable. The most concerning side effect is bowel perforation and the study by Cannistra et al. was stopped after recruiting 44 patients because of an 11% incidence of perforation of the bowel (321).

It was suggested that the bowel perforation complication could be avoided by carefully screening patients. Simpkins et al. limited bevacizumab treatment to patients without clinical symptoms of bowel obstruction or evidence of rectosigmoid involvement on pelvic examination or bowel involvement on CT scan (322). Their study included 25 patients with platinum-resistant ovarian cancer who were heavily pretreated, and they observed a response rate of 28% and no bowel perforations or any other grade 3 or 4 toxicities were reported. This highlights the importance of patient selection and suggests that increased experience with these agents will result in less toxicity.

VEGF Trap functions as a soluble decoy receptor soaking up ligand before it can interact with its receptor and is being evaluated in phase II trials in patients with recurrent ovarian cancer. There are other oral agents that target angiogenesis through tyrosine kinase inhibition that are in clinical trial (323).
Radiation Therapy

Whole-abdominal radiation therapy given as a treatment for recurrent or persistent disease is associated with a high morbidity and is not used. The principal problem associated with this approach is the development of acute and chronic intestinal morbidity. As many as 30% of patients treated with this approach develop intestinal obstruction, which necessitated exploratory surgery with potential morbidity (324).

Intestinal Obstruction

Patients with epithelial ovarian cancer often develop intestinal obstruction, either at the time of initial diagnosis or in association with recurrent disease (325–340). Obstruction may be related to a mechanical blockage or to carcinomatous ileus. The intestinal blockage can be corrected in most patients whose obstruction appears at initial diagnosis. The decision to perform an exploratory procedure to ease intestinal obstruction in patients with recurrent disease is more difficult. For patients whose life expectancy is very short (e.g., less than 2 months), surgical relief of the obstruction is not indicated (325–330). In those patients with a longer projected lifespan, features predicting a reasonable likelihood of correcting the obstruction include young age, good nutritional status, and the absence of rapidly accumulating ascites (326).

For most patients with recurrent ovarian cancer and intestinal obstruction, initial management should include proper radiographic documentation of the obstruction, hydration, correction of any electrolyte disturbances, parenteral alimentation, and intestinal intubation. For some patients, the obstruction may be alleviated by this conservative approach. A preoperative upper gastrointestinal radiographic series and a barium enema will define possible sites of obstruction.

If exploratory surgery is deemed appropriate, the type of operation to be performed will depend on the site and the number of obstructions. Multiple sites of obstruction are not uncommon in patients with recurrent epithelial ovarian cancer. More than one-half of the patients have small bowel obstruction, one-third have colonic obstruction, and one-sixth have both (327–331). If the obstruction is principally contained in one area of the bowel (e.g., the terminal ileum), this area can be either resected or bypassed, depending on what is easier to accomplish safely. Intestinal bypass is less morbid than resection, and in patients with progressive cancer, the survival time after these two operations is the same (332–337).

If multiple obstructions are present, resection of several segments of intestine is usually not indicated, and intestinal bypass and/or colostomy should be performed. A gastrostomy may be useful in this circumstance, and this can usually be placed percutaneously (336,339).

Surgery for bowel obstruction in patients with ovarian cancer carries an
operative mortality of about 10% and a major complications rate of about 30% (325–337). The need for multiple reanastomoses and prior radiation therapy increase the morbidity, which consists primarily of sepsis and enterocutaneous fistulae. The median survival ranges from 3 to 12 months, although about 20% of such patients survive longer than 12 months (337–340).
Survival

The prognosis for patients with epithelial ovarian cancer is related to several clinical variables. Survival analyses based on prognostic variables are presented (1,3,30,123–127). Including patients at all stages, patients younger than 50 years of age have a 5-year survival rate of about 40%, compared with about 15% for patients older than 50 years.

The 5-year survival rate for carefully and properly staged patients with stage I disease is as high as 94%, for stage II is 73%, for stage III or IV 28% (1). The 5-year survival rate for stage IIIA is 41%, for stage IIIB about 25%, for stage IIIC 23%, and for stage IV disease 11% (Fig. 37.16). An analysis of the National Cancer Institute’s Surveillance, Epidemiology, and End Results (SEER) database reveals a trend toward improved survival for ovarian cancer in the United States. In this cohort, the survival for stage I was 93%, for stage II 70%, for stage III 37%, and for stage IV 25% (341).

![Figure 37.16 Survival of patients with epithelial ovarian cancer by substages.](image)

Survival of patients with borderline tumors is excellent, with stage I lesions having a 98% 15-year survival (30). When all stages of borderline tumors are included, the 5-year survival rate is about 86% to 90%.

Patients with stage III disease with microscopic residual disease at the start of treatment have a 5-year survival rate of about 40% to 75%, compared with about 30% to 40% for those with optimal disease and only 5% for those with suboptimal disease (126,127,149). Patients whose Karnofsky index (KI) is low (<70) have a significantly shorter survival than those with a KI greater than 70 (30).
Nonepithelial Ovarian Cancers

Compared with epithelial ovarian cancers, other malignant tumors of the ovary are uncommon. **Nonepithelial malignancies of the ovary account for about 10% of all ovarian cancers** (2,3,342). Nonepithelial ovarian cancers include malignancies of germ cell origin, sex cord–stromal cell origin, metastatic carcinomas to the ovary, and a variety of extremely rare ovarian cancers (e.g., sarcomas). Although there are similarities in the presentation, evaluation, and management of these patients, the tumors have unique qualities that require a special approach (2,342–345).
Germ Cell Malignancies

Germ cell tumors are derived from the primordial germ cells of the ovary. Their incidence is about one-tenth the incidence of malignant germ cell tumors of the testis, so most of the advances in the management of these tumors are extrapolations from experience with the corresponding testicular tumors. Although malignant germ cell tumors can arise in extragonadal sites such as the mediastinum and the retroperitoneum, most germ cell tumors arise in the gonad from undifferentiated germ cells. The variation in the site of these cancers is explained by the embryonic migration of the germ cells from the caudal part of the yolk sac to the dorsal mesentery before their incorporation into the sex cords of the developing gonads (2,3,342).

Classification

A histologic classification of ovarian germ cell tumors is presented in Table 37.5 (3,342). Both α-fetoprotein (AFP) and human chorionic gonadotropin (hCG) are secreted by some germ cell malignancies; therefore, the presence of circulating hormones can be clinically useful in the diagnosis of a pelvic mass and in monitoring the course of a patient after surgery. Placental alkaline phosphatase (PLAP) and lactate dehydrogenase (LDH) are produced by up to 95% of dysgerminomas, and serial measurements of LDH may be useful for monitoring the disease. When the histologic and immunohistologic identification of these substances in tumors is correlated, a classification of germ cell tumors emerges (Fig. 37.17) (346).

**Figure 37.17 Relationship between types of pure malignant tumors.** Germ cell tumors and their secreted marker substances. (From Berek JS, Hacker NF. Berek & Hacker’s Gynecologic Oncology. 5th ed. Philadelphia: Lippincott Williams & Wilkins, 2010:511, with permission.

In this scheme, **embryonal carcinoma (a cancer composed of undifferentiated cells) synthesizes both hCG and AFP**, and this lesion is the progenitor of several other germ cell tumors (346–348). More differentiated germ cell tumors, such as the endodermal sinus tumor, which secretes AFP, and the choriocarcinoma, which secretes hCG, are derived from the extraembryonic tissues; the immature teratomas derived from the embryonic cells have lost the ability to secrete these substances. Pure germinomas do not secrete these markers.

**Epidemiology**

Although 20% to 25% of all benign and malignant ovarian neoplasms are of germ cell origin, only about 3% of these tumors are malignant (2,3). Germ cell malignancies account for fewer than 5% of all ovarian cancers in Western countries. Germ cell malignancies represent up to 15% of ovarian cancers in Asian and African American societies, where epithelial ovarian cancers are much less common.
In the first two decades of life, almost 70% of ovarian tumors are of germ cell origin, and one-third of these are malignant (2,3,342). Germ cell cancers are seen in the third decade, but thereafter they become quite rare.

Clinical Features

Symptoms

In contrast to the slower-growing epithelial ovarian tumors, germ cell malignancies grow rapidly and are characterized by subacute pelvic pain related to capsular distention, hemorrhage, or necrosis. The rapidly enlarging pelvic mass may produce pressure symptoms on the bladder or rectum, and menstrual irregularities may occur in menarcheal patients. Some young patients misinterpret the early symptoms of a neoplasm as those of pregnancy, which can lead to a delay in the diagnosis. Acute symptoms associated with torsion or rupture of the adnexa can develop. These symptoms may be confused with acute appendicitis. In more advanced cases, ascites may develop, and the patient can have abdominal distention (336).

Signs

For a patient with a palpable adnexal mass, the evaluation can proceed as outlined. Some patients with germ cell tumors will be premenarcheal and may require examination under anesthesia. If the lesions are principally solid or a combination of solid and cystic, as might be noted on an ultrasonographic evaluation, a neoplasm is probable and a malignancy is possible (see Fig. 14.8 and Chapter 14). During the remainder of the physical examination, effort should be directed to searching for signs of ascites, pleural effusion, and organomegaly.

Diagnosis

Adnexal masses measuring 2 cm or larger in premenarcheal girls or 8 cm or larger in other premenopausal patients will usually require surgical exploration. For young patients, blood tests should include serum hCG and AFP and LDH. A CT scan of the chest is important because germ cell tumors can metastasize to the lungs or mediastinum. A karyotype should be obtained preoperatively for all premenarcheal girls, particularly those with dysgerminomas, because of the propensity of these tumors to arise in dysgenetic gonads (343,349). A preoperative CT scan or MRI may document the presence and extent of retroperitoneal lymphadenopathy or liver metastases; however, because these patients require surgical exploration, preoperative imaging is not usually required. If postmenarcheal patients have predominantly cystic lesions up to 8 cm in diameter, they may be observed or given oral contraceptives for two menstrual cycles (350).

Dysgerminoma

Dysgerminoma is the most common malignant germ cell tumor, accounting for
about 30% to 40% of all ovarian cancers of germ cell origin (2,3,346). The tumors represent only 1% to 3% of all ovarian cancers, but they represent as many as 5% to 10% of ovarian cancers in patients younger than 20 years. Seventy-five percent of dysgerminomas occur between the ages of 10 and 30 years, 5% occur before the age of 10 years, and they rarely occur after 50 years of age (2,3,336). Because these malignancies occur in young women, 20% to 30% of ovarian malignancies associated with pregnancy are dysgerminomas.

Germinomas are found in both sexes and may arise in gonadal or extragonadal sites. The latter include the midline structures from the pineal gland to the mediastinum and the retroperitoneum. Histologically, they represent abnormal proliferations of the basic germ cell. In the ovary, the germ cells are encapsulated at birth (the primordial follicle), and the unencapsulated or free cells die. If either of the latter processes fails, it is possible that the germ cell could free itself of its normal control and multiply indiscriminately.

The size of dysgerminomas varies widely, but they are usually 5 to 15 cm in diameter (2,3). The capsule is slightly bosselated, and the consistency of the cut surface is fleshy and pale tan to gray-brown in color (Fig. 37.18).

Figure 37.18 Dysgerminoma of the ovary. Note that the lesion is principally solid with some cystic areas and necrosis.

The histologic characteristics of the dysgerminoma are very distinctive. The large round, ovoid, or polygonal cells have abundant, clear, very-pale–staining cytoplasm, large and irregular nuclei, and prominent nucleoli (Fig. 37.19). Mitotic
figures are seen in varying numbers, although they are usually numerous. Another characteristic feature is the arrangement of the elements in lobules and nests separated by fibrous septa, which are often extensively infiltrated with lymphocytes, plasma cells, and granulomas with epithelioid cells and multinucleated giant cells. When necrosis is extensive, the lesion may be confused with tuberculosis. Dysgerminomas may contain syncytiotrophoblastic giant cells and may be associated with precocious puberty or virilization. The presence of these cells does not seem to alter the behavior of the tumor (2,3). The presence of calcifications should prompt a search for a possible underlying gonadoblastoma.

**Figure 37.19 Dysgerminoma of ovary.** Primitive germ cells are divided into clusters and lobules by fibrous septa rich in lymphocytes.

Because the dysgerminoma is a germ cell tumor and parthenogenesis (stimulation of the basic germ cell to atypical division) is the accepted genesis for the more immature teratomas, it is logical that these two tumors may coexist. Choriocarcinoma, endodermal sinus tumor, and other extraembryonal lesions may be associated with the dysgerminoma.

**Approximately 5% of dysgerminomas are discovered in phenotypic women with abnormal gonads** (2,349,351). This malignancy can be associated with patients who have pure gonadal dysgenesis (46,XY, bilateral streak gonads), mixed gonadal dysgenesis (45,X/46,XY, unilateral streak gonad, contralateral testis), and the androgen insensitivity syndrome (46,XY, testicular feminization). For premenarcheal patients with a pelvic mass, the karyotype should be determined (see Chapter 29).

**For most patients with gonadal dysgenesis, dysgerminomas arise in gonadoblastomas,** which are benign ovarian tumors that are composed of germ cells
and sex cord stroma. If gonadoblastomas are left in situ in patients with gonadal dysgenesis, more than 50% will develop into ovarian malignancies (351).

About 65% of dysgerminomas are stage I (i.e., confined to one or both ovaries) at diagnosis (2,3,352–356). About 85% to 90% of stage I tumors are confined to one ovary; 10% to 15% are bilateral. Dysgerminoma is the only germ cell malignancy that has this significant rate of bilaterality. Other germ cell tumors are rarely bilateral.

For patients whose contralateral ovary is preserved, disease can develop in 5% to 10% of the retained gonads over the next 2 years (2). This figure includes those not given additional therapy and patients with gonadal dysgenesis.

In the 25% of patients who are diagnosed initially with metastatic disease, the tumor commonly spreads via the lymphatic system. It can spread hematogenously or by direct extension through the capsule of the ovary with exfoliation and dissemination of cells throughout the peritoneal surfaces. Metastases to the contralateral ovary may be present when there is no other evidence of spread. An uncommon site of metastatic disease is bone; when metastasis to this site occurs, the lesions are principally in the lower vertebrae. Metastases to the lungs, liver, and brain are often in patients with longstanding or recurrent disease. Metastasis to the mediastinum and supraclavicular lymph nodes is usually a late manifestation of disease (352,353).

Treatment

The treatment of patients with early dysgerminoma is primarily surgical, including resection of the primary lesion and proper surgical staging. Chemotherapy is administered to patients with metastatic disease. Because the disease principally affects girls and young women, special consideration must be given to the preservation of fertility and use of chemotherapy whenever possible. An algorithm for the management of ovarian dysgerminoma is presented in Figure 37.20.

Figure 37.20 Management of dysgerminoma of the ovary. BEP = bleomycin, etoposide, and cisplatin; CT = computed tomogram. (From Berek JS, Hacker NF. Berek & Hacker’s Gynecologic Oncology. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010:515, with permission.)
Surgery

The minimal surgical operation for ovarian dysgerminoma is a unilateral oophorectomy (354). If there is a desire to preserve fertility, as there almost always is, the contralateral ovary, fallopian tube, and uterus should be left in situ, even in the presence of metastatic disease, because of the sensitivity of the tumor to chemotherapy. If fertility need not be preserved, it may be appropriate to perform a total abdominal hysterectomy and bilateral salpingo-oophorectomy for patients with advanced disease (356). For patients whose karyotype analysis reveals a Y chromosome, both ovaries should be removed, although the uterus may be left in situ for possible future embryo transfer (351). Whereas cytoreductive surgery is of unproved value, bulky disease that can be readily resected (e.g., an omental cake) should be removed during the initial operation.

In patients in whom the neoplasm appears on inspection to be confined to the ovary, a careful staging operation should be undertaken to determine the presence of any occult metastatic disease. All peritoneal surfaces should be
inspected and palpated, and any suspicious lesions should be sampled for biopsy. Unilateral pelvic lymphadenectomy and careful palpation and biopsy of enlarged para-aortic nodes are particularly important parts of the staging. These tumors often metastasize to the para-aortic nodes around the renal vessels. Dysgerminoma is the only germ cell tumor that tends to be bilateral, excisional biopsy of any suspicious masses is desirable (354–356). If a small contralateral tumor is found, it may be possible to resect it and preserve some normal ovary.

Many patients with a dysgerminoma will have a tumor that is apparently confined to one ovary and will be referred after unilateral salpingo-oophorectomy without surgical staging. The options for such patients are (i) repeat laparotomy for surgical staging, (ii) regular pelvic and abdominal CT scans, or (iii) adjuvant chemotherapy. Because these are rapidly growing tumors, the preference is to perform regular surveillance. Tumor markers (LDH, AFP, and β-hCG) should be monitored in case occult mixed germ cell elements are present.

Radiation Therapy
Dysgerminomas are very sensitive to radiation therapy, and doses of 2,500 to 3,500 cGy may be curative, even for gross metastatic disease. Loss of fertility is a problem with radiation therapy, and radiation is rarely used as first-line treatment.

Chemotherapy
There is very good evidence to demonstrate the effectiveness of platinum-based chemotherapy, which is regarded as the treatment of choice (356–367). The obvious advantage is the preservation of fertility (368).

The most frequently used chemotherapeutic regimen for germ cell tumors is BEP (bleomycin, etoposide, and cisplatin), EP or EC (etoposide and carboplatin) (356–373) (Table 37.6).

*All doses given intravenously.

The GOG studied three cycles of the EC regimen, consisting of etoposide (120 mg/m² intravenously on days 1, 2, and 3 every 4 weeks) and carboplatin (400 mg/m² intravenously on day 1 every 4 weeks) for patients with completely resected ovarian dysgerminoma, stage IB, IC, II, or III (364). The results showed a sustained disease-free remission rate of 100%.

For patients with advanced, incompletely resected germ cell tumors, the GOG studied cisplatin-based chemotherapy in two consecutive protocols (357,358). In the first study, patients received four cycles of vinblastine (12 mg/m² every 3 weeks), bleomycin (20 units/m² intravenously every week for 12 weeks), and cisplatin (20 mg/m² per day intravenously for 5 days every 3 weeks). Patients with persistent or progressive disease at second-look laparotomy were treated with six cycles of VAC (vincristine, actinomycin D, and cyclophosphamide). In the second trial, patients received three cycles of BEP initially, followed by consolidation with VAC, which was later discontinued in patients with dysgerminomas (358). The VAC consolidation after BEP is no longer used. A total of 20 evaluable patients with stages III and IV dysgerminoma were treated in these two protocols, and 19 were alive and free of disease after 6 to 68 months (median = 26 months). Fourteen of these patients had a second-look laparotomy, and all findings were negative. Another study at M. D. Anderson Cancer Center used BEP in 14 patients with residual disease, and all patients were free of disease during long-term follow-up (361).

**These results demonstrate that patients with advanced-stage, incompletely resected dysgerminoma have an excellent prognosis when treated with cisplatin-based combination chemotherapy. The standard regimen is three to four cycles of BEP, depending on assigned risk based on the data from testicular cancers (372,373).**

**Recurrent Disease**

**About 75% of recurrences occur within the first year after initial treatment,** the most common sites being the peritoneal cavity and the retroperitoneal lymph nodes (2,335,336). These patients should be treated with chemotherapy, although radiation may be appropriate in selected patients. Patients with recurrent disease who had no therapy other than surgery should be treated with chemotherapy. If prior chemotherapy with BEP was given, there are a number of second-line options including TIP (paclitaxel, ifosfamide, cisplatin) or VIP (vinblastine, ifosfamide, cisplatin) (Table 35.7), and consideration should be given to the use of high-dose chemotherapy in selected patients. Patients with recurrent disease should be managed in specialized centers. Radiation therapy is effective for this disease, with the major disadvantage being loss of fertility if
pelvic and abdominal irradiation is required.

IV, intravenous.

The sequence of treatment schedules is two courses of POMB followed by ACE. POMB is then alternated with ACE until patients are in biochemical remission as measured by human chorionic gonadotropin (hCG) and α-fetoprotein (AFP), placental alkaline phosphatase (PLAP), and lactate dehydrogenase (LDH). The usual number of courses of POMB is three to five. Following biochemical remission, patients alternate ACE with OMB until remission has been maintained for approximately 12 weeks. The interval between courses of treatment is kept to the minimum (usually 9 to 11 days). If delays are caused by myelosuppression after courses of ACE, the first 2 days of etoposide are omitted from subsequent courses of ACE.

Pregnancy

Because dysgerminomas tend to occur in young patients, they may coexist with pregnancy. When a stage IA cancer is found, the tumor can be removed intact and the pregnancy continued. For patients with more advanced disease, continuation of the pregnancy depends on the gestational age of the fetus. Chemotherapy can be given in the second and third trimesters in the same dosages as given for the nonpregnant patient without apparent detriment to the fetus (368).

Prognosis

For patients whose initial disease is stage Ia (i.e., a unilateral encapsulated dysgerminoma), unilateral oophorectomy alone results in a 5-year disease-free survival rate of greater than 95% (355). The features associated with a higher tendency to recur, include lesions larger than 10 to 15 cm in diameter, age younger than 20 years, and a microscopic pattern that includes numerous mitoses, anaplasia, and a medullary pattern (2,346).

Surgery for advanced disease followed by pelvic and abdominal radiation resulted in a 5-year survival rate of 63% to 83%, for this same group of patients cure rates of 85% to 90% are reported with the use of VBP (vinblastine, bleomycin, cisplatin), BEP, or EC combination chemotherapy and radiation is infrequently indicated (356–376).

Immature Teratomas

Immature teratomas contain elements that resemble tissues derived from the embryo. Immature teratomatous elements may occur in combination with other germ cell tumors as mixed germ cell tumors. The pure immature teratoma accounts for fewer than 1% of all ovarian cancers, but it is the second most common germ cell malignancy and accounts for 10% to 20% of all ovarian malignancies seen in women younger than 20 years (2). About 50% of pure immature teratomas of the ovary occur in women between the ages of 10 and 20 years, and they rarely occur in postmenopausal women.

Pathology and Grading

Of fundamental importance in the understanding of the teratoma is recognition of the maturation of the various elements. If maturation continues along normal lines, the mature or adult teratoma results, and the prognosis is excellent. Conversely, abnormal maturation of these elements can result in an immature teratoma that has metastatic potential. Teratomas containing immature elements, although relatively rare, were recognized more often as pathologists became more alert to their presence (Fig. 37.21). Among the tumors with embryonal elements,
those containing neural tissues demonstrate the ability to mature.

**Figure 37.21 Ovarian teratoma.** This tumor contains both mature and immature neural elements with a neural tube-like structure near its center.

Semiquantification of immature neuroepithelium correlates with survival in ovarian immature teratoma and is the basis for grading of these tumors (377–379). **Those with less than one low power field (X 4) of immature neuroepithelium on the slide with the greatest amount of such tissue (grade 1) have a survival of at least 95%, whereas greater amounts of immature neuroepithelium (grades 2 and 3) appear to have a lower overall survival (approximately 85%)** (379). This may not apply to immature teratomas of the ovary in children because they have a good outcome with surgery alone, regardless of the degree of immaturity (380,381). The significant inter- and intraobserver difficulty with a three-tier system led some authorities to recommend the two-tier grading system in use, with immature teratomas categorized as either low grade or high grade (377). Immature ovarian teratomas may be associated with gliomatosis peritonei, a favorable prognostic finding if composed of completely mature tissues; reports using molecular methods indicate these glial implants are not tumor derived but represent teratoma-induced metaplasia of pluripotent müllerian stem cells in the peritoneum (382,383).

**Somatic malignant change in benign cystic teratomas** was recorded as occurring in 0.5% to 2% of cases, usually in patients older than 40 years of age (377). The most common malignancy developing in the initially benign teratoma is squamous cell carcinoma. Other neoplasms were reported (e.g., adenocarcinomas, melanomas, which may arise from the skin or retinal anlage, and sarcomas, including leiomyosarcomas and mixed mesodermal tumors) (2). Carcinomas may arise from any of the epithelial elements.
Diagnosis

The preoperative evaluation and differential diagnosis of immature teratomas are the same as for other germ cell tumors. Some of these lesions will contain calcifications similar to those of mature teratomas, which can be detected by a radiograph of the abdomen or by ultrasonography. Rarely they are associated with the production of steroid hormones and can be accompanied by sexual pseudoprecocity (342). Tumor markers are negative unless a mixed germ cell tumor is present.

Treatment

Surgery

In a premenopausal patient whose lesion appears to be confined to a single ovary, unilateral oophorectomy and surgical staging should be performed. For a postmenopausal patient, a total abdominal hysterectomy and bilateral salpingo-oophorectomy may be performed. Contralateral involvement is rare, and routine resection or wedge biopsy of the contralateral ovary is unnecessary (3,378,379). Any lesions on the peritoneal surfaces should be sampled and submitted for histologic evaluation. The most frequent site of dissemination is the peritoneum and, much less commonly, the retroperitoneal lymph nodes. Blood-borne metastases to organ parenchyma, such as the lungs, liver, or brain, are uncommon. When present, they are usually seen in patients with late or recurrent disease and most often in tumors that are poorly differentiated (i.e., grade 3).

It is unclear whether debulking of metastatic implants enhances the response to combination chemotherapy (384–390). Unlike epithelial lesions, immature teratomas are chemosensitive. Because cure depends on the prompt delivery of chemotherapy, any surgical resection that is potentially morbid and could delay chemotherapy should be resisted.

Chemotherapy

Patients with IA, grade 1 tumors have an excellent prognosis, and no adjuvant therapy is required. For patients whose tumors are stage IA, grade 2 or 3, adjuvant chemotherapy should be used (359–361,374,375–378). Chemotherapy is indicated for patients who have ascites, regardless of tumor grade. The standard approach is BEP. The most frequently used combination chemotherapeutic regimen was VAC, but this regimen is no longer used (359,360,391–397).

The GOG is prospectively studying three courses of BEP therapy for patients with completely resected stages I, II, and III ovarian germ cell tumors (359,360,397). Overall, the toxicity is acceptable, and 91 of 93 patients whose nondysgerminomatous tumors were treated are clinically free of disease. The BEP regimen, which is standard of care for testicular cancer, is also the most appropriate chemotherapy regimen for nondysgerminomatous germ cells tumors of the ovary. As these tumors can
progress rapidly, treatment should be initiated as soon as possible after surgery, preferably within 7 to 10 days (398).

The switch from VBP to BEP was prompted by the experience in patients with testicular cancer, in which the replacement of vinblastine with etoposide was associated with a better therapeutic index (i.e., equivalent efficacy and lower morbidity), especially less neurologic and gastrointestinal toxicity. The use of bleomycin seems to be important for this group of patients. In a randomized study of three cycles of etoposide plus cisplatin with or without bleomycin (EP versus BEP) in 166 patients with germ cell tumors of the testes, the BEP regimen had a relapse-free survival rate of 84% compared with 69% for the EP regimen (p = 0.03) (372). Cisplatin may be slightly better than carboplatin in the setting of metastatic germ cell tumors. One hundred ninety-two patients with germ cell tumors of the testes were entered into a study of four cycles of etoposide plus cisplatin (EP) versus four cycles of etoposide plus carboplatin (EC). There were three relapses with the EP regimen versus seven with the EC regimen, although the overall survival of the two groups is identical thus far (373). In view of these results, **BEP is the preferred treatment regimen for patients with gross residual disease and has replaced the VAC regimen for patients with completely resected disease.**

It is unclear whether adjuvant chemotherapy is indicated or required for all patients with resected immature teratomas. Several reports support the successful management of these patients with surgery alone and close surveillance (390, 399). In the largest series, an Intergroup study from the Pediatric Oncology Group and the Children’s Cancer Group, 73 children with immature teratoma (44 of ovarian origin) underwent surgery followed by surveillance. With a median follow-up of 35 months, the overall 3-year event-free survival rates for all patients and those with ovarian teratomas were 93% and 100%, respectively. Thirteen of the 44 girls with an immature ovarian teratoma had microscopic foci of yolk sac tumor in the teratoma; one developed recurrent disease and was successfully treated with cisplatin-based chemotherapy. Of note, 82% of the tumors were grade 1 or 2; however, 92% of those with foci of yolk sac tumor were grade 2 or 3.

**Second-Look Laparotomy**

The need for a second-look operation was questioned (375, 376). It seems not to be justified in patients who received chemotherapy in an adjuvant setting, because chemotherapy in these patients is effective. Second-look laparotomy in patients with macroscopic residual disease at the start of chemotherapy may be of value in selected patients, as some patients may have residual mature teratoma and are at risk of growing teratoma syndrome, a rare complication of immature teratomas (400, 401). Cancers can arise at a later date in residual mature teratoma. It is important to resect any residual mass and exclude persistent disease because further chemotherapy may be indicated. The principles of surgery are based on the much larger experience of surgery in males with residual masses following chemotherapy for germ cell tumors with a component of immature teratoma (402). Mathew et al. reported their experience of laparotomy in
assessing the nature of postchemotherapy residue in ovarian germ cell tumors. Sixty-eight patients completed combination chemotherapy with cisplatin regimes, and 35 had radiological residual masses. Twenty-nine of these 35 patients underwent laparotomy and 3 patients had viable tumor, 7 immature teratomas, 3 mature teratoma, and 16 only necrosis or fibrosis. None of the patients with dysgerminoma, embryonal carcinoma, absence of teratoma element in the primary tumor, and radiological residual mass of less than 5 cm had viable tumor; whereas all patients with tumors containing the teratoma component initially had residual tumor, strengthening the case for surgery in patients with immature teratoma and any residual mass (403,404).

Prognosis

The most important prognostic feature of the immature teratoma is the grade of the lesion (2,370). The stage of disease and the extent of tumor at the initiation of treatment have an impact on the curability of the lesion. Overall, the 5-year survival rate for patients with all stages of pure immature teratomas is 70% to 80%, and it is 90% to 95% for patients with surgically staged, stage I lesions (374,377,386).

Endodermal Sinus Tumors

Endodermal sinus tumors (EST) are referred to as yolk sac carcinomas because they are derived from the primitive yolk sac (2, 3). These lesions are the third most frequent malignant germ cell tumors of the ovary. ESTs occur in patients with a median age of 16 to 18 years (2,3,405). About one-third of the patients are premenarcheal at the time of diagnosis. Abdominal or pelvic pain is the most frequent initial symptom, occurring in about 75% of patients, whereas an asymptomatic pelvic mass is documented in 10% of patients (343).

Pathology

The gross appearance of an EST is soft grayish-brown. Cystic areas caused by degeneration or necrosis are present in these rapidly growing lesions. The capsule is intact in most cases.

The EST is unilateral in 100% of cases; thus, biopsy of the opposite ovary is contraindicated. The association of such lesions with gonadal dysgenesis must be appreciated, and chromosomal analysis should be performed preoperatively in premenarcheal patients (3).

Microscopically, the characteristic feature is the endodermal sinus, or Schiller-Duval body (Fig. 37.22). The cystic space is lined with a layer of flattened or irregular endothelium into which projects a glomerulus-like tuft with a central vascular core. These structures vary throughout the tumor, and the reticular, myxoid elements simulate undifferentiated mesoblast. The lining of the papillary infolding and the cavity is irregular, with an occasional cell containing clear, glassy cytoplasm, simulating the hobnail appearance of the epithelium in clear cell tumors. The association of EST with
dysgerminoma must be emphasized if diagnosis and therapy are to be optimal (2, 3).

Figure 37.22 Endodermal sinus tumor of the ovary. Note the classic Schiller-Duval body with its central vessel and mantle of endoderm.

Most EST lesions secrete AFP and, rarely, they may elaborate detectable alpha-1 antitrypsin (AAT). AFP can be demonstrated in the tumor by means of the immunoperoxidase technique. There is a good correlation between the extent of disease and the level of AFP, although discordance is observed. The serum level of these markers, particularly AFP, is useful in monitoring the patient’s response to treatment (405–409).

Treatment

Surgery

The treatment of the EST consists of surgical exploration, unilateral salpingo-oophorectomy, and a frozen section for diagnosis. The addition of a hysterectomy and contralateral salpingo-oophorectomy does not alter outcome (407). Any gross metastases should be removed, if possible, but thorough surgical staging is not indicated because all patients need chemotherapy. At surgery, the tumors tend to be solid and large, ranging in size from 7 to 28 cm (median, 15 cm) in the GOG series (397). Bilaterality does not occur, and the other ovary is involved with metastatic disease only when there are other metastases in the peritoneal cavity. Most patients have early-stage disease: 71%, stage I; 6%, stage II; and 23%, stage III (409).

Chemotherapy

All patients with ESTs are treated with either adjuvant or therapeutic chemotherapy. Before the routine use of combination chemotherapy for this disease,
the 2-year survival rate was only about 25%. After the introduction of the VAC regimen, this rate improved to 60% to 70%, indicating the chemosensitivity of most of these tumors (392,393). With conservative surgery and adjuvant chemotherapy, fertility can be preserved as with other germ cell tumors.

**Cisplatin-containing combination chemotherapy with three to four cycles of BEP should be used as primary chemotherapy for EST.** The GOG protocols used three to four treatment cycles given every 3 weeks (397,410).

### Rare Germ Cell Tumors of the Ovary

#### Embryonal Carcinoma

Embryonal carcinoma of the ovary is an extremely rare tumor that is distinguished from a choriocarcinoma of the ovary by the absence of syncytiotrophoblastic and cytotrophoblastic cells. The patients are very young; ages ranged between 4 and 28 years (median, 14 years) in two series (411). Older patients were reported (412). Embryonal carcinomas may secrete estrogen, with the patient exhibiting symptoms and signs of precocious pseudopuberty or irregular bleeding (2). The clinical picture is otherwise similar to that of the EST. The primary lesions tend to be large, and about two-thirds are confined to one ovary at the time of diagnosis. These lesions frequently secrete AFP and hCG, which are useful for following the response to subsequent therapy (408). The treatment of embryonal carcinomas is the same as for the EST (i.e., a unilateral oophorectomy followed by combination chemotherapy with BEP) (360,397).

#### Choriocarcinoma of the Ovary

Pure nongestational choriocarcinoma of the ovary is an extremely rare tumor. Histologically, it has the same appearance as gestational choriocarcinoma metastatic to the ovaries (413). Most patients with this cancer are younger than 20 years. The presence of hCG can be useful in monitoring the patient’s response to treatment. In the presence of high hCG levels, isosexual precocity occurs in about 50% of patients whose lesions appear before menarche (413,414).

There are only a few limited reports on the use of chemotherapy for nongestational choriocarcinomas, but complete responses were reported with the MAC (methotrexate, actinomycin D, and cyclophosphamide) regimen used in a manner described for gestational trophoblastic disease (379) (see Chapter 39). Alternatively, the BEP regimen can be used. The prognosis of ovarian choriocarcinomas is poor, with most patients having metastases to organ parenchyma at the time of diagnosis.

#### Polyembryoma

Polyembryoma of the ovary is another extremely rare tumor, which is composed of embryoid bodies. This tumor replicates the structures of early embryonic differentiation
Mixed Germ Cell Tumors

Mixed germ cell malignancies of the ovary contain two or more elements of the lesions described above. In one series, the most common component of a mixed malignancy was dysgerminoma, which occurred in 80%, followed by EST in 70%, immature teratoma in 53%, choriocarcinoma in 20%, and embryonal carcinoma in 16% (415). The most frequent combination was a dysgerminoma and an EST. The mixed lesions may secrete either AFP, hCG, or both or neither of these markers, depending on the components.

These lesions should be managed with combination chemotherapy, preferably BEP. The serum marker, if positive initially, may become negative during chemotherapy, but this finding may reflect regression of only a particular component of the mixed lesion. Therefore, for these patients, a second-look laparotomy may be indicated to determine the precise response to therapy if macroscopic disease was present at initiation of chemotherapy.

The most important prognostic features are the size of the primary tumor and the relative size of its most malignant component (416). For stage IA lesions smaller than 10 cm, survival is 100%. Tumors composed of less than one-third EST, choriocarcinoma, or grade 3, immature teratoma have an excellent prognosis, but it is less favorable when these components constitute most of the mixed lesions.

Late Effects of Treatment of Malignant Germ Cell Tumors of the Ovary

Although there are substantial data regarding late effects of cisplatin-based therapy in men with testicular cancer, sparse information is available for women with ovarian germ cell tumors. Among the adverse events from chemotherapy reported in men are renal and gonadal dysfunction, neurotoxicity, cardiovascular toxicity, and secondary malignancies.

Gonadal Function

An important cause of infertility in patients with ovarian germ cell tumors is unnecessary bilateral salpingo-oophorectomy and hysterectomy. Although temporary ovarian dysfunction or failure is common with platinum-based chemotherapy, most women will resume normal ovarian function, and childbearing is usually preserved (349,355). In one representative series of 47 patients treated with combination chemotherapy for germ cell malignancies, 91.5% resumed normal menstrual function, and there were 14 healthy live births and no birth defects (370). Factors such as older age at initiation of chemotherapy, greater cumulative drug dose, and longer
duration of therapy all have an adverse effect on future gonadal function.

**Secondary Malignancies**

An important cause of late morbidity and mortality in patients receiving chemotherapy for germ cell tumors is the development of secondary tumors. **Etoposide in particular was implicated in the development of treatment-related leukemias** (417,418).

The chance of developing treatment-related leukemia following etoposide is dose related. **The incidence of leukemia is approximately 0.4% to 0.5%** (representing a 30-fold increased likelihood) in patients receiving a cumulative etoposide dose of less than 2,000 mg/m², compared with as much as 5% (representing a 336-fold increased likelihood) in those receiving more than 2,000 mg/m² (417). In a typical three- or four-cycle course of BEP, patients receive a cumulative etoposide dose of 1,500 or 2,000 mg/m², respectively.

Despite the risk of secondary leukemia, risk-benefit analyses concluded that etoposide-containing chemotherapy regimens are beneficial in advanced germ cell tumors; one case of treatment-induced leukemia would be expected for every 20 additionally cured patients who receive BEP as compared with platinum, vincristine, bleomycin (PVB). The risk–benefit balance for low-risk disease, or for high-dose etoposide in the salvage setting, is less clear (418).
Sex Cord–Stromal Tumors

Sex cord–stromal tumors of the ovary account for about 5% to 8% of all ovarian malignancies (2,3,342,343,419–425). This group of ovarian neoplasms is derived from the sex cords and the ovarian stroma or mesenchyme. The tumors usually are composed of various combinations of elements, including the “female” cells (i.e., granulosa and theca cells) and “male” cells (i.e., Sertoli and Leydig cells), and morphologically indifferent cells. A classification of this group of tumors is presented in Table 37.8.

Table 37.8 Sex Cord–Stromal and Steroid Cell Tumors

1. Granulosa-stromal cell tumors
   A. Granulosa cell tumor
   B. Tumors in thecoma-fibroma group
      1. Thecoma
      2. Fibroma
      3. Unclassified
   C. Androblastomas; Sertoli-Leydig cell tumors
      A. Well-differentiated
         1. Sertoli cell tumor
         2. Sertoli-Leydig cell tumor
         3. Leydig cell tumor; hilus cell tumor
      B. Moderately differentiated
      C. Poorly differentiated (sarcomatoid)
      D. With heterologous elements
   3. Gynandroblastoma
   4. Sex cord tumor with annular tubules
   5. Sex cord-stromal tumors, unclassified
   6. Steroid cell tumors
      A. Stromal luteoma
      B. Leydig cell tumor
      C. Steroid cell tumor, not otherwise classified

Granulosa-Stromal Cell Tumors

Granulosa-stromal cell tumors include granulosa cell tumors, thecomas, and fibromas. The granulosa cell tumor is a low-grade malignancy; rarely, thecomas and fibromas have morphologic features of malignancy and may be referred to as fibrosarcomas.

Figure 37.23 Granulosa cell tumor of the ovary. Note the classic Call-Exner bodies with a minimal stromal
Granulosa cell tumors, which secrete estrogen, are seen in women of all ages. They are found in prepubertal girls in 5% of cases; the remainder are found in women throughout their reproductive and postmenopausal years (422). Granulosa cell tumors are bilateral in only 2% of patients.

**Pathology**

Granulosa cell tumors range from a few millimeters to 20 cm or more in diameter. The tumors are rarely bilateral and have a smooth, lobulated surface. The solid portions of the tumor are granular, frequently trabeculated, and yellow or gray-yellow in color. After clear cell carcinoma, the granulosa-theca cell tumor is probably the most inaccurately diagnosed tumor of the female gonad. Of 477 ovarian tumors from the Emil Novak Ovarian Tumor Registry diagnosed initially as granulosa-theca cell tumors, almost 15% were reclassified after histologic review. Lesions misdiagnosed as granulosa cell tumors included primary or metastatic carcinomas, teratoid tumors, and poorly differentiated mesothelial tumors (419).

The classic adult granulosa cell is round or ovoid with scant cytoplasm. The nucleus contains compact, finely granular chromatin and is either euchromatic or hypochromatic (3). “Coffee bean” grooved nuclei are characteristic; mitotic figures may be present, but numerous mitotic figures should prompt consideration for poorly differentiated or undifferentiated carcinoma. In the most common variety, the adult granulosa cells show a tendency to arrange themselves in small clusters or rosettes around a central cavity, so there is a resemblance to primordial follicles (i.e., Call-Exner bodies) (Fig. 37.23). The stroma is similar to the theca and may be luteinized. In children and adolescents, the granular cell tumors are often cystic, contain luteinized...
cells, and can be associated with precocious puberty. Juvenile granulosa cell tumors, so named because of their tendency to occur in younger patients, feature rounder, more hyperchromatic nuclei and may contain numerous mitotic figures. The presence of large, irregular follicle spaces is an additional distinguishing feature of the juvenile granulosa cell tumor. The adult granulosa cell tumor tends to occur in older women and the juvenile tumor in children and young women, but the diagnosis is not based on age of presentation, but on histology. Adult granulosa cell tumors, but not juvenile granulosa cell tumors, harbor a somatic mutation in the FOXL2 gene (426).

Diagnosis
Granulosa cell tumors, which secrete estrogen, are seen in women of all ages. They are found in prepubertal girls in 5% of cases (typically the juvenile form); the remainder are distributed throughout the reproductive and postmenopausal years (422–425). They are bilateral in only 2% of patients.

Of the rare prepubertal lesions, 75% are associated with sexual pseudoprecocity because of the estrogen secretion (422). Most reproductive-age patients have menstrual irregularities or secondary amenorrhea, and, frequently, cystic hyperplasia of the endometrium. Abnormal uterine bleeding is often the initial symptom for postmenopausal women. The estrogen secretion in these patients can be sufficient to stimulate the development of endometrial cancer. Low-grade endometrial cancer occurs in association with granulosa cell tumors in at least 5% of cases, and 25% to 50% are associated with endometrial hyperplasia (2,413,419–422,426).

The other symptoms and signs of granulosa cell tumors are nonspecific and the same as most ovarian malignancies. Ascites is present in about 10% of cases, and, rarely, a pleural effusion is present (419–422). Granulosa tumors tend to be hemorrhagic; occasionally, they rupture and produce a hemoperitoneum.

Adult granulosa cell tumors are usually stage I at diagnosis, but may recur 5 to 30 years after initial diagnosis (421). Most juvenile granulosa cell tumors are clinically benign; only about 10% recur and when they do so, it is generally within 5 years of the initial diagnosis. The tumors may spread hematogenously, and metastases can develop in the lungs, liver, and brain years after initial diagnosis. When adult granulosa cell tumors do recur, they can progress rapidly. Malignant thecomas are extremely rare, and their signs and symptoms, management, and outcome are similar to those of the granulosa cell tumors (419). Inhibin is secreted by some granulosa cell tumors and is a useful marker for the disease (427–431). An elevated serum inhibin level in a premenopausal woman presenting with amenorrhea and infertility is suggestive of a granulosa cell tumor (432).

Treatment
The treatment of granulosa cell tumors depends on the age of the patient and the extent of disease. For most patients, surgery alone is sufficient primary therapy; radiation and
chemotherapy are reserved for the treatment of recurrent or metastatic disease (422–429,433–436).

**Surgery**

Because granulosa cell tumors are bilateral in only about 2% of patients, a unilateral salpingo-oophorectomy is appropriate therapy for stage IA tumors in children or in women of reproductive age (420). At the time of laparotomy, if a granulosa cell tumor is identified by frozen section, a staging operation is performed, including an assessment of the contralateral ovary. If the opposite ovary appears enlarged, it should be sampled for biopsy. For perimenopausal and postmenopausal women for whom ovarian preservation is not important, a hysterectomy and bilateral salpingo-oophorectomy should be performed. For premenopausal patients in whom the uterus is left in situ, an endometrial biopsy should be performed because of the possibility of a coexistent adenocarcinoma of the endometrium (422).

**Radiation Therapy**

There is no evidence to support the use of adjuvant radiation therapy for granulosa cell tumors, although pelvic irradiation may help to palliate isolated pelvic recurrences (422,434).

**Chemotherapy**

There is no evidence that adjuvant chemotherapy will prevent recurrence of disease (436–439). Metastatic lesions and recurrences were treated with a variety of antineoplastic drugs. Although the data are inconclusive, BEP or carboplatin and paclitaxel are used in selected patients with stage III or IV tumors or recurrent disease (433). In a GOG study, 37% (14 of 30) patients treated with BEP had a negative second-look laparotomy, and these patients had a median time to progression of 24.4 months (440). Granulosa cell tumors are potentially hormonally responsive, with about 30% of granulosa tumors expressing estrogen receptors and almost 100% expressing progesterone receptors. Hormonal agents such as progestins or luteinizing hormone-releasing hormone agonists are used to treat these patients because they are often elderly (441–445). There are case reports of durable response to aromatase inhibitors in patients with metastatic granulosa cell tumors who received multiple prior treatment (443). Small clinical series and case reports indicated that luteinizing hormone-releasing hormone agonists had a 50% response rate in 13 patients, while 4 of 5 patients in the literature responded to a progestational agent. Two case series reported durable responses in a total of six patients receiving aromatase inhibitors among those who progressed on or were intolerant of chemotherapy (442–445).

**Prognosis**

Adult granulosa cell tumors have a prolonged natural history and a tendency toward late relapse, reflecting their low-grade biology. Ten-year survival rates of
about 90% are reported, with 20-year survival rates dropping to 75% (420–422,432,433). Most histologic types have the same prognosis, but patients with the more poorly differentiated diffuse or sarcomatoid type tend to do worse (419).

**The DNA ploidy of the tumors is correlated with survival.** Holland et al. reported DNA aneuploidy in 13 of 37 patients (35%) with primary adult granulosa cell tumors (437). The presence of residual disease is the most important predictor of progression-free survival, but DNA ploidy is an independent prognostic factor. **Patients with residual-negative DNA diploid tumors had a 10-year progression-free survival of 96%.

Juvenile granulosa cell tumors of the ovary are rare and constitute less than 5% of ovarian tumors in childhood and adolescence (446). About 90% are diagnosed in stage I, and they have a favorable prognosis. The juvenile subtype behaves less aggressively than the adult type. Only about 10% of juvenile granulosa cell tumors are malignant and late relapse is unusual. Advanced-stage tumors are successfully treated with platinum-based combination chemotherapy (e.g., BEP) (433,440).

**Sertoli-Leydig Tumors**

**Sertoli-Leydig tumors occur most frequently in the third and fourth decades of life; 75% of these tumors are seen in women younger than 40 years.** These neoplasms are extremely rare and account for less than 0.2% of ovarian cancers (2,447,448). Sertoli-Leydig cell tumors are most frequently low-grade malignancies; a poorly differentiated variety may behave more aggressively (Fig. 37.24) (447–449).

**Figure 37.24 Sertoli-Leydig cell tumor of the ovary.** Note the aggregates of eosinophilic Leydig cells in the stroma adjacent to Sertoli cell tubules.
The tumors typically produce androgens, and clinical virilization is noted in 70% to 85% of patients (449). Signs of virilization include oligomenorrhea followed by amenorrhea, breast atrophy, acne, hirsutism, clitoromegaly, deepening of the voice, and a receding hairline. Measurement of plasma androgens may reveal elevated testosterone and androstenedione, with normal or slightly elevated dehydroepiandrosterone sulphate (2,450). Rarely, the Sertoli-Leydig tumor is associated with manifestations of estrogenization (i.e., isosexual precocity, irregular or postmenopausal bleeding).

Treatment

Because these low-grade lesions are only rarely bilateral (<1%), the usual treatment is unilateral salpingo-oophorectomy and evaluation of the contralateral ovary for patients who are in their reproductive years (3,422). For older patients, hysterectomy and bilateral salpingo-oophorectomy are appropriate (447,448). There are insufficient data to document the utility of radiation or chemotherapy for patients with persistent disease, but some responses in patients with measurable disease were reported with pelvic irradiation and the VAC chemotherapy regimen (3,451–455).

Prognosis

The 5-year survival rate is 70% to 90%, and recurrences thereafter are uncommon (3,450–455). Most fatalities occur in the presence of poorly differentiated tumors.
Uncommon Ovarian Cancers
There are several varieties of malignant ovarian tumors that together constitute only 0.1% of ovarian malignancies (2). Two of these lesions are the lipoid (or lipid) cell tumors and the primary ovarian sarcomas.

Lipoid Cell Tumors
Lipoid cell tumors are believed to arise in adrenal cortical rests that reside in the vicinity of the ovary. More than 100 cases were reported, and bilateral disease was noted in only a few (2). Most are associated with virilization and, occasionally, with obesity, hypertension, and glucose intolerance, reflecting corticosteroid secretion. Rare cases of estrogen secretion and isosexual precocity were reported.

Most of these tumors have benign or low-grade behavior, but about 20%, most of which are initially larger than 8 cm in diameter, are associated with metastatic lesions. Metastases are usually in the peritoneal cavity but can occur at distant sites. The primary treatment is surgical extirpation of the primary lesion. There are no data regarding the effectiveness of radiation or chemotherapy for this disease.

Sarcomas
Malignant mixed mesodermal tumors (MMMT) of the ovary or carcinosarcomas are uncommon. Clinical, morphologic and molecular data suggest that MMMTs are monoclonal and are metaplastic carcinomas in which the mesenchymal part reflects dedifferentiation. Most tumors are heterologous, and 80% occur in postmenopausal women. The signs and symptoms are similar to those of most ovarian malignancies. These tumors are biologically aggressive, and most patients have evidence of metastases at presentation. They are treated either with carboplatin and paclitaxel or ifosphamide and cisplatin, but in general have a poor prognosis.

Small Cell Carcinoma, Hypercalcemic Type
This rare tumor occurs at an average age of 24 years (range 2 to 46 years) (456). The tumors are typically unilateral. Approximately two-thirds of the tumors are accompanied by paraendocrine hypercalcemia. This tumor accounts for one-half of all of the cases of hypercalcemia associated with ovarian tumors. About 50% of the tumors have spread beyond the ovaries when they are diagnosed (456). Immunohistochemical stains are helpful to differentiate this tumor from a lymphoma, leukemia, or sarcoma.

The management of these malignancies consists of surgery followed by platinum-based chemotherapy or radiation therapy or both. In addition to the primary treatment of the disease, control of the hypercalcemia may require aggressive hydration, loop diuretics, and the use of bisphosphonates or calcitonin. The prognosis tends to be poor, with most patients dying within 2 years of diagnosis in spite of
Figure 37.25 Metastatic carcinoma in the ovary. Note the linear, single cell pattern found in this metastatic breast carcinoma.
Metastatic Tumors

About 5% to 6% of ovarian tumors are metastatic from other organs, most frequently from the female genital tract, the breast, or the gastrointestinal tract (457–473). The metastases may occur from direct extension of another pelvic neoplasm, by hematogenous or lymphatic spread, or by transcoelomic dissemination, with surface implantation of tumors that spread in the peritoneal cavity.
**Gynecologic**

Nonovarian cancers of the genital tract can spread by direct extension or metastasize to the ovaries. Tubal carcinoma involves the ovaries secondarily in 13% of cases, usually by direct extension (2,3). Under some circumstances, it is difficult to know whether the tumor originated in the tube or in the ovary when both are involved. Cervical cancer spreads to the ovary only in rare cases (<1%), and most of these are of an advanced clinical stage or are adenocarcinomas. Adenocarcinoma of the endometrium can spread and implant directly onto the surface of the ovaries in about 5% of cases, but two synchronous primary tumors probably occur with greater frequency (472). In these cases, an endometrioid carcinoma of the ovary is usually associated with the adenocarcinoma of the endometrium.
Nongynecologic

The frequency of metastatic breast carcinoma to the ovaries varies according to the method of determination, but the phenomenon is common (Fig. 37.25). In autopsy data of women who died of metastatic breast cancer, the ovaries were involved in 24% of cases, and 80% of the involvement was bilateral (457–462). Similarly, when ovaries are removed to palliate advanced breast cancer, about 20% to 30% of the cases reveal ovarian involvement, 60% of those bilaterally. The involvement of ovaries in early-stage breast cancer seems to be considerably lower, but precise figures are not available. In almost all cases, either ovarian involvement is occult or a pelvic mass is discovered after other metastatic disease becomes apparent.

Krukenberg Tumor

The Krukenberg tumor, which can account for 30% to 40% of metastatic cancers to the ovaries, arises in the ovarian stroma and has characteristic mucin-filled, signet-ring cells (463–465) (Fig. 37.26). The primary tumor is frequently located in the stomach and less commonly in the colon, appendix (so-called goblet cell carcinoid), breast, or biliary tract. Rarely, the cervix or the bladder may be the primary site. Krukenberg tumors can account for about 2% of ovarian cancers at some institutions, and they are usually bilateral. The lesions are usually not discovered until the primary disease is advanced, and, therefore, most patients die of their disease within 1 year. In some cases, a primary tumor is never found.

Figure 37.26 Krukenberg tumor of the ovary metastatic from a gastric carcinoma. Malignant cells have discrete vacuoles that push nuclei eccentrically, giving a signet-ring appearance. Mucicarmine stain demonstrates the cytoplasmic vacuoles to be mucin.
Other Gastrointestinal Tumors

In other cases of metastasis from the gastrointestinal tract to the ovary, the tumor does not have the classic histologic appearance of a Krukenberg tumor; most of these are from the colon and, less commonly, the pancreato-biliary tract, appendix, and small intestine (Fig. 37.27). As many as 1% to 2% of women with intestinal carcinomas will develop metastases to the ovaries during the course of their disease (459). Before exploration for an adnexal tumor in a woman older than 40 years, a barium enema is indicated to exclude a primary gastrointestinal carcinoma with metastases to the ovaries, particularly if there are any gastrointestinal symptoms. Metastatic colon cancer can mimic a mucinous cystadenocarcinoma of the ovary histologically, and the histological distinction between the two can be difficult (458,459,466–470). Lesions that arise in the appendix may be associated with ovarian metastasis and confused with primary ovarian malignancies, especially when associated with pseudomyxoma peritonei (466,470). It is reasonable to consider the performance of prophylactic bilateral salpingo-oophorectomy at the time of surgery for women with colon cancer (471).

Figure 37.27 Metastatic colorectal carcinoma in the ovary often has areas of necrotic debris (so-called dirty necrosis) adjacent to partial gland structures showing a cribriform pattern.
Melanoma

Rare cases of malignant melanoma metastatic to the ovaries were reported (473). In these circumstances, the melanomas are usually widely disseminated. Removal would be warranted for palliation of abdominal or pelvic pain, bleeding, or torsion. Malignant melanoma can arise, rarely, in a mature cystic teratoma (474).

Carcinoid Tumors

Metastatic carcinoid tumors represent fewer than 2% of metastatic lesions to the ovaries (475). Only about 2% of patients with primary carcinoids have evidence of ovarian metastasis, and only 40% of them have the carcinoid syndrome at the discovery of the metastatic carcinoid. In perimenopausal and postmenopausal women explored for an intestinal carcinoid, it is reasonable to remove the ovaries to prevent subsequent ovarian metastasis. The discovery of an ovarian carcinoid should prompt a careful search for a primary intestinal lesion (476).

Lymphoma and Leukemia

Lymphomas and leukemia can involve the ovary. When they do, the involvement is usually bilateral (477–479). About 5% of patients with Hodgkin's lymphoma will have lymphomatous involvement of the ovaries, but this involvement occurs typically with advanced-stage disease. With Burkitt’s lymphoma, ovarian involvement is very common. Other types of lymphoma involve the ovaries less frequently, and leukemic infiltration of the ovaries is uncommon (479). Sometimes the ovaries can be the only apparent sites of involvement of the abdominal or pelvic viscera with a lymphoma; if this circumstance is found, a careful surgical exploration may be necessary. Intraoperatively, a hematologist-oncologist should be consulted to determine the need for these procedures if frozen section of a solid ovarian mass reveals a lymphoma. Most lymphomas no longer require extensive surgical staging; biopsy of enlarged lymph nodes should be performed. In some cases of Hodgkin's lymphoma, a more extensive evaluation may be necessary. Treatment involves that of the lymphoma or leukemia. Removal of a large ovarian mass may improve patient comfort and facilitate a response to subsequent radiation or chemotherapy.
Fallopian Tube Cancer

Historically, carcinoma of the fallopian tube accounted for 0.3% of all cancers of the female genital tract (2,3,480–486). Data suggest primary fallopian tube carcinoma may be more common. In histologic features and behavior, fallopian tube carcinoma is similar to ovarian cancer; thus, the evaluation and treatment are essentially the same (Fig 37.28). The fallopian tubes frequently are involved secondarily from other primary sites, most often the ovaries, endometrium, gastrointestinal tract, or breast. They may be involved in primary peritoneal carcinomatosis. Almost all cancers are of epithelial origin, frequently of serous histology. Rarely, sarcomas are reported.

Figure 37.28 Carcinoma of the fallopian tube. This is a high-grade serous carcinoma that has invaded the lamina propria of the tubal mucosa. Most primary fallopian tube carcinomas arise in the distal (fimbria) portion of the fallopian tube.
As noted above, there is growing evidence to suggest that many high-grade serous carcinomas of the ovary may prove to arise from the fimbrial end of the fallopian tube (5,7). The true incidence of fallopian tube cancer may be historically underestimated because of the convention of assigning many of these as ovarian cancer when the site of origin is unclear. Despite the uncertainty concerning site of origin, all evidence suggests that our evaluation and treatment of these high-grade serous carcinomas should be the same. In recognition of this, many pathologists resorted to diagnosing these tumors as (nonuterine) high-grade serous carcinomas without definite assignment to primary site.
Clinical Features
Tubal cancers are seen most frequently in the fifth and sixth decades, with a mean age of 55 to 60 years (480). Women who have germline mutations in BRCA1 and BRCA2 are at substantially higher risk for developing fallopian tube carcinoma; therefore, prophylactic surgery in these women should include a complete removal of both tubes along with the ovaries (78,487).

Symptoms and Signs
The classic triad of symptoms and signs associated with fallopian tube cancer is (i) a prominent watery vaginal discharge (i.e., hydrops tubae profluens), (ii) pelvic pain, and (iii) a pelvic mass. This triad is noted in fewer than 15% of patients, and may be less common based on the histopathologic origins of fallopian tube cancers (3).

Vaginal discharge or bleeding is the most common symptom reported by patients with tubal carcinoma and is documented in more than 50% of patients (3,481). Lower abdominal or pelvic pressure and pain are noted in many patients. The symptoms may be rather vague and nonspecific. For perimenopausal and postmenopausal women with unusual, unexplained, or persistent vaginal discharge, in the absence of bleeding, the clinician should be concerned about the possibility of occult tubal cancer. Fallopian tube cancer may be found incidentally in asymptomatic women at the time of abdominal hysterectomy and bilateral salpingo-oophorectomy.

On examination, a pelvic mass is present in about 60% of patients, and ascites may be present if advanced disease exists. For patients with tubal carcinoma, the results of dilation and curettage will be negative, although abnormal or adenocarcinomatous cells may be seen in cytologic specimens obtained from the cervix in 10% of patients (483).

Spread Pattern
Tubal cancers spread in the same manner as epithelial ovarian malignancies, principally by the transcoelomic exfoliation of cells that implant throughout the peritoneal cavity. In about 80% of the patients with advanced disease, metastases are confined to the peritoneal cavity at the time of diagnosis (482).

The fallopian tubes are richly permeated with lymphatic channels, as are the ovaries, and spread to the para-aortic and pelvic lymph nodes is common. Metastases to the para-aortic lymph nodes are documented in at least 33% of the patients with all stages of disease (486).
Staging

Fallopian tube cancer is staged according to FIGO (480,485). The staging is based on the surgical findings at laparotomy (Table 37.9). According to this system, about 20% to 25% of patients have stage I disease, 20% to 25% have stage II disease, 40% to 50% have stage III disease, and 5% to 10% have stage IV disease (480). A somewhat lower incidence of advanced disease is seen in these patients than in patients with epithelial ovarian carcinomas, presumably because of the earlier occurrence of symptoms, particularly vaginal bleeding or unusual vaginal discharge. Findings on transvaginal ultrasonography and CT scan may be suspicious for tubal carcinomas (488).

IIIC Abdominal implants greater than 2 cm in diameter and/or positive retroperitoneal or inguinal nodes.

Growth involving one or both fallopian tubes with distant metastases. If pleural effusion is present, there must be positive cytology to be stage IV. Parenchymal liver metastases equals stage IV.

FIGO, International Federation of Gynecology and Obstetrics.

Treatment

The treatment of this disease is the same as that of epithelial ovarian cancer ([480,483,489–495]). Exploratory laparotomy is necessary to remove the primary tumor, to stage the disease, and to resect metastases. After surgery, the chemotherapy is the same as with epithelial ovarian cancer (i.e., carboplatin and paclitaxel).

Surgery

Patients with tubal carcinoma should undergo total abdominal hysterectomy and bilateral salpingo-oophorectomy ([3]). If there is no evidence of gross tumor spread, a staging operation is performed. The retroperitoneal lymph nodes should be adequately evaluated, and peritoneal cytologic studies and biopsies should be performed, along with an infracolic omentectomy.

In patients with metastatic disease, an effort should be made to remove as much tumor bulk as possible. The role of cytoreductive surgery in this disease is unclear, but extrapolation from the experience with epithelial ovarian cancer indicates that significant benefit might be expected, particularly if all macroscopic disease can be resected ([490]).

Chemotherapy

As with epithelial ovarian cancer, the most active agents are platinum and the taxanes ([489,490]). The recommended treatment for fallopian tube cancer is the same as that for epithelial ovarian cancer (i.e., platinum and taxane-based chemotherapy). A variety of other chemotherapeutic agents that are effective against recurrent ovarian cancer appear to be active in recurrent or persistent fallopian tube carcinomas. These agents include docetaxel, etoposide, topotecan, gemcitabine, and liposomally encapsulated doxorubicin ([491–495]). As data on well-staged lesions are scarce, it is unclear whether patients with disease confined to the fallopian tube (i.e., a stage IA, grade 1 or 2 carcinoma) benefit from additional therapy.
Prognosis

The overall 5-year survival for patients with epithelial tubal carcinomas is about 40%. This number is higher than for patients with ovarian cancer and reflects the somewhat higher proportion of patients diagnosed with early-stage disease. These data may reflect the fact that some advanced stage tubal cancers were classified as ovarian cancers. The reported 5-year survival rate for patients with stage I disease is only about 65%. The 5-year survival rate for patients with stage II disease is 50% to 60%, but it is only 10% to 20% for patients with stages III and IV disease (480,485).
Tubal Sarcomas

Tubal sarcomas, particularly malignant mixed mesodermal tumors, are described, but rare. They occur mainly in the sixth decade and typically are advanced at the time of diagnosis. If all gross disease can be resected, platinum-based combination chemotherapy should be tried. Survival is poor, and most patients die of their disease within 2 years (2,450).

Vulvar lesions require biopsy to avoid delay in diagnosis.
The modern approach to patients with vulvar cancer is multidisciplinary and individualized.
Management of the primary lesion and groin nodes is determined separately.
Most T₁, T₂, and early T₃ lesions can be managed with radical local excision.
Large T₃ and T₄ primary tumors are best treated with chemoradiation followed by more
limited surgical resection.
When groin dissection is indicated, it should be a thorough inguinofemoral
lymphadenectomy.
The potential role of the sentinel lymph node procedure to eliminate the need of a
complete inguinofemoral lymphadenectomy is being investigated.
The single most important prognostic factor is lymph node status: 5-year survival without
groin node metastases is greater than 90%; with groin node metastases 5-year survival is 50%.
Postoperative radiation decreases the risk of groin recurrence in patients with multiple
positive inguinofemoral lymph nodes.
Recurrence in the groin is almost universally fatal.

With 3,900 new cases and 920 deaths annually in the United States, vulvar cancer
is uncommon, representing about 4% of malignancies of the female genital tract and
0.6% of all cancers in women (1,2). Squamous cell carcinomas account for about 90% of
all primary vulvar malignancies, whereas melanomas, adenocarcinomas, basal cell
carcinomas, and sarcomas are less common. The incidence of in situ vulvar cancer is increasing worldwide, primarily because of the increasing occurrence in
young women, who account for 75% of the cases. The overall rate of invasive vulvar carcinoma is increasing, but at a much lower rate (3,4). In women younger
than 50 years, there is a striking increase in the incidence of in situ and invasive
squamous cell carcinoma of the vulva (5).

Following the reports of Taussig in the United States and Way in Great Britain, radical vulvectomy and en bloc groin dissection, with or without pelvic lymphadenectomy, was standard treatment for all patients with operable disease (6,7). Postoperative morbidity was high and prolonged hospitalization common. During the past 25 years, there were significant advances in the management of vulvar cancer, reflecting a paradigm shift toward a more conservative surgical approach without compromised survival and with markedly decreased physical and psychological morbidity:

Individualization of treatment for all patients with invasive disease
Vulvar conservation for patients with unifocal tumors and an otherwise normal vulva
Omission of the groin dissection for patients with microinvasive tumors (T1a, ≤2 cm diameter and ≤1 mm of stromal invasion)
Elimination of routine pelvic lymphadenectomy
The role of the sentinel lymph node procedure to eliminate requirement for complete inguinofemoral lymphadenectomy is being investigated
The use of separate incisions for the groin dissection to improve wound healing
Omission of the contralateral groin dissection in patients with lateral T1 lesions and negative ipsilateral nodes
The use of preoperative radiation therapy to obviate the need for exenteration in patients with advanced disease
The use of postoperative radiation therapy to decrease the incidence of groin recurrence in patients with multiple positive groin nodes
Etiology

The etiology of vulvar cancer is only partially elucidated and likely to be multifactorial. Reported risk factors for vulvar cancer include human papillomavirus (HPV) infection, vulvar intraepithelial neoplasia (VIN), cervical intraepithelial neoplasia (CIN), lichen sclerosus, squamous hyperplasia, cigarette smoking, alcohol consumption, immunosuppression, a prior history of cervical cancer, and northern European ancestry (8,9). Based on histopathologic and environmental factors, there appear to be at least two distinct etiologic entities of squamous cell carcinoma of the vulva:

Basaloid or warty types, which tend to be multifocal, occur generally in younger patients and are related to HPV infection, VIN, and cigarette smoking.

Keratinizing, differentiated, or simplex types, which tend to be unifocal, occur predominantly in older patients, are not related to HPV, and often are found in areas adjacent to lichen sclerosus and squamous hyperplasia.

High-grade vulvar intraepithelial neoplasia (VIN 3) was closely studied as a potential precancerous lesion. The direct progression of VIN to cancer is difficult to document, but a review of 3,322 published patients with VIN 3 reports a 9% progression rate to cancer for untreated cases (10). VIN is found adjacent to basaloid or warty vulvar squamous cell carcinomas in more than 80% of cases and 10% to 20% of vulvar carcinoma in situ lesions harbor an occult invasive component (11,12). HPV DNA is documented in 89% of patients with VIN 3, in 60% of vulvar cancers overall, and in up to 86% of warty or basaloid type carcinomas of the vulva; but it occurs in less than 10% of the keratinizing type of carcinomas of the vulva (13). HPV 16 and 33 are the prevalent subtypes, accounting for 55.5% of all HPV-related vulvar cancers (14). Epidemiologic risk factors for the basaloid or warty type squamous cell carcinoma of the vulva are similar to those for cervical cancer and include a history of multiple lower genital tract neoplasias, immunosuppression, and smoking (13,15).

Frequently implied as an etiologic variable for the keratinizing carcinoma is the itch-scratch cycle associated with lichen sclerosus and squamous hyperplasia, with atypical changes occurring in the repaired epithelium. Differentiated (or simplex) VIN is a precursor to squamous cell carcinoma and is associated with lichen sclerosus. In keratinizing carcinoma, associated lichen sclerosus or squamous hyperplasia is found in more than 80% of patients (16,17). Women with vulvar lichen sclerosus are at increased risk of developing invasive squamous cell cancer of the vulva, reported at 2.5% to 7.2% with a median follow-up of 4.7 to 6.2 years (18–20). Supportive evidence that some of these lesions could be precancerous comes from molecular studies that demonstrate aneuploid DNA content, p53 overexpression, high Ki67 expression, indicating high proliferation indices and monoclonal expansion of keratinocytes in lichen sclerosus and associated squamous hyperplasia (21–23). An area of active research explores whether treatment of lichen sclerosus with superpotent topical steroids can impact the malignancy risk (18–20). Some studies reported vulvar cancer to be more common in patients who are obese, have hypertension and diabetes mellitus, or are nulliparous, but
a case-control study of vulvar cancer did not confirm any of these as risk factors (15, 24, 25).
Types of Invasive Vulvar Cancer

The histologic subtypes of invasive vulvar cancer are shown in Table 38.1.

Squamous Cell Carcinoma

Approximately 90% to 92% of all invasive vulvar cancers are of the squamous cell type. Squamous carcinomas of the vulva can be divided into distinct histologic subtypes designated as basaloid carcinoma, warty carcinoma, and keratinizing squamous carcinoma (16). Mitoses are noted in these malignancies, but atypical keratinization is the histologic hallmark of invasive vulvar cancer (26). Most vulvar squamous carcinomas reveal keratinization (Fig. 38.1). Histologic features that correlate with the occurrence of inguinal lymph node metastasis are lymph–vascular space invasion, tumor thickness, depth of stromal invasion, histologic pattern of invasion (spray and stellate versus broad and pushing), and increased amount of keratin (27–30).

Figure 38.1 Squamous cell carcinoma of the vulva, keratinizing type. The multiple pearl formations consist of laminated keratin.

Microinvasive carcinoma of the vulva (T1a) is defined as a lesion 2 cm or less in diameter with 1 mm or less stromal invasion (31). Depth of stromal invasion is measured vertically from the epithelial–stromal junction (basement membrane) of the adjacent most superficial dermal papilla to the deepest point of tumor invasion (Fig. 38.2). When the tumor invades 1 mm or less, metastasis to the inguinal lymph nodes is extremely rare among reported series. When invasion is greater than 1 mm, there is a significant risk of inguinal lymph node metastasis.

Figure 38.2 Early invasive carcinoma of vulva originating from vulvar intraepithelial neoplasia. An irregular nest of malignant cells extend from the base of rete pegs. Desmoplastic stromal reaction and chronic inflammation are useful diagnostic signs of stromal invasion. The depth of stromal invasion is measured from the base of the most superficial dermal papilla vertically to the deepest tumor cells.
Clinical Features

Squamous cell carcinoma of the vulva is predominantly a disease of postmenopausal women. The mean age at diagnosis is about 65 years and 15% of patients who develop vulvar cancer do so before age 40. There may be a longstanding history of an associated vulvar intraepithelial disorder, such as lichen sclerosus, squamous hyperplasia, or VIN. As many as 27% of patients with vulvar cancer have a second primary malignancy (32–34). Based on data from the National Cancer Institute’s Surveillance Epidemiology and End Results (SEER) program, patients with invasive vulvar cancer have an increased risk of 1.3% for developing a subsequent cancer. Most of the excess second cancers were smoking related (e.g., cancers of the lung, buccal cavity and pharynx, esophagus, nasal cavity, and larynx) or related to infection with human papillomavirus (e.g., cervix, vulva, vagina, and anus) (35).

Most patients are asymptomatic at the time of diagnosis. If symptoms exist, vulvar pruritus, a lump, or a mass are the most common findings. Less frequent symptoms include a bleeding or ulcerative lesion, discharge, pain, or dysuria. Occasionally, a large metastatic mass in the groin is the initial symptom.

A careful inspection of the vulva should be part of every gynecologic examination. On physical examination, vulvar carcinoma is usually raised and may be fleshy, ulcerated, plaquelike or warty in appearance. It may be pigmented, red or white, and tender or painless. The lesion may be clinically indistinct, especially in the presence of VIN or vulvar dystrophies (12). Any lesion of the vulva warrants a biopsy.

Most squamous carcinomas of the vulva occur on the labia majora and minora (60%), but the clitoris (15%) and perineum (10%) may be primary sites. Approximately 10% of the cases are too extensive to determine a site of origin, and
about 5% of the cases are multifocal.

As part of the clinical evaluation, a careful assessment of the extent of the lesion, including whether it is unifocal or multifocal, should be performed. The groin lymph nodes should be evaluated carefully, and a complete pelvic examination should be performed. A cytologic sample should be taken from the cervix, and **colposcopy of the cervix and vagina should be performed because of the common association with other squamous intraepithelial or invasive neoplasms of the lower genital tract.**

**Diagnosis**

Diagnosis requires a Keys punch biopsy or wedge biopsy, which can be obtained in the office using local anesthesia. The biopsy must include sufficient underlying dermis to assess for microinvasion.

**Physician delay is a common problem in the diagnosis of vulvar cancer, particularly if the lesion has a warty appearance. Any large or confluent warty lesion requires biopsy before medical or ablative therapy is initiated.**

**Routes of Spread**

Vulvar cancer spreads by the following routes:

- **Direct extension**, to involve adjacent structures such as the vagina, urethra, and anus
- **Lymphatic embolization** to the regional inguinal and femoral lymph nodes
- **Hematogenous spread** to distant sites, including the lungs, liver, and bone.

**Lymphatic metastases may occur early in the disease. Twelve percent of tumors 2 cm in diameter or smaller have regional metastases** (32,36). Initially, spread is usually to the inguinal lymph nodes, which are located between Camper’s fascia and the fascia lata (37). From these superficial groin nodes, the disease spreads to the deep femoral nodes, which are located medial to the femoral vessels (Fig. 38.3). Cloquet’s or Rosenmüller’s node, situated beneath the inguinal ligament, is the most cephalad of the femoral node group. **Metastases to the femoral nodes without involvement of the inguinal nodes is reported** (38–41). A study from the M. D. Anderson Cancer Center reported a 9% groin recurrence rate in 104 patients with vulvar cancer who had negative nodes on superficial inguinal lymphadenectomy at initial surgery, and intraoperative lymphatic mapping studies found the sentinel node deep to the cribriform fascia in 5% to 16% of these cases (42–44).

**Figure 38.3 Inguinal-femoral lymph nodes.** (From Berek JS, Hacker NF. Berek & Hacker’s Gynecologic Oncology, 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010:541, with permission.)
From the inguinal-femoral nodes, the cancer spreads to the pelvic nodes, particularly the external iliac group. Although direct lymphatic pathways from the clitoris and Bartholin gland to the pelvic nodes were described, these channels seem to be of minimal clinical significance (45–47). The lymphatics from either side of the vulva form a rich network of anastomoses along the midline. Lymphatic drainage from the clitoris, anterior labia minora, and perineum is bilateral. Metastases to contralateral lymph nodes in the absence of ipsilateral nodal involvement is very rare (0% to 0.4%) for lateral vulvar tumors that are either 2 cm or less in diameter or with 5 mm or less invasion (36,48).

The overall incidence of inguinal-femoral lymph node metastases is reported to be about 32% (41,43,46–56) (Table 38.2). Metastases to pelvic nodes occur in about 12% of cases. Pelvic nodal metastases are rare (0.6%) in the absence of groin node involvement, but they occur in about 16% of cases with positive groin nodes (Table 38.2). The risk increases to 33% in the presence of clinically suspicious groin nodes and to 40% to 50% if there are three or more pathologically positive inguinal-femoral nodes (33,48,57–60). The incidence of lymph node metastases correlates positively with depth of invasion, as shown in Table 38.3. Hematogenous spread usually occurs late in the course of vulvar cancer and is rare in the absence of lymph node metastases.

**Staging**

Initially, vulvar carcinoma was staged clinically based on tumor size and location, palpable regional lymph node status, and a limited search for distant metastases. The prognostic importance of the lymph node status is significant, but clinical assessment of the lymph nodes has limited accuracy. This led the Cancer Committee of FIGO to introduce a surgical staging system for vulvar cancer in 1988, which underwent several revisions, most recently in 2009, to provide better prognostic discrimination between stages and less heterogeneity within stages (31,61,62) (Table 38.4). The main changes are:

</table>
Lesions ≤2 cm in size, confined to the vulva or perineum and with stromal invasion ≤1 mm,* no nodal metastasis

Lesions >2 cm in size or with stromal invasion >1 mm, confined to the vulva or perineum, with negative nodes

Tumor of any size with extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus) with negative nodes

Tumor of any size with or without extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus) with positive inguino-femoral lymph nodes

(i) with 1 lymph node metastasis (≥5 mm) or (ii) 1–2 lymph node metastasis(es) (<5 mm)

(i) with 2 or more lymph node metastasis (≥5 mm) or (ii) 3 or more lymph node metastases (<5 mm)

with positive nodes with extracapsular spread

Tumor invades other regional (2/3 upper urethra, 2/3 upper vagina), or distant structures

Tumor invades any of the following:

(i) upper urethral and/or vaginal mucosa, bladder mucosa, rectal musosa, or fixed to pelvic bone or (ii) fixed or ulcerated inguino-femoral lymph nodes

Any distant metastasis including pelvic lymph nodes

*The depth of stromal invasion is measured from the epithelial–stromal junction of the adjacent most superficial dermal papilla to the deepest point of invasion.

aTNM Classification: (This table needs to be replaced with the one on the middle of the page 545 in Berek & Hacker, 5th edition)
the vulva or perineum

T1b Tumor of any size with extension to adjacent perineal structures (lower 1/3 of urethra, lower of 1/3 vagina, anal involvement)

T2 Tumor of any size with extension to any of the following: upper 2/3 of urethra, upper 2/3 of vagina, bladder mucosa, rectal mucosa, or fixed to pelvic bone

T3 Tumor of any size with extension to any of the following: upper 2/3 of urethra, upper 2/3 of vagina, bladder mucosa, rectal mucosa, or fixed to pelvic bone

N Regional lymph nodes (femoral and inguinal nodes)

Nx Regional lymph nodes cannot be assessed

N0 No regional lymph node metastases

N1 One or two regional lymph node metastases with the following features:

N1a One or two lymph node metastases each <5 mm

N1b One lymph node metastasis ≥5 mm

N2 Regional lymph node metastases with the following features

N2a ≥3 lymph node metastases, each <5 mm in diameter

N2b ≥2 lymph node metastases ≥5 mm

N[MB2] [MB2] 2c Lymph node metastases with extracapsular spread

N3 Fixed or ulcerated regional lymph node metastasis

M Distant metastasis

M0 No distant metastasis

M1 Distant metastasis (including pelvic lymph node metastasis)

While stage Ia remains unchanged as the only group of patients with a negligible risk of lymph node metastases, former stages I and II have been combined into stage Ib. The new stage II segregates patients whose tumors involve the lower adjacent perineal structures from those with positive lymph nodes. For stages III and IV, the number and morphology of the involved nodes are taken into account and the bilaterality of lymph nodes is discounted.

The new FIGO staging system was validated in 269 patients, 42% of whom were restaged (63). The number of positive nodes negatively correlated with survival, as did the presence of extracapsular growth. This study confirmed Gynecologic Oncology Group (GOG) and SEER data indicating that in patients with negative nodes, tumor size was not predictive of survival (62). This study confirmed reports demonstrating that, when corrected for the number of positive nodes, bilaterality of nodal metastases was not predictive of survival (64–67).

Paralleling the changes to the FIGO staging, the American Joint Committee on Cancer (AJCC) significantly modified the vulvar cancer tumor-node-metastasis (TNM) classification with the release of the 2009 edition of the AJCC Cancer Staging Manual.
Prognosis and Survival

Survival of patients with vulvar cancer correlates with FIGO stage (69). The prognosis for patients with early-stage disease is generally good (Table 38.5). The single most important prognostic factor is lymph node status (54-56,59,70,71). A report from the Mayo Clinic on 330 patients with primary squamous cell carcinoma of the vulva demonstrated a significant correlation between lymph node status and risk of treatment failure, especially in the first 2 years following initial therapy: 44.2% overall recurrence rate with positive versus 17.5% with negative lymph nodes. More than one-third of relapses presented 5 years or more after initial therapy (72). There is a strong negative correlation between the number of positive lymph nodes and survival (Table 38.6). Patients with negative lymph nodes have a 5-year survival rate of over 80%; for patients with positive nodes 5-year survival falls below 50%. The number of positive nodes is of critical importance: Patients with one microscopically positive lymph node have a prognosis similar to those with all negative lymph nodes, whereas patients with three or more positive nodes have a poor prognosis and a 2-year survival rate of 20% (73). The survival rate for patients with positive pelvic nodes is about 11% (74). In addition to the number of nodes involved, the morphology of the positive groin nodes is of prognostic significance. As demonstrated in several studies, significant negative predictors of survival are the size of the nodal metastasis, the proportion of the node replaced by tumor cells, and the presence of any extracapsular spread (62,70,75,76). Histologic grade, tumor thickness, depth of stromal invasion, and lymph–vascular space involvement contribute to the risk of lymph node involvement but are not independent predictors of survival (73).

Treatment
After the pioneering work of Taussig and Way, en bloc radical vulvectomy and bilateral dissection of the groin and pelvic nodes were the standard treatment for most patients with operable vulvar cancer (6,7). When the disease involved the anus, rectovaginal septum, or proximal urethra, some type of pelvic exenteration was combined with the dissection.

Although the survival rate improved markedly with this aggressive surgical approach, several factors led to modifications of this treatment plan. These factors are summarized as follows:

An increasing proportion of patients present with early-stage disease—up to 50% of patients in many centers have tumors 2 cm in diameter or smaller.

Concerns about the postoperative morbidity and associated long-term hospitalization common with the en bloc radical dissection.

Increasing awareness of the psychosexual consequences of radical vulvectomy.

To individualize the patient’s care and determine the appropriate therapy, it is necessary to independently manage the primary lesion and groin lymph nodes. Before initiation of therapy, all patients should undergo colposcopy of the cervix, vagina, and vulva. Preinvasive (and rarely invasive) lesions may be present at other sites along the lower genital tract.

Management of the Primary Lesion

Microinvasive Vulvar Cancer (T1a)
Tumors 2 cm or less in diameter with 1 mm or less invasion are appropriately treated with a wide local excision, which is as effective as radical surgery for the prevention of vulvar recurrences for these tumors (77). The excision should go sufficiently deep into the dermis that depth of invasion is fully assessed.

Early Vulvar Cancer (T1b)
The modern approach to the management of patients with T1b carcinoma of
the vulva should be individualized. There is no standard approach applicable to every patient, and emphasis is on performing the most conservative operation that is consistent with cure of the disease. Radical vulvectomy was considered the standard treatment for primary vulvar lesions, but this operation is associated with significant surgical morbidity and disturbances of sexual function and body image. Psychosexual sequelae are a major long-term morbidity associated with the treatment of vulvar cancer (37). One study reported that sexual arousal was reduced to the eighth percentile and body image was reduced to the fourth percentile for women who had undergone vulvectomy when compared with healthy adult women (66). Traditionally, the concern was that without an en bloc resection of vulva and groin nodes, intervening tissue left between the primary tumor and the regional lymph nodes contained microscopic tumor foci in draining lymphatics. Experience with a separate incision technique for node dissection confirmed that metastases rarely occur in the skin bridge in patients without clinically suspicious nodes in the groin (78).

During the past 20 years, several investigators advocated a radical local excision rather than a radical vulvectomy for the primary lesion for patients with T\textsubscript{1b} tumors (37,49,79,80). Regardless of whether a radical vulvectomy or a radical local excision is performed, the surgical margins adjacent to the tumor are the same. An analysis of the literature indicates that the incidence of local invasive recurrence after radical local excision or radical hemivulvectomy is not higher than that after radical vulvectomy (36,49,74,81–83). This finding suggests that in the presence of an otherwise normal-appearing vulva, radical local excision is a safe surgical option, regardless of the size of the tumor or the depth of invasion. Based on cumulative data of 413 patients reported in four studies, an 8 mm or greater histopathological resection margin results in a high rate of local disease control (81,84–86). Of the 252 patients whose tumors were resected with margins of 8 mm or greater, 2.4% experienced a local recurrence, compared to 30.3% of the 161 patients whose margins were less than 8 mm. Neither clinical tumor size nor the presence of coexisting benign vulvar pathology correlated with local recurrence. It is important to bear in mind that paraffin-embedded tissue shrinks by about 25%. At the time of radical local excision, at least a 1-cm grossly negative margin, without putting the skin under tension, should be obtained and extended down to the level of the inferior fascia of the urogenital diaphragm.

When vulvar cancer arises in the presence of VIN, vulvar dystrophy, or some nonneoplastic epithelial disorder, treatment is influenced by the patient’s age. Elderly patients who often had many years of chronic itching may not be disturbed by the prospect of a vulvectomy. In younger women, it is desirable to conserve as much of the vulva as possible. Radical local excision should be performed for the invasive disease, and the associated intraepithelial disease should be treated in the manner most appropriate to the patient. For example, topical steroids may be required for lichen sclerosus or squamous hyperplasia, whereas VIN may require superficial local excision with primary closure or laser ablation.

Radical local excision is most appropriate for lesions on the lateral or posterior
aspects of the vulva (Fig. 38.4). Midline lesions pose special challenges because of their proximity to clitoris, urethra, or anus. For anterior lesions, conservative clitoris-sparing surgery allows for excellent local control as long as pathological margins are at least 8 mm (87). For tumors that involve the clitoris or that are in close proximity to it, any type of surgical excision will have psychosexual consequences. In addition, marked edema of the posterior vulva may occur. For young patients with periclitoral lesions, the primary lesion can be treated with a small field of radiation therapy, possibly with concomitant sensitizing chemotherapy. Small vulvar lesions should respond very well to about 5,000 cGy external radiation, and biopsy can be performed after therapy to confirm the absence of any residual disease (61).

Figure 38.4 Small (T1) vulvar carcinoma at the posterior fourchette. (From Berek JS, Hacker NF. Gynecologic Oncology. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010:547, with permission.)

Early T2 Vulvar Cancer
The indications for vulvar conservation can be extended to selected patients with early T2 tumors. The tumor-free margin should be the same, whether or not a radical vulvectomy or a radical local excision is performed. It seems both feasible and desirable to extend the indications for vulvar conservation, particularly for younger patients. Tumors that are suitable for a conservative
resection are those involving the posterior vulva and lower vagina, where preservation of the anus, clitoris, and urethra is feasible.

For patients with more advanced T<sub>2</sub> lesions, management consists of radical vulvectomy and/or chemoradiation therapy, as discussed below. When the disease involves the distal urethra or anus, partial resection of these organs is required. Alternatively, it is often preferable to give preoperative radiation therapy with chemosensitization to allow for a less radical resection (see below).

**Closure of Large Defects**

*After radical local excision, primary closure without tension can be accomplished for smaller defects. If an extensive dissection is required to treat a large primary lesion, a number of options are available to repair the defect:*

- An area may be left open to granulate, which it will usually do over a period of 6 to 8 weeks (88).
- Full-thickness skin flaps may be devised (89–92). The rhomboid flap is best suited to covering large defects of the posterior vulva, whereas for lateral defects, a mons pubis pedicle flap is advocated (89,92).
- Myocutaneous flaps may be developed to cover the defect. Unilateral or bilateral gracilis myocutaneous grafts are useful when an extensive area from the mons pubis to the perianal area was resected. Because the graft brings a new blood supply to the area, it is particularly applicable if the vulva is poorly vascularized from prior surgical resection or radiation (93).
- If extensive defects exist in the groin and vulva, the tensor fascia lata myocutaneous graft may be the most applicable (94).

**Advanced Disease: Large T<sub>2</sub> and T<sub>3</sub> Primary Tumors**

To achieve primary surgical clearance for tumors involving the upper urethra, anus, rectum, or rectovaginal septum, pelvic exenteration is needed in addition to radical vulvectomy and inguinal-femoral lymphadenectomy, which carries an extremely high physical and psychological morbidity (95,96). Reported 5-year survival rates with this approach are about 50% (97–100). For many of these patients, a combined approach of surgery and radiation therapy offers improved survival and reduced morbidity and is the preferred treatment approach. Numerous small prospective and retrospective series report on the use of external beam radiation, often with concomitant chemotherapy to shrink the primary tumor. Reported initial response rates to chemoradiation are 80% to 90%, and operability is achieved in 63% to 92% of cases (101–108). **It is important that this chemoradiation is followed by a more limited resection of the tumor bed on an individualized basis.** About one-half of the specimens will contain residual tumor, and local relapse rates are as high as 50% to 79% with external radiation alone (with or without concomitant chemotherapy), emphasizing the need for a combined approach that involves radiation and surgery (109–112).
As experience with this combination therapy evolved, it appeared that external beam therapy is appropriate for most cases, with more selective use of brachytherapy. The extensiveness of the surgery is significantly modified. A limited vulvar resection is advocated, and bulky N2 and N3 nodes are resected without full groin lymphadenectomy to avoid the leg edema associated with groin lymphadenectomy and radiation. With this combined radiation-surgical approach, 5-year survival rates as high as 76% are reported (110). With the experience accrued, preoperative radiation, with or without concurrent chemotherapy, is regarded as the first treatment of choice for patients with advanced vulvar cancer who would otherwise require some type of pelvic exenteration or stoma. Neoadjuvant therapy is not justified in patients with tumors that can be adequately treated with primary radical vulvectomy and bilateral groin node dissection.

Management of the Lymph Nodes

Appropriate groin dissection is the single most important factor in decreasing the mortality from early vulvar cancer.

When assessing a patient for groin dissection, the following facts should to be kept in mind:

- The only patients with virtually no risk of lymph node metastases are those whose tumor is small and invades the stroma to 1 mm or less (T\textsubscript{1a}).
- Patients who develop recurrent disease in an undissected groin have a greater than 90% mortality (113).
- Based on the laterality of the vulvar lesions and the status of the ipsilateral groin, an ipsilateral or bilateral lymphadenectomy becomes necessary.

Groin dissection is associated with postoperative wound infection and breakdown. Although the incidence of wound breakdown is reduced significantly when separate incisions are used for the groin dissection, lymphocyst formation and chronic leg edema remain a major problem (Fig. 38.5) (78).

**Figure 38.5** Skin incision for groin dissection through a separate incision. A line is drawn 1 cm above and parallel to the groin crease, and a narrow ellipse of skin is removed. (Revised from Berek JS, Hacker NF. Practical Gynecologic Oncology. 2nd ed. Baltimore, MD: Williams & Wilkins, 1994:418, with permission.)
All patients whose tumors demonstrate more than 1 mm of stromal invasion or whose tumors are larger than 2 cm (T\textsubscript{1b} and above) require inguinal-femoral lymphadenectomy. If there is any question regarding the need for inguinofemoral lymphadenectomy, a Keys biopsy or wedge biopsy of the primary tumor should be obtained, and the depth of invasion should be determined. If it is smaller than 1 mm on the wedge biopsy specimen, the entire lesion should be locally excised and analyzed histologically to determine the depth of invasion. If the lesion is 2 cm in diameter or smaller and there is no invasive focus larger than 1 mm, groin dissection may be omitted, provided there is no lymph–vascular space invasion and there are no clinically suspicious groin lymph nodes. An occasional patient with less than 1 mm of stromal invasion has documented groin node metastases, but the incidence is so low that it is of no practical significance (114,115).

Inguinal-Femoral Lymphadenectomy

If groin dissection is indicated in patients with vulvar cancer, it should be a thorough inguinal-femoral lymphadenectomy. The GOG reported six groin recurrences among 121 patients with tumors 2 cm or less after a superficial (inguinal) dissection, although the removed inguinal nodes were negative, and a study from the M. D. Anderson Cancer Center reported a 9% groin recurrence rate in 104 patients with vulvar cancer and negative nodes on superficial inguinal lymphadenectomy (41,42). Whether all of these recurrences were in the femoral nodes is unclear, but both studies indicate that an incomplete groin dissection will increase the number of groin recurrences and mortality. GOG data indicate that radiation therapy cannot substitute for groin dissection followed by selective radiation as indicated, even in patients with clinically nonsuspicious lymph nodes (116). This GOG study was closed early because a significantly higher incidence of recurrences occurred in women who were receiving groin radiation therapy only (19% versus 0%). The dose of radiation was 5,000 cGy given in
daily 200-cGy fractions to a depth of 3 cm below the anterior skin surface. Although the radiation regimen prescribed was criticized extensively, other uncontrolled studies give no evidence for better groin control with radiotherapy (117,118). Surgery remains the treatment of choice for the groin for women with vulvar cancer.

**Unilateral versus Bilateral Groin Dissection**

It is not necessary to perform a bilateral groin dissection if the primary lesion is unilateral and the ipsilateral lymph nodes are negative. In a patient with a unilateral lesion and negative ipsilateral groin nodes, the risk of contralateral lymph node metastasis is very low (36,48). In a study from the Mayo Clinic, 8 of 163 patients with unilateral vulvar cancers (4.8%) had bilateral lymph node metastases and only 3 (1.8%) had isolated contralateral lymph node metastases. None of the patients with unilateral vulvar lesions that were either 2 cm or less or had 5 mm or less depth of invasion had bilateral groin node involvement at diagnosis (48). There is an increase in the risk of contralateral nodal involvement proportional to the number of positive ipsilateral inguinal nodes (60,48). It is recommended that patients with any bulky or multiple microscopically positive ipsilateral groin lymph nodes undergo contralateral inguinal-femoral lymphadenectomy. Bilateral inguinal-femoral lymphadenectomy should be performed for midline lesions (clitoris, anterior labia minora, posterior fourchette) or those within 2 cm of the midline because of the more frequent contralateral lymph flow from these regions (119).

**Management of Bulky Groin Nodes**

All clinically or radiologically suspicious groin nodes should be resected. If nodal metastasis is confirmed by frozen section, the question arises whether a full inguinofemoral lymphadenectomy may be safely omitted to decrease morbidity without compromising survival. One small, retrospective, multi-institutional study suggests that targeted nodal debulking compared with full lymphadenectomy does not jeopardize survival when both are followed by groin and pelvic radiation (120). Patients with fixed, unresectable groin nodes should be treated with primary chemoradiation. If there is no other evidence of metastatic disease following chemoradiation, GOG data suggest that it may be appropriate to resect the residual nodes (121).

**Management of Pelvic Lymph Nodes**

In the past, pelvic lymphadenectomy was part of the routine surgery for invasive vulvar cancer. The incidence of pelvic lymph node metastasis is rare in the absence of groin node involvement, and a more selective approach is preferred (Table 38.2). Patients most prone to pelvic lymph node metastasis are those with three or more pathologically positive groin nodes (33,45,57,122). In addition to the number of nodes involved, the morphology of the positive groin nodes is of prognostic significance. As demonstrated in several studies, significant negative predictors of survival are the number of positive nodes, the size of the nodal metastasis, the proportion of the node replaced by tumor.
cells, and the presence of any extracapsular spread (65,70,75,76). In these patients, the pelvis requires treatment by radiation (discussed below). **If a preoperative pelvic imaging study reveals bulky pelvic lymph nodes, resection of these nodes should be performed via an extraperitoneal approach prior to radiation because of the limited ability of external beam radiation therapy to sterilize bulky positive pelvic nodes.**

**Sentinel Lymph Node Studies**

Considerable investigation was conducted regarding the use of intraoperative lymphatic mapping using lymphoscintigraphy with technetium-99m-labeled nanocolloid or isosulfan blue dye to identify a sentinel node that would predict the presence or absence of regional nodal metastases (43,123–125). A systematic review of 29 small studies of 961 groins found lymphoscintigraphy to be the most accurate technique, with a pooled sensitivity and negative likelihood ratio of 97% and 0.12, respectively (126). Studies suggested that a sentinel node could be identified in most patients (127–129). A GOG study of 403 evaluable patients in whom 697 groins were assessed demonstrated that a sentinel node was successfully identified in 78.8% (67 of 85) of patients using blue dye only and in 96.2% (306 of 318) using combination of radiolocalization and blue dye, demonstrating the superiority of the combination of blue dye and radiocolloid over blue dye alone for sentinel node identification (130). The sensitivity of the sentinel node assessment is enhanced by ultrastaging using serial sectioning or immunohistochemistry to detect micrometastases (129,131–133).

The strong interest in the sentinel node concept lies in the desire to reduce the significant lifelong morbidity of lymphedema associated with a thorough inguinofemoral lymphadenectomy. Reliable identification of the sentinel node and forgoing full lymphadenectomy in patients with clinically nonsuspicious groin lymph nodes and a negative sentinel node may significantly reduce the number of patients who undergo unnecessary, extensive lymphadenectomy in the absence of disease. This is contingent upon a negative sentinel lymph node reliably predicting the absence of any other nodal metastases given the greater than 90% mortality associated with a groin recurrence.

The largest study published to date on the safety of the sentinel node procedure in vulvar cancer, GROINSS-V, included 403 assessable patients with a sentinel node procedure performed in 623 groins (Table 38.2) (129). Metastatic sentinel nodes were found in 26% of patients. In eight of 276 patients (3%) groin recurrences were diagnosed at a median follow-up time of 35 months. At the time of groin recurrence these patients all underwent bilateral inguinofemoral lymphadenectomy followed by chemoradiotherapy; six of the eight patients died of disease.

False-negative sentinel nodes were reported by others, but were thought to occur with low incidence in patients with clinically nonsuspicious nodes (44,134,135). Two recent studies of sentinel nodes in vulvar cancer, one single institution study of 56 patients and one multi-institution study of 127 patients with inclusion criteria similar to those in GROINSS-V, showed an unexpectedly high false-negative rate (27% and 7.7%, respectively).
respectively), some of which may be attributable to insufficient experience of low-volume providers (128,136). This highlights one of the key concerns that any wide implantation of the sentinel node procedure beyond select expert centers might carry with it an unjustifiable rise in the frequency of groin recurrences.

The 2008 International Sentinel Node Society’s expert panel statement stresses the importance of a well-informed patient treated by a skilled multidisciplinary team of a gynecologic oncologist, a nuclear medicine specialist, and a pathologist with expertise in the sentinel lymph node technique (137). They recommended the following eligibility criteria for the performance of the sentinel node procedure: unifocal primary tumor of 4 cm or less in diameter with greater than 1 mm invasion; and absence of any obvious metastatic disease on physical examination or imaging studies, including the absence of suspicious groin nodes. Until data from prospective randomized controlled trials document comparable survival for patients undergoing the sentinel node procedure compared to full inguinofemoral lymphadenectomy, complete inguinofemoral lymphadenectomy remains indicated in all but stage Ia disease, given the high mortality of recurrence in an undissected groin. The sentinel node technique should be limited to carefully selected patients in expert centers, ideally on research protocols.

Postoperative Management

Despite the age and general medical condition of many elderly patients with vulvar cancer, surgery is usually remarkably well tolerated. Patients should be able to commence eating a low-residue diet on the first postoperative day. In the past, bed rest was advised for 3 to 5 days postoperatively to allow for immobilization of the wounds and to foster healing. Because radical local excisions are being performed with increasing frequency and groin lymphadenectomy is done through separate incisions, patients begin ambulation on postoperative day 1 or 2. Pneumatic calf compression or subcutaneous heparin should be given to help prevent deep venous thrombosis, and active leg movements are to be encouraged. Frequent dressing changes are performed to keep the vulvar wound dry. Meticulous perineal hygiene is maintained. Suction drainage of each side of the groin is continued until output is minimal to help decrease the incidence of groin seromas. It is not uncommon for suction drainage to continue for 10 or more days. The Foley catheter is removed when the patient is ambulatory. If there is significant periurethral swelling, prolonged bladder drainage may be advisable. If there is breakdown of the vulvar wound, sitz baths or whirlpool therapy is helpful, followed by drying of the perineum with a hair dryer.

Early Postoperative Complications

The major immediate morbidity is related to groin wound infection, necrosis, and breakdown. This complication is reported in as many as 53% to 85% of patients having an en bloc operation (32,33). With the separate-incision approach, the incidence of wound breakdown can be reduced to about 44%; major breakdown occurs in about 14% of patients (34,78,138,139). With appropriate antibiotics, debridement, and
wound dressings, the area will granulate and re-epithelialize over several weeks and may be managed with home nursing. Whirlpool therapy is effective for areas of extensive breakdown. The most common complications with the separate incision approach continues to be wound infection requiring antibiotic therapy and lymphocyst formation, both reported in about 40% of cases (139). Symptomatic lymphocysts should be managed by periodic sterile aspiration.

Other early postoperative complications include urinary tract infection, seromas in the femoral triangle, deep venous thrombosis, pulmonary embolism, myocardial infarction, hemorrhage, and, rarely, osteitis pubis. Anesthesia of the anterior thigh resulting from femoral nerve injury is common and usually resolves slowly.

Late Complications

One major late complication is chronic lymphedema, which occurs in about 30% of patients (32–34,138–140). Recurrent lymphangitis or cellulitis of the leg develops in about 10% of patients and usually responds to oral antibiotics. Urinary stress incontinence, with or without genital prolapse, occurs in about 10% of patients after radical vulvectomy and may require corrective surgery. Introital stenosis can lead to dyspareunia and may require a vertical relaxing incision, which is sutured transversely. An uncommon late complication is femoral hernia, which can be prevented intraoperatively by closure of the femoral canal with a suture from the inguinal ligament to Cooper's ligament. Pubic osteomyelitis and rectovaginal or rectoperineal fistulas are rare late complications.

Other major long-term treatment complications associated with the extent of vulvar surgery include depression, altered body image, and sexual dysfunction (96,97). Modifications in the radical extent of the surgical approach and appropriate preoperative and postoperative counseling may help lessen some of the psychological trauma.

Role of Radiation Therapy

Radiation therapy traditionally had a limited role in the management of patients with vulvar cancer. In the orthovoltage era, local tissue tolerance was poor and vulvar necrosis was common, but with megavoltage therapy, tolerance improved significantly. Radiation therapy, frequently with concurrent chemotherapy, has an increasingly important role in the management of patients with vulvar cancer. It is important to remember that, with a rare exception, radiation therapy alone has little place in the primary management of vulvar cancer. It is indicated in conjunction with surgery.

The indications for radiation therapy for patients with primary vulvar cancer are evolving. Radiation seems to be indicated in the following situations:

Preoperatively, in patients with advanced disease who would otherwise require pelvic exenteration or suffer loss of anal or urethral sphincteric function.
Preoperatively, in patients with fixed, unresectable groin nodes (141)
Postoperatively, to treat the pelvic lymph nodes and groins of patients with multiple microscopically positive groin nodes, one or more macrometastasis (10 mm or larger), or any evidence of extracapsular spread.

Possible roles for radiation therapy include the following:

Postoperatively, to help prevent local recurrences in patients with involved or close surgical margins (141–143)

As primary therapy for patients with small primary tumors, particularly clitoral or periclitoral lesions in young and middle-aged women, for whom surgical resection would have significant psychological consequences (80).

No additional treatment is recommended if one microscopically positive groin node (5 mm or less tumor deposit) is found in a fully dissected groin. The prognosis for this group of patients is excellent, and only careful observation is required (57). If unilateral groin dissection was performed for a lateral lesion, there seems to be no indication for dissection of the other side, because contralateral lymph node involvement is likely only if there are multiple microscopic or any gross ipsilateral inguinal node metastases (57,60).

For patients with a single groin node metastasis, a recent retrospective SEER database review suggests that adjuvant radiation may provide a therapeutic benefit, especially if the groin dissection was limited (144).

**If clinically evident groin metastases (any extracapsular spread or two or more microscopically positive groin nodes) are found, the patient is at increased risk of groin and pelvic recurrence and should receive postoperative groin and pelvic irradiation.** In 1977, the GOG initiated a prospective trial in which patients with positive groin nodes were randomized to either ipsilateral pelvic node dissection or bilateral pelvic plus groin irradiation (60). The survival rate for the radiation group (68% at 2 years) was significantly better than the survival rate for the pelvic lymphadenectomy group (54% at 2 years) \((p = 0.03)\). The survival advantage was limited to patients with clinically evident groin nodes or more than one microscopically positive groin node. Groin recurrence occurred in 3 of 59 patients (5%) treated with radiation, compared with 13 of 55 (23.6%) patients treated with lymphadenectomy \((p = 0.02)\). Four patients who received radiation had a pelvic recurrence, compared with one who had lymphadenectomy. These data indicate no benefit from pelvic irradiation compared with pelvic lymphadenectomy for the prevention of pelvic recurrence, but they do highlight the value of groin irradiation in preventing groin recurrence in patients with multiple positive groin nodes.

**Recurrent Vulvar Cancer**

Recurrence of vulvar cancer correlates closely with the number of positive groin nodes (57). Patients with fewer than three positive nodes, particularly if the nodes are only microscopically involved, have a low incidence of recurrence at any site, whereas patients with three or more positive nodes have a high incidence of local, regional, and systemic recurrences (57,60).
Most recurrences of vulvar cancer occur within the first 2 years from initial therapy, with groin recurrences occurring sooner (median time to recurrence 6 to 7 months) than vulvar recurrences (median time to recurrence 3 years) \((72,145–147)\). About one-third of vulvar cancer relapses present 5 or more years after initial therapy \((72)\). In a long-term follow-up study at the Mayo Clinic, nearly 1 in 10 patients with vulvar cancer had a late (longer than 5 years) reoccurrence of disease \((72)\). Over 95% of those late relapses had local reoccurrences (same site recurrence or second primary vulvar site). Because of this propensity for late local reoccurrence, regular and long-term careful examinations of the vulva and groin constitute the cornerstone of posttreatment surveillance for these patients.

The published literature on the management and outcome of recurrent disease is limited. The timing and primary site of recurrence is critical to the prognosis postrecurrence. Although groin recurrences tend to occur early and are nearly always fatal, 5-year overall survival rates of 50% to 70% are reported for patients with surgically treated isolated vulvar recurrences and more than 60% of patients with local recurrence or reoccurrence were alive at 20 years in the Mayo Clinic long-term follow-up study \((72,147,148)\).

**Local Recurrence**

Margin status at the time of radical resection of the vulvar cancer is the most powerful predictor of local vulvar recurrence, with an almost 50% recurrence risk with margins closer than 0.8 cm \((84)\). Margin status does not predict survival \((71)\). Local vulvar recurrences are likely in patients with primary lesions larger than 4 cm in diameter, especially if lymph–vascular space invasion is present, and in patients with deeply invasive tumors \((141,149,150)\). When detected early, isolated local failure is usually treatable by additional surgical therapy, often with a myocutaneous graft to cover the defect \((34,41,49,78,151)\). Radiation therapy, particularly a combination of external beam therapy plus interstitial needles, at times combined with chemotherapy, is used to treat vulvar recurrences \((152)\).

Three distinct patterns of local recurrence were described: remote vulvar recurrence (greater than 2 cm of the primary tumor site), primary tumor site recurrence (within 2 cm of the primary tumor site), and skin bridge recurrence \((81,150)\). Although reported treatment rates are excellent for remote site recurrences with 3-year survival rates of 67% to 100%, the literature is controversial as to the prognostic significance of primary tumor site recurrences, with one study reporting a 3-year survival rate of only 15% and the other a 5-year survival of 93% \((81,150)\). Patients with skin bridge recurrence have a very poor prognosis, similar to those with groin recurrence.

**Regional and Distant Recurrence**

Regional and distant recurrences are difficult to manage and are associated with a poor prognosis \((141,145,146)\). Radiation therapy may be used in conjunction with surgery for groin recurrence, whereas chemotherapeutic agents that have activity against squamous carcinomas may be offered for distant metastases. The literature on
the use of chemotherapy for recurrent vulvar cancer consists mainly of small series. The most extensively studied regimens contain bleomycin, methotrexate, and lomustine (a nitrosourea); bleomycin and mitomycin C; or cisplatin, vinorelbine, and paclitaxel, but response rates are low and the duration of response is usually disappointing (153–157). Long-term survival is very uncommon with regional or distant recurrence. Symptom control and quality of life are important treatment goals, and early involvement of a multidisciplinary palliative care team is generally indicated.
Melanoma

Vulvar melanomas are rare, with an incidence of 0.1 to 0.19 per 100,000 women (158,159). They account for 4% to 10% of all cases and are the second most common form of vulvar malignancy. Most melanomas arise de novo, but they may arise from a preexisting junctional nevus (160). Vulvar melanomas occur most frequently in postmenopausal white women, but are commonly seen in individuals with darker pigmented skin. Contrary to cutaneous melanoma, based on SEER data, there are low racial differences in vulvar melanomas, the development of which appears to be determined by factors other than ultraviolet radiation exposure and the photoprotective effects of melanin seen in cutaneous melanoma (161). The incidence of cutaneous melanomas worldwide is increasing significantly, but not that of vulvar melanoma (161). Vulvar melanomas appear to behave in a manner similar to that of other truncal cutaneous melanomas (162–165).

Most patients with vulvar melanoma have no symptoms other than a pigmented lesion that may be enlarging. Some patients have itching or bleeding, and a few have a groin mass. Vulvar melanomas occur most frequently on the labia minora or the clitoris (Fig. 38.6), and extension into the urethra or vagina at discovery is not uncommon. Any pigmented lesion on the vulva should be excised or, if the lesion is large, sampled for biopsy unless it is known to have been present and unchanged for some years. Most vulvar nevi are junctional and may be precursor lesions to melanoma; any nevus of the vulva should be removed.

Figure 38.6 Melanoma of the vulva involving the right labium minus. (From Berek JS, Hacker NF. Berek & Hacker’s Gynecologic Oncology. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010:564, with permission.)
Histopathology

There are three basic histologic types of vulvar melanoma (Fig. 38.7):

**Figure 38.7 Vulvar melanoma.** Spindle-shaped melanoma cells form interlacing bundles, and some contain melanin pigment (right upper corner). Epidermal invasion is evident in the form of Pagetoid migration (left upper corner).

The mucosal lentiginous melanoma is a flat freckle that may become quite extensive but tends to remain superficial.

The superficial spreading melanoma tends to remain relatively superficial early in its development.

The nodular melanoma, which is the most aggressive, is characterized by a raised lesion that penetrates deeply and may metastasize widely.

In one of the largest reported series, more than one-fourth of the cases of melanomas were macroscopically amelanotic (158). Vulvar melanoma tends to spread early, not only lymphatically but also hematogenously.
The FIGO staging used for squamous lesions is not applicable to melanomas because the lesions are usually much smaller and the prognosis is related to the depth of tumor invasion rather than to the diameter of the lesion (162,165,166). The leveling system established by Clark et al. for cutaneous melanomas is less readily applicable to vulvar lesions because of the different skin morphology (166). The vulvar skin lacks a well-defined papillary dermis. Breslow measured the thickest portion of the melanoma from the surface of intact epithelium to the deepest point of invasion (167). This system is more adequate for the vulva. Chung et al. proposed a modified system that retained Clark's definitions for levels I and V but arbitrarily defined levels II, III, and IV, using measurements in millimeters (165). A comparison of these systems is shown in Table 38.7.

The revised 2009 AJCC staging for cutaneous melanoma indicates that tumor thickness remains the primary determinant of the T staging, but mitotic rate was integrated to subcategorize T1 tumors in addition to the presence of ulcerations. Specific immunohistochemistry criteria for the detection of micrometastases were included. The number and volume of metastatic nodes, site(s) of distant metastatic disease, serum lactate dehydrogenase level, and sentinel node results remained part of the staging (168).
Treatment
With better understanding of the prognostic significance of the microstage, some individualization of treatment developed. Treatment of vulvar melanoma continues to be controversial, in part because of the lack of large prospective studies, which makes it difficult to draw conclusions regarding its behavior and best treatment. Treatments are guided by experience from cutaneous melanoma and squamous cell carcinomas of the vulva. Paralleling the trend toward more conservative surgical management of cutaneous melanoma, there is a shift toward more conservative management of vulvar melanoma (163,164,169–171).

It is accepted that lesions with less than 1 mm of invasion may be treated with radical local excision alone (165,172). With more invasive lesions, en bloc resection of the primary tumor and regional groin nodes was traditionally recommended. In the past 15 years, radical vulvectomy was performed less frequently and survival did not seem to be compromised (173). One study reported on 32 patients with vulvar melanoma who underwent local excision (n = 14), simple vulvectomy (n = 7), or radical resection (n = 11) (174). No group had a superior survival rate, although the overall survival rate at 5 years was only 25%. Another study reported on 59 patients who underwent radical vulvectomy and 19 who underwent more conservative resections (163). Survival was not improved by the more radical approach, and they recommended radical local excision for the primary tumor, with groin dissection for tumors with a thickness of more than 1 mm. A recent SEER data analysis of 644 patients with vulvar melanoma did not find a survival difference in patients with localized disease treated with more conservative versus radical surgery. Five-year disease specific survival rates for patients undergoing conservative surgery for localized disease were 75% versus 79% for those undergoing radical surgery (174). Literature on cutaneous melanoma suggests that a 1-cm margin of skin and subcutaneous tissue is sufficient for the treatment of superficial localized melanoma (Breslow tumor thickness <0.76 mm), whereas a 2-cm margin suffices for intermediate-thickness lesions (1 to 4 mm) (175,176). At least a 1-cm tumor-free deep surgical margin is recommended, irrespective of tumor thickness. Because melanomas commonly involve the clitoris and labia minora, the vaginourethral margin of resection is a common site of failure, and care should be taken to obtain an adequate “inner” resection margin (177). A 10-year survival rate of 61% was shown for lateral lesions, compared with 37% for medial lesions (p = 0.027) (149).

Controversy exists as to which patients may benefit from inguinal-femoral lymphadenectomy. A prospective study by the GOG demonstrated that the risk ofinguinal-femoral lymph node metastasis correlated with the Breslow microstage (165). As with cutaneous melanoma, it appears that for superficial lesions (Breslow tumor thickness <0.76 mm), the risk for nodal spread is so low that routine lymphadenectomy is not indicated as long as the nodes appear clinically free of disease. For intermediate-thickness (1 to 4 mm) cutaneous melanoma, a randomized controlled trial of elective lymph node dissection versus observation showed a 5-year survival advantage for patients who underwent elective lymph node dissection, who
were younger than 60 years, and whose tumors were characterized by 1- to 2-mm thickness and no ulcerations (178). Patients with deeply invasive cutaneous melanomas (>4-mm tumor thickness) have a high risk of regional and systemic metastases and are unlikely to benefit from regional lymphadenectomy (179). Given some of the epidemiologic, histologic, and prognostic differences between vulvar and cutaneous melanoma, extrapolation of these data to the vulva should be done with caution (180). Specific to patients with vulvar melanoma, there is a small body of literature to suggest that there may be a clinical benefit in elective groin lymphadenectomy and the resection of clinically positive nodes (162,163). The role of the sentinel lymph node procedure in vulvar melanoma is under investigation. In cutaneous melanoma, sentinel lymph node biopsy replaced elective lymph node dissection in patients with clinically negative nodes, as it provides the same prognostic information with reduced morbidity. Only patients with metastatic disease undergo completion lymphadenectomy. Results from an interim analysis of the Multicenter Selective Lymphadenectomy Trial confirmed the prognostic value of the sentinel node procedure. These data suggest that an immediate completion lymphadenectomy following detection of a positive sentinel lymph node improves survival in patients with regional nodal metastases (181). Studies on the sentinel lymph node procedure for vulvar melanoma are limited. A review of the literature estimates a false-negative rate of about 15% (182). Although the sentinel node procedure appears appropriate for select patients with vulvar melanoma, the importance of an expert team familiar with the procedure and consisting of a gynecologic oncologist, a nuclear medicine specialist, and a pathologist with expertise in microstaging cannot be overemphasized.

Pelvic node metastases do not occur in the absence of groin node metastases (177,183,184). The prognosis for patients with positive pelvic nodes is so poor that there seems to be no value in performing pelvic lymphadenectomy for this disease. Immunotherapy and chemotherapy have demonstrated modest results in cutaneous melanoma. Several randomized cooperative and Intergroup trials of high-risk melanoma patients demonstrated a small but significant improvement in disease-free and overall survival with adjuvant interferon alpha (185–187). Dacarbazine (DTIC) is considered the most active single-agent chemotherapy, with a response rate of 16%, and randomized controlled trials failed to demonstrate superiority of any multiagent regimen (188). Targeted therapy is an area of promising development as single agents, in combination, and combined with chemotherapy. A vaccine stimulating both antibody and T-cell responses against melanoma is a promising but experimental treatment that is under investigation (189). Estrogen receptors were demonstrated in human melanomas, and an occasional response to tamoxifen was reported (190,191). Traditionally, melanomas were thought to be radiation resistant. There is a growing body of literature for advanced, high-risk, lymph node–metastatic cutaneous melanoma, demonstrating improved locoregional disease control compared to surgery with therapeutic lymphadenectomy alone (192,193).
Prognosis

The behavior of melanomas can be unpredictable, but the prognosis is poor. The reported 5-year overall survival rate for vulvar melanoma is in the range of 50% to 60% \(^{(158,159,171)}\). A SEER database analysis showed disease-specific survival rates for patients with localized, regional, and distant disease of 76%, 39%, and 22%, respectively \(^{(171)}\). Localized disease, negative lymph nodes, and younger age were significant independent prognostic factors for improved survival. Because vulvar melanoma has a propensity for late recurrences, 5-year survival may not reflect cure. Prognosis is best predicted by microstaging. Patients with lesions invading to 1 mm or less have a good prognosis, but as depth of invasion increases, the prognosis worsens \((Table 38.8)\). Tumor volume is reported to correlate with prognosis; patients whose lesions have a volume less than 100 mm\(^3\) have an excellent prognosis \(^{(184)}\). Additional prognostic factors are the patient’s age, AJCC stage, presence of multifocal or satellite lesions, tumor ulceration, central tumor location, histologic growth pattern, lymph–vascular space involvement, and aneuploidy \(^{(158,162–164,194–197)}\).

DOD, died of disease.

\(^a\) All but one of these seven deaths were reported in one study with an unusually low 5-year survival of 48% for 12 patients with superficial melanomas of Breslow thickness <0.76 mm. If these 12 cases were excluded, 5% of patients with superficial melanoma of the vulva died of disease.

From references 160, 165, 174, 185, 186, 196–199.
Bartholin Gland Carcinoma

Epidemiology

Primary carcinoma of the Bartholin gland is a rare form of vulvar cancer, which accounts for about 2% to 7% of vulvar malignancies (198). Because of its rarity, individual experience with the tumor is limited, and recommendations for management must be based on the review of small published series. Only about 300 cases are reported (46,198,199). Bartholin gland carcinoma is five times more common in postmenopausal than in premenopausal women (200).
Histopathology

The bilateral Bartholin glands are greater vestibular glands situated posterolaterally in the vulva. Their main duct is lined with stratified squamous epithelium, which changes to transitional epithelium as the terminal ducts are reached. Because tumors may arise from the gland or the duct, a variety of histologic types occur, including adenocarcinomas, squamous carcinomas, and, rarely, transitional cell, adenosquamous, and adenoid cystic carcinomas.

Classification of a vulvar tumor as a Bartholin gland carcinoma typically required that it fulfill Honan’s criteria, which are as follows:

The tumor is in the correct anatomic position
The tumor is located deep in the labium majus
The overlying skin is intact
There is some recognizable normal gland present.

Strict adherence to these criteria results in underdiagnosis of some cases. Large tumors may ulcerate through the overlying skin and obliterate the residual normal gland. Although transition between normal and malignant tissue is the best criterion, some cases will be diagnosed on the basis of their histologic characteristics and anatomic location.
Signs and Symptoms

The most common initial symptom of Bartholin gland carcinoma is a vulvar mass or perineal pain. About 10% of patients have a history of inflammation of the Bartholin gland, and malignancies may be mistaken for benign cysts or abscesses. Delay of diagnosis is common, particularly for premenopausal patients. The differential diagnosis of any pararectovaginal neoplasm should include cloacogenic carcinoma and secondary neoplasm (199).
Treatment

Traditionally, treatment was radical vulvectomy with bilateral groin and pelvic node dissection (201). There seems to be no indication for dissection of the pelvic nodes in the absence of positive groin nodes, and good results were reported with hemivulvectomy or radical local excision for the primary tumor (199). Because these lesions are deep in the vulva, extensive dissection is required in the ischiorectal fossa; surgical margins are often close. Postoperative radiation to the vulva decreased the likelihood of local recurrence from 27% (6 of 22 patients) to 7% (1 of 14 patients) (199). If the ipsilateral groin nodes are positive, bilateral groin and pelvic irradiation may decrease regional recurrence. If the tumor is fixed to the inferior pubic ramus or involves adjacent structures, such as the anal sphincter or rectum, preoperative radiation and chemotherapy is preferable to avoid ultraradical surgery. A recent report of 10 consecutive patients with primary Bartholin gland carcinoma suggests that treatment with radiation or chemoradiation using teletherapy combined with a boost to the primary site or regional nodes and/or interstitial brachytherapy may offer an effective alternative to surgery with 3- and 5-year survival rates of 72% and 66%, respectively (202).
Prognosis

Because of the deep location of the gland, disease tends to be more advanced than squamous carcinomas at the time of diagnosis but, stage for stage, the prognosis is similar. Five-year disease-free survival rates by stage are summarized in Table 38.9.

Adenoid Cystic Carcinoma of the Bartholin Gland

The adenoid cystic variety accounts for 15% of Bartholin gland carcinomas. A review of 62 cases reported in the literature demonstrates that adenoid cystic carcinoma of the Bartholin gland is a slow growing tumor characterized by perineural infiltration and a marked propensity for local relapse preceding distant recurrences by years. It is less likely to metastasize to lymph nodes and carries a somewhat better prognosis (Fig. 38.8) (203–205). The slowly progressive nature of these tumors and the tendency for late recurrences is reflected in the disparity between progression-free interval and overall survival (204).

Figure 38.8 Adenoid cystic tumor of the Bartholin gland. Basaloid cells form cribriform, sievelike spaces containing mucinous material. The hyaline stroma is another distinct feature of this tumor.
Other Adenocarcinomas

Adenocarcinomas of the vulva usually arise in a Bartholin gland or occur in association with Paget disease. They may arise rarely from the skin appendages, paraurethral glands, minor vestibular glands, aberrant breast tissue, endometriosis, or a misplaced cloacal remnant (206).
Adenosquamous Carcinoma

A particularly aggressive type of carcinoma is the adenosquamous carcinoma. This tumor has a number of synonyms, including cylindroma, pseudoglandular squamous cell carcinoma, adenoid squamous cell carcinoma, and adenoacanthoma of the sweat gland of Lever. The tumor has a propensity for perineural invasion, early lymph node metastasis, and local recurrence. One study noted a crude 5-year survival rate of 5.5% (1 of 18) for adenosquamous carcinoma of the vulva, compared with 62.3% (48 of 77) for patients with squamous cell carcinoma (207). Treatment should be radical vulvectomy and bilateral groin dissection. Postoperative radiation therapy may be appropriate.
Basal Cell Carcinoma

**Basal cell carcinomas represent about 2% of vulvar cancers.** As with other basal cell carcinomas, vulvar lesions commonly appear as a “rodent ulcer” with rolled edges, although nodules and macules are other morphologic varieties that occur. Most lesions are smaller than 2 cm in diameter and are usually situated on the anterior labia majora. Giant lesions occasionally occur (208). Basal cell carcinoma usually affects postmenopausal white women and is locally aggressive. Symptoms are frequently present for a prolonged period and most often include pruritus, soreness, and irritation (209). It is diagnosed by biopsy, and **radical local excision is adequate treatment** (210). **Metastasis to regional lymph nodes is reported but is rare** (211–213). The local recurrence rate is about 10% to 20% (209,214). Basal cell carcinoma of the vulva is associated with a high incidence of antecedent or concomitant malignancies elsewhere (209). In a series of 28 women with vulvar basal cell carcinoma, 10 patients had other basal cell carcinomas, and 10 patients suffered from other primary malignancies (209).

**About 3% to 5% of basal cell carcinomas contain a malignant squamous component, the so-called basosquamous carcinoma.** These lesions are more aggressive and should be treated as squamous carcinomas (213). Another subtype of basal cell carcinoma is the adenoid basal cell carcinoma, which must be differentiated from the more aggressive adenoid cystic carcinoma arising in a Bartholin gland or the skin (213).
Verrucous Carcinoma

Verrucous carcinoma is a variant of squamous cell carcinoma and has distinctive clinical and pathologic characteristics (215). Although most commonly found in the oral cavity, verrucous lesions may be found on any moist membrane composed of squamous epithelium (216). In the female genital tract, these lesions may develop on the cervix, vulva, and vagina. The cause of the lesion in the female genital tract is not fully understood, but associated HPV-6 and HPV-11 were found in some studies, whereas others find it to have no association with HPV infection (217,218). Some studies found as many as one-third of the cases to have coexisting squamous carcinoma of the vulva, underscoring the importance of careful histopathologic assessment of these tumors (219).

Grossly, the tumors have a cauliflower-like appearance; microscopically, they contain multiple papillary fronds that lack the central connective tissue core that characterizes condylomata acuminata (Fig. 38.9). The gross and microscopic features of a verrucous carcinoma are very similar to those of the giant condyloma of Buschke-Loewenstein, and they probably represent the same disease entity (206). Adequate biopsy from the base of the lesion is required to differentiate a verrucous carcinoma from a benign condyloma acuminatum or a squamous cell carcinoma with a verrucous growth pattern.

Figure 38.9 Verrucous carcinoma of the vulva. Note the exophytic hyperkeratotic papillary fronds and endophytic bulky rete pegs with smooth borders.

Verrucous carcinomas usually occur in postmenopausal women, and they are
slow-growing but locally destructive lesions. Even bone may be invaded. Metastasis to regional lymph nodes is rare but was reported (220). Radical local excision is the basic treatment, although any palpably suspicious groin nodes should be evaluated with fine-needle aspiration cytology or excisional biopsy. Usually, enlarged nodes will be caused by inflammatory hypertrophy (221). If the nodes contain metastases, radical vulvectomy and bilateral inguinal-femoral lymphadenectomy are indicated.

Several small studies failed to document any therapeutic advantage with radiation therapy (221). There is concern that radiation may induce anaplastic transformation with subsequent regional and distant metastasis (222). One study reported a corrected 5-year survival rate of 94% for 17 patients treated with surgery alone, compared with 42% for 7 patients treated with surgery and radiation (221). The latter patients had more advanced disease. If there is a recurrence, further surgical excision is the treatment of choice, which occasionally may necessitate some type of exenteration.
Vulvar Sarcoma

Sarcomas represent 1.5% of vulvar malignancies and constitute a heterogeneous group of tumors (223). Leiomyosarcomas are the most common, and other histologic types include fibrosarcomas, neurofibrosarcomas, liposarcomas, rhabdomyosarcomas, angiosarcomas, epithelioid sarcomas, and malignant schwannomas.

Leiomyosarcomas usually appear as enlarging, often painful masses, usually in the labium majus. Smooth muscle tumors of the vulva that show at least three of the following four criteria should be regarded as sarcomas: (i) diameter greater than 5 cm, (ii) infiltrating margins, (iii) 5 or more mitotic figures per 10 high-power fields, (iv) moderate-to-severe cytological atypia (224). The absence of one, or even all, of these features does not guarantee against recurrence (225). Lymphatic metastases are uncommon, and radical local excision is the usual treatment.

Epithelioid sarcomas characteristically develop in the soft tissues of the extremities of young adults but rarely may occur on the vulva. In a description of two cases and review of three other reports, the authors concluded that these tumors might mimic a Bartholin cyst, leading to inadequate initial treatment (226). They believed that vulvar epithelioid sarcomas behave more aggressively than their extragenital counterparts, with four of the five patients dying of metastatic disease. They suggested that early recognition and wide excision should improve the prognosis.

Rhabdomyosarcomas are the most common soft tissue sarcomas in childhood, and 20% involve the pelvis or genitourinary tract (227). Dramatic gains were made in the treatment of these tumors during the past 20 years. Previously, radical pelvic surgery was the standard approach, but results were poor. A multimodal approach evolved, and survival rates improved significantly, with a corresponding decrease in morbidity. In a report of the experience of the Intergroup Rhabdomyosarcoma Study I and II (1972 to 1984) with primary tumors of the female genital tract, nine patients aged 1 to 19 years had primary vulvar tumors, and these tumors were often regarded as a form of Bartholin gland infection before biopsy (228). They were all managed with chemotherapy (vincristine, or actinomycin D and cyclophosphamide and doxorubicin), with or without radiotherapy. Wide local excision of the tumor, with or without inguinal-femoral lymphadenectomy, was carried out before or after the chemotherapy. Seven of the nine patients were free of disease 4 or more years from diagnosis, one patient was free of disease when lost to follow-up at 5 years, and one patient was alive with disease.
Rare Vulvar Malignancies
In addition to the previously mentioned tumors, a number of malignancies more commonly seen in other areas of the body may rarely occur as isolated vulvar tumors.
Lymphomas

The genital tract may be involved primarily by malignant lymphomas but, more commonly, involvement is a manifestation of systemic disease. In the lower genital tract, the cervix is most often involved, followed by the vulva and the vagina (229). Most patients are in their third to sixth decades of life, and about three-fourths of the cases involve diffuse large cell or histiocytic non-Hodgkin’s lymphomas. The remainder are nodular or Burkitt’s lymphomas. Treatment is by surgical excision followed by chemotherapy and radiation or both, and the overall 5-year survival rate is about 70% (229).
Endodermal Sinus Tumor
There were four case reports of endodermal sinus tumor of the vulva, and three of the four patients died of distant metastases (230). All patients were in their third decade of life, but none was treated with modern chemotherapy.
Merkel Cell Carcinoma

Merkel cell carcinomas are primary small cell carcinomas of the skin that resemble oat cell carcinomas of the lung. They metastasize widely and have a very poor prognosis (231–233). They should be locally excised and treated with cisplatin-based chemotherapy.
Dermatofibrosarcoma Protuberans

This rare, low-grade cutaneous malignancy occasionally involves the vulva. It has a marked tendency for local recurrence but a low risk of systemic spread (234). Radical local excision should be sufficient treatment.
Eight percent of vulvar tumors are metastatic. The most common primary site is the cervix, followed by the endometrium, kidney, and urethra. Most patients in whom vulvar metastases develop have advanced primary tumors when diagnosed, and in about one-fourth of the patients, the primary lesion and the vulvar metastasis are diagnosed simultaneously (235).

Complete molar pregnancies are generally diploid and all chromosomes are of paternal origin.
Partial molar pregnancies are triploid and the extra set of chromosomes is paternal.
Complete moles are diagnosed earlier in pregnancy and less frequently present with the classic signs and symptoms.
Single-agent chemotherapy achieves a high remission rate in nonmetastatic and low-risk metastatic gestational trophoblastic neoplasia.
After achieving remission with chemotherapy, patients with gestational trophoblastic neoplasia can anticipate normal reproduction in the future.

Gestational trophoblastic disease (GTD) is the term used to describe the heterogeneous group of interrelated lesions that arise from abnormal proliferation of placental trophoblasts. GTD lesions are histologically distinct and can be benign or malignant. Benign lesions consist of hydatidiform moles, complete and partial, whereas malignant lesions consist of invasive mole, placental-site trophoblastic tumor (PSTT), and choriocarcinoma. This subset of malignant lesions that have varying propensities for local invasion and metastasis is referred to as gestational trophoblastic neoplasia (GTN). GTNs are among the rare human tumors that can be cured even in the presence of widespread dissemination (1,2). Although GTNs commonly follow a molar pregnancy, they can occur after any gestational event, including induced or spontaneous abortion, ectopic pregnancy, or term pregnancy.
Hydatidiform Mole

Epidemiology

Estimates of the incidence of molar pregnancy vary dramatically in different regions of the world. For example, the incidence of molar pregnancy in Japan (2:1,000 pregnancies) is reported to be about threefold higher than the incidence in Europe or North America (about 0.6 to 1.1 per 1,000 pregnancies) (3). In Taiwan, 1 in 125 pregnancies are molar, while in the United States the incidence is 1 in 1,500 live births. The incidences of choriocarcinoma and partial hydatidiform mole in Ireland were investigated by reviewing all products of conception from first- and second-trimester abortions (4). Based on a thorough pathologic review, the incidence of choriocarcinoma and partial hydatidiform mole was 1:1,945 and 1:695 pregnancies, respectively.

While variations in the worldwide incidence of molar pregnancy may result in part from reporting population-based versus hospital-based data, a number of studies suggest that the high incidence in some populations can be attributed to socioeconomic and nutritional factors. The decreasing incidence of molar pregnancy in South Korea is attributed to a more Western diet and improved standard of living (5). Case-control studies from Italy and the United States show that the rate of choriocarcinoma increases with decreasing consumption of dietary carotene (vitamin A precursor) and animal fat (6,7). Maternal age and reproductive history influence the rate of molar pregnancy. Women older the 40 years have a 5- to 10-fold greater risk of having a choriocarcinoma, while one in three pregnancies in women older than 50 years results in a molar gestation (8,9). These findings suggest that ova from older women may be more susceptible to abnormal fertilization, resulting in a complete hydatidiform mole.

Limited information is available concerning risk factors for partial molar pregnancy. The epidemiologic characteristics of complete and partial mole appear to differ significantly (8–11). The risk for partial mole is associated with the use of oral contraceptives and a history of irregular menstruation, but not with dietary factors (10). Nor does there appear to be an association between maternal age and the risk for partial mole.
Pathology and Cytogenetics

Hydatidiform moles may be categorized as either complete or partial moles on the basis of gross morphology, histopathology, and karyotype (Table 39.1).

Complete Hydatidiform Mole

Complete hydatidiform moles exhibit characteristic swelling and trophoblastic hyperplasia (Fig. 39.1). They usually have a 46,XX karyotype, but about 10% have a 46,XY karyotype (12,13). The molar chromosomes are entirely of paternal origin, with mitochondrial DNA of maternal origin (Fig. 39.2) (14). Complete moles usually arise from an ovum fertilized by a haploid sperm, which duplicates its own chromosomes. The ovum nucleus may be absent or inactivated (15).

Figure 39.1 Photomicrograph of complete mole demonstrating enlarged villous with central cavitation and surrounding trophoblastic hyperplasia.

Figure 39.2 The karyotype of complete hydatidiform mole.
Partial Hydatidiform Mole

Partial hydatidiform mole is characterized by the following pathologic features (16) (Fig. 39.3):

Figure 39.3 Photomicrograph of partial mole showing marked disparity in villous size, trophoblastic inclusions (center), and mild trophoblastic hyperplasia. (From Berkowitz RS, Goldstein OP. Gestational trophoblastic diseases. In: Ryan KJ, Berkowitz R, Barbieri R, eds. Kistner’s gynecology principles and practice, 5th ed. Chicago: Year Book Medical Publishers, 1990:433, with permission.)
Chorionic villi of varying size with focal hydatidiform swelling, cavitation, and trophoblastic hyperplasia
Marked villous scalloping
Prominent stromal trophoblastic inclusions
Identifiable embryonic or fetal tissues

Partial moles have a triploid karyotype (69 chromosomes); the extra haploid set of chromosomes usually is derived from the father (Fig. 39.4) (17). It is possible that nontriploid partial moles do not exist (18). When a fetus is present in conjunction with a partial mole, it generally exhibits the stigmata of triploidy, including growth retardation and multiple congenital malformations such as syndactyly and hydrocephaly (Fig. 39.5).

Figure 39.4 The karyotype of partial hydatidiform mole.

Figure 39.5 Photomicrograph of a fetal hand demonstrating syndactyly. The fetus had a triploid karyotype, and the chorionic tissues were a partial mole.
When molar pregnancy is diagnosed early in the first trimester, the pathologist can have difficulty distinguishing complete hydatidiform mole from partial hydatidiform mole or hydropic abortions because of smaller villi, less trophoblastic hyperplasia, more primitive villous stroma, and less global necrosis (19,20). Accurate diagnosis can be facilitated through the use of flow cytometry to determine ploidy (i.e., diploid vs. triploid moles) (21) and through assessment of biomarkers of paternally imprinted and maternally expressed gene products (22). Biomarkers that take advantage of imprinted genes to distinguish complete mole and hydropic abortions from other gestations are identified. Because complete moles generally have no maternal chromosomes, paternally imprinted gene products normally expressed only by maternal chromosomes, should be absent. In complete moles, the nuclei of the villous stroma and cytotrophoblastic cells do not express p57, whereas all other gestations, including partial moles, are characterized by nuclear immunostaining in these cells. Thus, a complete mole is diploid and negative for p57, a hydropic abortion is diploid (sometimes triploid) and positive for p57, and a partial mole is triploid and positive for p57.

Familial Recurrent Molar Pregnancy

Evaluation of families with recurrent molar pregnancy suggests that dysregulation of normal parental imprinting of genes, with loss of maternally transcribed genes, is likely to contribute to the pathogenesis of molar pregnancy. Familial recurrent hydatidiform mole, is a rare occurrence, characterized by recurrent complete hydatidiform mole of biparental origin, rather than the more usual androgenetic origin (23). Genetic mapping shows that in most families the gene responsible is located in a 1.1 Mb region on chromosome 19q13.4. Mutations in the gene result in dysregulation of imprinting in the female germ line with abnormal development of both embryonic and extraembryonic tissue.
Clinical Features

Patients with complete molar pregnancy are diagnosed increasingly earlier in pregnancy and treated before they develop the classic clinical signs and symptoms. This is the result of many changes in clinical practice, such as the frequent use of human chorionic gonadotropin (hCG) measurement and transvaginal ultrasonography in early pregnancy for women with vaginal staining and for determining the gestational dates in asymptomatic women. The following is a description of the classic and current clinical features of complete molar pregnancy (24,25).

Complete Hydatidiform Mole

Vaginal Bleeding

Vaginal bleeding is the most common symptom causing patients to seek treatment for complete molar pregnancy. It had been reported to occur in 97% of cases, whereas currently it is reported to occur in 84% of patients. Molar tissues may separate from the decidua and disrupt maternal vessels, and large volumes of retained blood may distend the endometrial cavity. Because vaginal bleeding may be considerable and prolonged, one-half of these patients had anemia (hemoglobin <10 g/100 mL). Anemia is present in only 5% of patients.

Excessive Uterine Size

Excessive uterine enlargement relative to gestational age is one of the classic signs of a complete mole, although it was present in only about half of patients. Currently, excessive uterine size occurs in only 28% of patients. The endometrial cavity may be expanded by both chorionic tissue and retained blood. Excessive uterine size is generally associated with markedly elevated levels of hCG, because uterine enlargement results in part from trophoblastic overgrowth.

Preeclampsia

Preeclampsia was observed in 27% of patients with a complete hydatidiform mole. Preeclampsia is now reported in only 1 of 74 patients with complete mole at the initial visit. Although preeclampsia is associated with hypertension, proteinuria, and hyperreflexia, eclamptic convulsions rarely occur. Preeclampsia develops almost exclusively in patients with excessive uterine size and markedly elevated hCG levels. Hydatidiform mole should be considered whenever preeclampsia develops early in pregnancy.

Hyperemesis Gravidarum

Hyperemesis requiring antiemetic or intravenous replacement therapy occurred in one-fourth of women with a complete mole, particularly those with excessive uterine size and markedly elevated hCG levels. Severe electrolyte
Hyperthyroidism

Clinically evident hyperthyroidism was observed in 7% of patients with a complete molar gestation. These women may have tachycardia, warm skin, and tremor, and the diagnosis can be confirmed by detection of elevated serum levels of free thyroxine ($T_4$) and tri-iodothyronine ($T_3$). Clinical evidence of hyperthyroidism with complete mole is rare.

Anesthesia or surgery may precipitate thyroid storm. Thus, if hyperthyroidism is suspected before the induction of anesthesia for molar evacuation, $\beta$-adrenergic blocking agents should be administered. Thyroid storm may be manifested by hyperthermia, delirium, convulsions, tachycardia, high-output heart failure, or cardiovascular collapse. Administration of $\beta$-adrenergic blocking agents prevents or rapidly reverses many of the metabolic and cardiovascular complications of thyroid storm. After molar evacuation, thyroid function test results rapidly return to normal.

Hyperthyroidism develops almost exclusively in patients with very high hCG levels. Some investigators suggest that hCG is the thyroid stimulator in women with molar pregnancy because positive correlations between serum hCG levels and total $T_4$ or $T_3$ concentrations were observed. However, in one study in which thyroid function was measured in 47 patients with a complete mole, no significant correlation was found between serum hCG levels and serum values of free $T_4$ index or free $T_3$ index (26). Although some investigators speculated about a separate chorionic thyrotropin, this substance is not yet isolated.

Trophoblastic Embolization

Respiratory distress rarely occurs in patients with a complete mole. It is usually diagnosed in patients with excessive uterine size and markedly elevated hCG levels. These patients may have chest pain, dyspnea, tachypnea, and tachycardia and may experience severe respiratory distress during and after molar evacuation. Auscultation of the chest usually reveals diffuse rales, and chest radiographic evaluation may show bilateral pulmonary infiltrates. Respiratory distress usually resolves within 72 hours with cardiopulmonary support. In some circumstances, patients may require mechanical ventilation. Respiratory insufficiency may result from trophoblastic embolization and the cardiopulmonary complications of thyroid storm, preeclampsia, and massive fluid replacement.

Theca Lutein Ovarian Cysts

Prominent theca lutein ovarian cysts (6 cm in diameter) develop in about one-half of patients with a complete mole (27). Theca lutein ovarian cysts result from high serum hCG levels, which cause ovarian hyperstimulation (28). Because the uterus
may be excessively enlarged, theca lutein cysts can be difficult to palpate during physical
examination; however, ultrasonography can accurately document their presence and size. **After molar evacuation, theca lutein cysts normally regress spontaneously within 2 to 4 months.**

Prominent theca lutein cysts may cause symptoms of marked pelvic pressure, and they can be decompressed by laparoscopic or ultrasonographically directed aspiration. If acute pelvic pain develops, laparoscopy should be performed to assess possible cystic torsion or rupture.

**Partial Hydatidiform Mole**

Patients with partial hydatidiform mole usually do not have the dramatic clinical features characteristic of complete molar pregnancy. **These patients have the signs and symptoms of incomplete or missed abortion, and partial mole is diagnosed after histologic review of the tissue obtained by curettage (29).**

In a survey of 81 patients with a partial mole, the main initial sign was vaginal bleeding, which occurred in 59 patients (72.8%) (30). Excessive uterine enlargement and preeclampsia were present in three patients (3.7%) and two patients (2.5%), respectively. No patient had theca lutein ovarian cysts, hyperemesis, or hyperthyroidism. The initial clinical diagnosis was an incomplete or missed abortion in 74 patients (91.3%) and hydatidiform mole in five patients (6.2%). Pre-evacuation hCG levels were measured in 30 patients and were higher than 100,000 mIU/mL in two patients (6.6%).
Complete Hydatidiform Mole

Complete moles have a potential for local invasion and dissemination. **After molar evacuation, local uterine invasion occurs in 15% of patients, and metastasis occurs in 4%** (27).

A review of 858 patients with complete hydatidiform mole at the New England Trophoblastic Disease Center (NETDC) revealed that two-fifths of the patients had the following signs of marked trophoblastic proliferation at the time they sought treatment:

- hCG level >100,000 mIU/mL
- Excessive uterine enlargement
- Theca lutein cysts 6 cm in diameter

**In this review, patients with any one of these signs were considered at high risk for developing postmolar tumor.** After molar evacuation, local uterine invasion occurred in 31%, and metastases developed in 8.8% of the 352 high-risk patients. For the 506 low-risk patients, local invasion was found in only 3.4%, and metastases developed in 0.6%.

**Older patients are at increased risk of developing postmolar GTN.** One study reported that persistent tumor developed after a complete molar pregnancy in 37% of women older than 40 years (27), whereas in another study this finding occurred in 60% of women older than 50 years (31).

Partial Hydatidiform Mole

Persistent tumor, usually nonmetastatic, develops in approximately 2% to 4% of patients with a partial mole, and chemotherapy is required to achieve remission (32). Patients who develop persistent disease have no distinguishing clinical or pathologic characteristics (33).
Diagnosis

Ultrasonography is a reliable and sensitive technique for the diagnosis of complete molar pregnancy. Because the chorionic villi exhibit diffuse hydropic swelling, complete moles produce a characteristic vesicular ultrasonographic pattern as soon as in the first trimester (Fig. 39.6).

Figure 39.6 Ultrasonogram of a uterus showing a typical pattern of a complete hydatidiform mole. Note the characteristic vesicular ultrasonographic pattern.

Ultrasonography may contribute to the diagnosis of partial molar pregnancy by demonstrating focal cystic spaces in the placental tissues and an increase in the transverse diameter of the gestational sac (34). When these criteria are present, the positive predictive value for partial mole is 90%.
Treatment

When molar pregnancy is diagnosed, the patient should be evaluated for the presence of associated medical complications, including preeclampsia, hyperthyroidism, electrolyte imbalance, and anemia. After the patient’s condition is stabilized, a decision must be made concerning the most appropriate method of evacuation.

Suction Curettage

Suction curettage is the preferred method of evacuation, regardless of uterine size, for patients who desire to preserve fertility (32). It involves the following steps:

**Oxytocin infusion**—This procedure is begun before the induction of anesthesia.

**Cervical dilation**—As the cervix is being dilated, uterine bleeding often increases. Retained blood in the endometrial cavity may be expelled during cervical dilation. Active uterine bleeding should not deter the prompt completion of cervical dilation.

**Suction curettage**—Within a few minutes of commencing suction curettage, uterine size may decrease dramatically, and the bleeding will be well controlled. The use of a 12-mm cannula is strongly advised to facilitate evacuation. If the uterus is larger than 14 weeks of gestation, one hand should be placed on top of the fundus, and the uterus should be massaged to stimulate uterine contraction and reduce the risk of perforation.

**Sharp curettage**—When suction evacuation is believed to be complete, gentle sharp curettage is performed to remove any residual molar tissue.

Because trophoblast cells express RhD factor, patients who are Rh negative should receive Rh immune globulin at the time of evacuation.

Hysterectomy

If the patient desires surgical sterilization, a hysterectomy may be performed with the mole in situ. The ovaries may be preserved at the time of surgery, even in the presence of prominent theca lutein cysts. Large ovarian cysts may be decompressed by aspiration. Hysterectomy does not prevent metastasis; patients still require follow-up with assessment of hCG levels.

Prophylactic Chemotherapy

The use of prophylactic chemotherapy at the time of molar evacuation is controversial. The debate concerns the wisdom of exposing all patients to potentially toxic treatment when only about 20% are at risk of developing persistent tumor.

In a study of 247 patients with complete molar pregnancy who prophylactically received a single course of actinomycin D (ActD) at the time of evacuation, local uterine invasion developed in 10 patients (4%), and no patients experienced metastasis (35). All 10 patients with local invasion achieved remission after one additional course of chemotherapy. Prophylactic chemotherapy, prevented metastasis and reduced
the incidence and morbidity of local uterine invasion.

In two prospective randomized studies of prophylactic chemotherapy in patients with a complete mole, a significant decrease in persistent tumor was detected in patients with high-risk mole who received prophylactic chemotherapy (47% and 50% vs. 14%) (36–38). **Prophylaxis may be particularly useful in the management of high-risk complete molar pregnancy, especially when hCG assessments for follow-up are unavailable or unreliable.**
Follow-Up

Human Chorionic Gonadotropin

After molar evacuation, patients should be monitored with weekly determinations of β-subunit hCG levels until these levels are normal for 3 consecutive weeks, followed by monthly determinations until the levels are normal for 6 consecutive months (39). The average time to achieve the first normal hCG level after evacuation is about 9 weeks (40). After achieving nondetectable serum hCG levels, the risk of developing GTN approaches zero (41–43). If these findings are confirmed, it is possible that postmolar hCG surveillance could be safely abbreviated.

Contraception

Patients are encouraged to use effective contraception during the entire interval of hCG follow-up. Because of the potential risk of uterine perforation, bleeding, and infection, intrauterine devices should not be inserted until the patient achieves a normal hCG level. If the patient does not desire surgical sterilization, either oral contraceptives or barrier methods should be used.

Increased incidence of postmolar persistent tumor was reported among patients who used oral contraceptives before gonadotropin remission (44). However, data from a prospective trial and other centers indicate that oral contraceptive use does not increase the risk of postmolar trophoblastic disease (45–47). It appears that oral contraceptives may be used safely after molar evacuation during the entire interval of hormonal follow-up.
Gestational Trophoblastic Neoplasia

Nonmetastatic Disease
Locally invasive GTN develops in about 15% of patients after evacuation of a complete mole and infrequently after other gestations (1). These patients usually present with the following symptoms:

- Irregular vaginal bleeding
- Theca lutein cysts
- Uterine subinvolution or asymmetric enlargement
- Persistently elevated serum hCG levels.

The trophoblastic tumor may perforate the myometrium, causing intraperitoneal bleeding, or erode into uterine vessels, causing vaginal hemorrhage. Bulky, necrotic tumor may involve the uterine wall and serve as a nidus for infection. Patients with uterine sepsis may have a purulent vaginal discharge and acute pelvic pain.

After molar evacuation, persistent GTN may exhibit the histologic features of either hydatidiform mole or choriocarcinoma. After a nonmolar pregnancy, persistent GTN always has the histologic pattern of choriocarcinoma. Histologic characterization of choriocarcinoma depends on sheets of anaplastic syncytiotrophoblast and cytotrophoblast without chorionic villi.

Placental-Site Trophoblastic Tumor
Placental-site trophoblastic tumor is an uncommon but important variant of choriocarcinoma that consists predominantly of intermediate trophoblast (48). Relative to their mass, these tumors produce small amounts of hCG and human placental lactogen (hPL), and they tend to remain confined to the uterus, metastasizing late in their course. In contrast to other trophoblastic tumors, placental-site tumors are relatively insensitive to chemotherapy.
Metastatic Disease

Metastatic GTN occurs in about 4% of patients after evacuation of a complete mole, but it is seen more often when GTN develops after nonmolar pregnancies (1). GTN usually metastasizes as choriocarcinoma because of its tendency for early vascular invasion with widespread dissemination. Trophoblastic tumors often are perfused by fragile vessels and are frequently hemorrhagic. Symptoms of metastases may result from spontaneous bleeding at metastatic foci. The most common sites of metastases are lung (80%), vagina (30%), pelvis (20%), liver (10%), and brain (10%).

Pulmonary

At the time of diagnosis, lung involvement is visible by chest radiography in 80% of patients with metastatic GTN. Patients with pulmonary metastasis may have chest pain, cough, hemoptysis, dyspnea, or an asymptomatic lesion visible by chest radiography. Respiratory symptoms may be acute or chronic, persisting over many months.

GTN may produce four principal pulmonary patterns:

- An alveolar or “snowstorm” pattern
- Discrete rounded densities
- Pleural effusion
- An embolic pattern caused by pulmonary arterial occlusion.

Because respiratory symptoms and radiographic findings may be dramatic, the patient may be thought to have a primary pulmonary disease. Some patients with extensive pulmonary involvement have minimal, if any, gynecologic symptoms because the reproductive organs may be free of trophoblastic tumor. The diagnosis of GTN may be confirmed only after thoracotomy is performed, particularly in patients with a nonmolar antecedent pregnancy.

Pulmonary hypertension may develop in patients with GTN secondary to pulmonary arterial occlusion by trophoblastic emboli. The development of early respiratory failure requiring intubation is associated with a poor clinical outcome (49).

Vaginal

Vaginal metastases occur in 30% of the patients with metastatic tumor. These lesions are highly vascular and may bleed vigorously when biopsied. Metastases to the vagina may occur in the fornices or suburethrally and may produce irregular bleeding or a purulent discharge.

Hepatic

Liver metastases occur in 10% of patients with disseminated trophoblastic tumor. Hepatic involvement is encountered when there is a protracted delay in diagnosis.
and the patient has an extensive tumor burden. Epigastric or right upper quadrant pain may develop if metastases stretch the hepatic capsule. Hepatic lesions may be hemorrhagic, causing hepatic rupture and exsanguinating intraperitoneal bleeding.

Central Nervous System

**Metastatic trophoblastic disease involves the brain in 10% of patients.** Cerebral involvement is seen in patients with advanced disease; virtually all patients with brain metastasis have concurrent pulmonary or vaginal involvement or both. Because cerebral lesions frequently hemorrhage spontaneously, most patients develop acute focal neurologic deficits (50,51).
Staging and Prognostic Score

Staging

An anatomic staging system for GTN was adopted by the International Federation of Gynecology and Obstetrics (FIGO) (Table 39.2). It is hoped that this staging system will encourage the objective comparison of data from various centers (52).

Table 39.2 Staging of Gestational Trophoblastic Neoplasia

</tbody>
</table>

Format as Table 15.7 in Berek & Hacker’s 5th edition, page 602

Stage I: Patients have persistently elevated hCG levels and tumor confined to the uterine corpus.

Stage II: Patients have metastases to the genital tract.

Stage III: Patients have pulmonary metastases with or without uterine, vaginal, or pelvic involvement. The diagnosis is based on a rising hCG level in the presence of pulmonary lesions viewed by chest radiography.

Stage IV: Patients have advanced disease and involvement of the brain, liver, kidneys, or gastrointestinal tract. These patients are in the highest risk category because they are most likely to be resistant to chemotherapy. Choriocarcinoma is usually present, and the disease commonly follows a nonmolar pregnancy.

Prognostic Scoring System

In addition to anatomic staging, it is important to consider other variables to predict the likelihood of drug resistance and to assist in selecting appropriate chemotherapy (53). A prognostic scoring system proposed by the World Health Organization reliably predicts the potential for resistance to chemotherapy (Table 39.3).

Table 39.3 Scoring System Based on Prognostic Factors

a
When the prognostic score is higher than 6, the patient is categorized as high risk and requires multimodal therapy, which includes intensive combination chemotherapy, and may also include surgery and radiation to achieve remission. Patients with stage I disease usually have a low-risk score, and those with stage IV disease have a high-risk score. The distinction between low and high risk applies mainly to patients with stage II or III disease.

*The total score for a patient is obtained by adding the individual scores for each prognostic factor. Total score: <7, low risk; ≥7, high risk.*
Diagnostic Evaluation

Optimal management of persistent GTN requires a thorough assessment of the extent of the disease before the initiation of treatment. All patients with persistent GTN should undergo a careful pretreatment evaluation, including the following:

- Complete history and physical examination
- Measurement of the serum hCG level
- Hepatic, thyroid, and renal function tests
- Determination of baseline peripheral white blood cell and platelet counts

The metastatic workup should include the following:

- Chest radiograph or computed tomography (CT) scan
- Ultrasonography or CT scan of the abdomen and pelvis
- CT or magnetic resonance imaging (MRI) scan of the head

When the pelvic examination and chest radiographic findings are negative, metastatic involvement of other sites is uncommon.

Liver ultrasonography and CT or MRI scanning will disclose most hepatic metastases in patients with abnormal liver function tests. CT or MRI scan of the head facilitates the early diagnosis of asymptomatic cerebral lesions. Chest CT scans may detect micrometastases not visible on chest radiography. Chest CT will demonstrate pulmonary micrometastases in about 40% of patients with presumed nonmetastatic disease (54).

In patients with choriocarcinoma or metastatic disease, hCG levels may be measured in the cerebrospinal fluid (CSF) to exclude cerebral involvement if the results of CT scanning of the brain are normal. The ratio of plasma-to-CSF hCG tends to be lower than 60 in the presence of cerebral metastases (55). A single plasma-to-CSF hCG ratio may be misleading, because rapid changes in plasma hCG levels may not be reflected promptly in the CSF (56).

Pelvic ultrasonography appears to be useful in detecting extensive trophoblastic uterine involvement and may aid in identifying sites of resistant uterine tumor (57). Because ultrasonography can accurately and noninvasively detect extensive uterine tumor, it may help identify patients who would benefit from hysterectomy.
Management of GTN

A protocol for the management of GTN is presented in Table 39.4.

Low-Risk Disease

Low-risk GTN includes patients with both nonmetastatic (stage I) and metastatic GTN whose prognostic score is less than 7. In patients with stage I disease, the selection of treatment is based primarily on whether the patient desires to retain fertility.

Hysterectomy Plus Chemotherapy

If the patient does not wish to preserve fertility, hysterectomy with adjuvant single-agent chemotherapy may be performed as primary treatment. Adjuvant chemotherapy is administered for three reasons:
To reduce the likelihood of disseminating viable tumor cells at surgery
To maintain a cytotoxic level of chemotherapy in the bloodstream and tissues in case viable tumor cells are disseminated at surgery
To treat any occult metastases that may be present at the time of surgery

Chemotherapy can be administered safely at the time of hysterectomy without increasing the risk of bleeding or sepsis. In a series of 31 patients treated with primary hysterectomy and a single course of adjuvant chemotherapy, all achieved complete remission with no additional therapy (58).

Hysterectomy is performed in all patients with stage I placental-site trophoblastic tumor. Because placental-site tumors are resistant to chemotherapy, hysterectomy for presumed nonmetastatic disease is the only curative treatment. Patients with metastatic placental site trophoblastic tumor may still achieve remission, but their tumors are less responsive to chemotherapy (59).

**Chemotherapy Alone**

Single-agent chemotherapy is the preferred treatment in patients with stage I disease who desire to retain fertility (60). At the NETDC from July 1965 through June 2008, primary single-agent chemotherapy was administered to 561 patients with stage I GTN and 434 patients (77.4%) attained complete remission. The remaining 127 patients with resistant disease subsequently achieved remission after combination chemotherapy or surgical intervention.

When a patient’s disease is resistant to single-agent chemotherapy and she desires to preserve fertility, combination chemotherapy should be administered. If the patient’s disease is resistant to single-agent and combination chemotherapy and she wants to retain fertility, local uterine resection may be considered. When local resection is planned, a preoperative ultrasonography, MRI, or arteriography may help to define the site of the resistant tumor.

**Low-Risk Metastatic GTN (Stages II and III)**

**Vaginal and Pelvic Metastasis**

Low-risk disease treated with primary single-agent chemotherapy has a high (approximately 80%) rate of remission in contrast to high-risk disease that usually does not achieve remission with single-agent treatment and require treatment with primary intensive combination chemotherapy.

Vaginal metastases may bleed profusely because they are highly vascular and friable. When bleeding is substantial, it may be controlled by packing the vagina or by wide local excision. Infrequently, arteriographic embolization of the hypogastric arteries may be required to control hemorrhage from vaginal metastases (61).

**Pulmonary Metastasis**
At the NETDC from July 1965 through June 2008, of the 139 patients with low-risk stages II or III disease, 114 (82%) attained complete remission with single-agent chemotherapy. The remaining 25 (18%) patients who had disease resistant to single-agent treatment subsequently achieved remission with combination chemotherapy.

Thoracotomy
Thoracotomy has a limited but important role in the management of pulmonary metastases. **If a patient has a persistent viable pulmonary metastasis following intensive chemotherapy, thoracotomy may be indicated to excise the resistant focus.** A thorough metastatic workup should be performed before surgery is undertaken to exclude other sites of persistent disease. It is important to realize that fibrotic pulmonary nodules may persist indefinitely on chest radiography, even after complete gonadotropin remission is attained. In patients undergoing thoracotomy for resistant disease, chemotherapy should be administered postoperatively to treat potential occult sites of micrometastasis.

Hysterectomy
**Hysterectomy may be required in patients with metastatic disease to control uterine hemorrhage or sepsis.** In patients with extensive uterine tumor, hysterectomy may substantially reduce the trophoblastic tumor burden and limit the need for multiple courses of chemotherapy (62).

Follow-Up
All patients with low-risk GTN (stages I through III) should undergo follow-up with:
- Weekly measurement of hCG levels until they are normal for 3 consecutive weeks.
- Monthly measurement of hCG values until levels are normal for 12 consecutive months.
- Effective contraception during the entire interval of hormonal follow-up.

High-Risk Metastatic GTN (Stages II–IV)
All patients with high-risk GTN (stages II–IV) should be treated with primary intensive combination chemotherapy and the selective use of radiation therapy and surgery. Between July 1965 and June 2008, of the 103 patients with high-risk GTN stages II–IV treated at the NETDC, 83 (80.5%) achieved complete remission. Before 1975, when single agent therapy was used primarily to treat patients with stage IV GTN, only 6 of 20 patients (30%) attained complete remission. Since 1975, 17 of 21 patients (80.9%) achieved remission. This improvement in survival resulted from the use of multimodal therapy, including primary combination chemotherapy in conjunction with radiation and surgical treatment. Patients with stage IV disease are at the greatest risk of
developing rapidly progressive and unresponsive tumors despite intensive multimodal therapy. They should be referred to centers with special expertise in the management of trophoblastic disease.

**Hepatic Metastasis**

The management of resistant hepatic metastasis is particularly difficult (63). If a patient becomes resistant to systemic chemotherapy, hepatic arterial infusion of chemotherapy may induce complete remission in selected cases. Hepatic resection may be required to control acute bleeding or to excise a focus of resistant tumor. New techniques of arterial embolization may reduce the need for surgical intervention.

**Cerebral Metastasis**

At the NETDC, cerebral metastases are treated with whole-brain irradiation (3,000 cGy in 10 fractions) in conjunction with combination chemotherapy. Because irradiation may be hemostatic and tumoricidal, the risk of spontaneous cerebral hemorrhage may be lessened by the concurrent use of combination chemotherapy and brain irradiation. Excellent remission rates (86%) were reported in patients with cranial metastases treated with intensive intravenous combination chemotherapy and intrathecal methotrexate (MTX) (64).

**Craniotomy**

Craniotomy may be required to provide acute decompression or to control bleeding. It should be performed to manage life-threatening complications so that the patient ultimately will be cured with chemotherapy. In a study of six patients (65), the use of craniotomy to control bleeding resulted in complete remission in three patients. Infrequently, cerebral metastases that are resistant to chemotherapy may be amenable to local resection (66). Patients with cerebral metastases who achieve sustained remission generally have no residual neurologic deficits.

**Follow-Up**

Patients with stage IV disease should receive follow-up with:

- Weekly determination of hCG levels until they are normal for 3 consecutive weeks.
- Monthly determination of hCG levels until they are normal for 24 consecutive months.

These patients require prolonged gonadotropin follow-up because they are at increased risk of late recurrence.

An algorithm for the management of persistent GTN is presented in Figure 39.7.

Figure 39.7 Management of gestational trophoblastic tumor. GTN, gestational trophoblastic neoplasia; hCG, human chorionic gonadotropin; RT, radiotherapy. (From Berkowitz RS, Goldstein DP. Gestational trophoblastic neoplasia. In: Berek JS, Hacker NF. Berek and Hacker’s Gynecologic Oncology, 5th ed.)
Chemotherapy

Single-Agent Treatment
Single-agent chemotherapy with either actinomycin D (ActD) or MTX achieved comparable and excellent remission rates in both nonmetastatic and low-risk metastatic GTN (67). Several protocols using these agents are available. ActD can be given every other week as a 5-day regimen or in a pulsatile fashion; similarly, MTX can be given either in a 5-day regimen or pulsatile weekly (68,69). No study compared all of these protocols with regard to success. An optimal regimen should maximize the response rate while minimizing morbidity and cost.

An important phase III randomized trial examining MTX and ActD in the treatment of low-risk GTN was published by the Gynecologic Oncology Group (GOG) (70). Two hundred sixteen patients were randomized to receive either biweekly ActD 1.25mg/m² intravenous (IV) bolus or weekly MTX 30 mg/m² intramuscular (IM). The remission rate was 58% in the MTX arm and 73% in the ActD arm. These results suggest that ActD is superior to the weekly MTX regimen in treating low-risk GTN. Before recommending pulse ActD as the primary modality in the treatment of patients with low-risk GTN, it is important to be aware of the potential for significant toxicity of this regimen compared to those receiving MTX. All patients with low-risk disease in this study ultimately achieved remission, regardless of their initial response. Regarding the true comparative effectiveness of these agents, it would be prudent to compare the biweekly ActD regimen to the more commonly used 5-day or 8-day MTX regimens, which offer a high initial remission rate with minimal toxicity.

The administration of methotrexate with folinic acid (MTX-FA) in GTN to limit systemic toxicity was first reported in 1964 (71). Subsequently, it has been confirmed that MTX-FA is both effective and safe in the management of GTN.

An evaluation of 185 patients treated with MTX-FA revealed that complete remission was achieved in 162 patients (87.6%); of these patients, 132 (81.5%) required only one course of MTX-FA to attain remission (72). MTX-FA induced remission in 147 of 163 patients (90.2%) with stage I GTN and in 15 of 22 patients (68.2%) with low-risk stages II and III GTN. Resistance to therapy was more common in patients with choriocarcinoma, metastasis, and pretreatment serum hCG levels higher than 50,000 mIU/mL. After treatment with MTX-FA, thrombocytopenia, granulocytopenia, and hepatotoxicity developed in 3 (1.6%), 11 (5.9%), and 26 (14.1%) patients, respectively. Thus, MTX-FA achieved an excellent therapeutic outcome with minimal toxicity and attained this goal with limited exposure to chemotherapy.

Technique of Single-Agent Treatment
The serum hCG level is measured weekly after each course of chemotherapy.
The hCG regression curve serves as the primary basis for determining the need for additional treatment.

After the first treatment:

Further chemotherapy is withheld as long as the hCG level is falling progressively.

Additional single-agent chemotherapy is not administered at any predetermined or fixed interval.

A second course of chemotherapy is administered under the following conditions:

- If the hCG level plateaus for more than 3 consecutive weeks or begins to rise again.
- If the hCG level does not decline by 1 log within 18 days after completion of the first treatment.

If the patient’s response to the first treatment was adequate and a second course of MTX-FA is required, the dosage of MTX is unaltered. An adequate response is defined as a fall in the hCG level by 1 log after a course of chemotherapy.

If the response to the first treatment is inadequate, the dosage of MTX is increased from 1.0 mg/kg/day to 1.5 mg/kg/day for each of the 4 treatment days. If the response to two consecutive courses of MTX-FA is inadequate, the patient is considered to be resistant to MTX, and ActD is promptly substituted. If the hCG levels do not decline by 1 log after treatment with ActD, the patient is considered resistant to ActD as a single agent. She must be treated intensively with combination chemotherapy to achieve remission.
Combination Chemotherapy

**Triple Therapy**

Prior to the introduction of etoposide in combination with MTX, ActD, cyclophosphamide, and vincristine (EMA-CO), triple therapy with MTX, ActD, and cyclophosphamide was the treatment of choice as initial therapy for patients with low-risk disease resistant to single-agent therapy and as primary therapy for high-risk patients. Collectively, data from three centers indicate that triple therapy induced remission in 21 (49%) of 43 patients with metastasis and a high-risk score (score >6) \(^{(73–75)}\). **Triple therapy is no longer indicated in patients with high-risk disease.** It maybe useful in selected patients with low-risk scores resistant to single agents.

**EMA-CO**

Etoposide induces complete remission in 56 (95%) of 60 patients with nonmetastatic and low-risk metastatic GTN \(^{(76)}\). **The use of EMA-CO induced an 83% remission rate in patients with metastasis and a high-risk score** \(^{(77)}\). Another study confirmed that primary EMA-CO induced complete remission in 76% of the patients with metastatic GTN and a high-risk score \(^{(78)}\). Another study reported that EMA-CO induced complete sustained remission in 87 (90.6%) of 96 patients with high-risk (score >6) GTN \(^{(79)}\). Remission occurred with EMA-CO in 30 (86%) of 35 patients with brain metastasis \(^{(65)}\).

The EMA-CO regimen is well tolerated, and treatment seldom has to be suspended because of toxicity. The EMA-CO regimen is the preferred primary treatment in patients with metastasis and a high-risk prognostic score (score >6).

**EMA-EP**

Patients resistant to EMA-CO can be treated successfully by substituting etoposide and cisplatin on day 8 (EMA-EP). **EMA-EP induced remission alone or with surgery in 16 (76%) of 21 patients who were resistant to EMA-CO** \(^{(80)}\). The optimal combination drug protocol will most likely include etoposide, MTX, and ActD and perhaps other agents administered in the most dose-intensive manner.
Management of Refractory GTN

Efforts continue to identify new agents and regimens effective in treating patients who prove resistant to all standard chemotherapy regimens. A combination of cisplatin, vinblastine, and bleomycin (PVB) was used effectively in patients with drug-resistant tumor (74,75,81). Although ifosfamide and paclitaxel were used successfully, further studies are needed to define their potential role in either primary or second-line therapy (82,83). Osborne et al. reported that a novel three-drug doublet regimen consisting of paclitaxel, etoposide, and cisplatin (TE/TP) induced complete remission in two patients with relapsed high-risk GTN (84). Wan et al. demonstrated that floxuridine (FUDR)-containing regimens induced complete remission in all of 21 patients with drug-resistant GTN (85). Matsui et al. found that 5-fluorouracil (5-FU) in combination with ActD induced remission in 9 of 11 (82%) patients with drug resistance (86). The potential role for autologous bone marrow transplantation or stem cell rescue in conjunction with ultra-high-dose chemotherapy has yet to be defined, although complete remissions was reported in patients with refractory GTN (87,88).
Duration of Therapy

Patients who require combination chemotherapy must be treated intensively to attain remission. Combination chemotherapy should be given as often as toxicity permits until the patient achieves three consecutive normal hCG levels. After normal hCG levels are attained, at least two additional courses of chemotherapy are administered to reduce the risk of relapse.
False-Positive hCG Tests

The concept of false-positive hCG tests caused by heterophile antibodies is critical to remember when following patients with molar gestation or GTN. Some assay systems used by commercial laboratories are particularly vulnerable to false-positive tests resulting from the presence of heterophilic antibodies in the test kits they were using (89). For the most part this problem was corrected by adding blocking antibodies to the test systems. Since the hCG molecules in GTN are significantly more degraded or heterogeneous than in normal pregnancy, with higher proportions of free B-hCG, nicked hCG, and B-core fragments, it is important to use an assay that detects both intact hCG and its metabolites and fragments in order to accurately assess the tumor burden (90–92). Additionally, cross-reactivity with luteinizing hormone (LH) can cause confusion when dealing with women in the perimenopausal age group whose hCG level may plateau above assay even when there is no longer active tumor. The use of hormone suppression will suppress LH and prevent unnecessary treatment. False-positive hCG tests caused by heterophile agglutinins or LH release may cause confusion in the diagnosis of early pregnancy, ectopic pregnancy, and so-called phantom choriocarcinoma. When there is concern about the possibility of a false-positive serum hCG test, a urine sample should be tested, because patients with phantom hCG generally have no measurable hCG in a parallel urine sample.
Persistent Low-Level “Real” hCG

Some patients with molar pregnancy and GTN have persistent (weeks to months) very low levels of real hCG (usually <500 mIU/mL). In these women, extensive radiologic and clinical evaluations fail to reveal any lesions, and chemotherapy is usually not effective. This condition of “real” low-level hCG, where hCG is not hyperglycosylated, is called “quiescent GTN.” These patients should be managed with careful follow-up, because 6% to 10% ultimately will relapse into active disease and rising hCG levels. The risk of relapse to active disease is correlated with the amount of hyperglycosylated hCG. If relapse does occur, chemotherapy usually proves effective (93).
Subsequent Pregnancies

Pregnancies After Uncomplicated Hydatidiform Mole

Patients with hydatidiform moles can anticipate normal reproduction in the future (94). At the NETDC from 1965 until 2007, patients with uncomplicated complete mole had 1,337 subsequent pregnancies that resulted in 912 term live births (68.1%), 101 premature deliveries (67%), 11 ectopic pregnancies (0.9%), 7 stillbirths (0.5%), and 20 repeat molar pregnancies (1.5%). First- and second-trimester spontaneous abortions occurred in 245 (39%) pregnancies. Major and minor congenital malformations were detected in 40 infants (3.9%), and primary cesarean delivery was performed in 81 of 414 (19.6%) term or preterm births from 1979 to 2007.

Although data regarding pregnancies after partial mole are limited (296 subsequent pregnancies), the information is reassuring (94). Patients with both complete and partial mole should be reassured that they are at no increased risk of complications in later gestations.

When a patient has had a molar pregnancy, either partial or complete, she should be informed of the increased risk of having a molar gestation in subsequent conceptions. After one molar pregnancy, the risk of having molar disease in a future gestation is about 1% to 1.5%. Of 35 patients with at least two documented molar pregnancies, every possible combination of repeat molar pregnancy was observed. After two molar gestations, these 35 patients had 39 later conceptions resulting in 24 (61.5%) term deliveries, 7 (17.9%) moles (6 complete, 1 partial), 3 spontaneous abortions, 3 therapeutic abortions, 1 intrauterine fetal death, and 1 ectopic pregnancy. In six patients, the medical records indicated that the patient had a different partner at the time of different molar pregnancies (95).

For any subsequent pregnancy, it seems prudent to undertake the following approach:

- Perform pelvic ultrasonographic examination during the first trimester to confirm normal gestational development.
- Obtain an hCG measurement 6 weeks after completion of the pregnancy to exclude occult trophoblastic neoplasia.

Pregnancies After GTN

Patients with GTN who are treated successfully with chemotherapy can expect normal reproduction in the future. Patients who were treated with chemotherapy at the NETDC from 1965 to 2007 had 631 subsequent pregnancies that resulted in 422 term live births (66.9%), 42 preterm deliveries (6.7%), 7 ectopic pregnancies (1.1%), 9 stillbirths (1.4%), and 9 repeat molar pregnancies (1.7%) (94). First- and second-trimester spontaneous abortions occurred in 114 (188%) pregnancies. Major and minor congenital malformations were detected in 10 infants (2.1%). Primary cesarean delivery
was performed in 81 (21.8%) of 371 subsequent term and preterm births from 1979 to 2007. The frequency of congenital anomalies is not increased, although chemotherapeutic agents have teratogenic and mutagenic potential.
References

Breast cancer accounts for one-third of cancers in women. The risk of breast cancer increases with a positive family history and the use of hormone therapy. Breast cancer may be either in situ (ductal carcinoma in situ or lobular carcinoma in situ) or invasive (infiltrating ductal carcinoma, infiltrating lobular carcinoma).

The standard screening modalities for detection of breast cancer include yearly mammography and physical examination.

Tissue diagnosis is achieved using fine-needle aspiration cytology (FNAC) or core needle biopsy (CNB). Open biopsy is performed if FNAC or CNB results are equivocal or discordant with the clinical findings.

The combination of segmental mastectomy (with negative surgical margins), axillary lymph node dissection, and postoperative radiation therapy has the same overall survival compared to modified radical mastectomy for the management of patients with stages I and II breast cancer.

Axillary lymph node status and the number of involved nodes are the most important prognostic indicators in primary breast cancer.

Sentinel lymph node dissection alone can replace axillary lymph node dissection if the sentinel lymph node is found to be negative on pathology.

Adjuvant systemic therapy prolongs survival and is recommended for women with a greater than 10% chance of relapse within 10 years.

Breast cancer accounts for approximately one-third of all cancers in women and is second only to lung cancer as the leading cause of cancer deaths among women. Breast cancer has the highest incidence rate of all cancers. According to statistics from the American Cancer Society (ACS), over 230,000 new cases of invasive breast cancer will be diagnosed in women during 2011 in the United States as well as
over 55,000 patients of in situ cancers, with almost 40,000 women succumbing to the disease during the same period (1). Over the past 50 years, the incidence of breast cancer in the United States increased significantly; one in every seven women will develop the disease during her lifetime. Fortunately, the mortality rate has declined since 1990.
Predisposing Factors

Less than 1% of breast cancers occur in women younger than 25 years of age. After age 30, there is a sharp increase in the incidence of breast cancer. Except for a short plateau between the ages of 45 and 50 years, the incidence increases steadily with age (2).
Of women who develop breast cancer, 20% to 30% have a family history of the disease. Although any family history of breast cancer increases the overall relative risk, this risk is not significantly increased if the disease was diagnosed postmenopausally in a first-degree or more distant relative (3). If a woman’s mother or sister had unilateral breast cancer premenopausally, her lifetime risk of developing the disease approaches 30%, whereas a woman whose mother or sister had bilateral breast cancers premenopausally has at least a 40% to 50% lifetime risk. The increased incidence in these women is probably the result of inherited oncogenes.

Approximately 5% to 10% of breast cancers have an inherited basis. All inherited genes are autosomal dominant but have variable penetrance. Men carry the gene 50% of the time. The most common mutations are the BRCA1 (chromosome 17q21) and BRCA2 (chromosome 13q12-13) gene deletions. Carriers of these germline mutations have up to a 4% per year risk of developing breast cancer and a lifetime risk that ranges from 35% to 85% (4). These individuals have up to a 65% risk of developing a contralateral breast cancer. The BRCA1 mutation is associated with an increased risk of ovarian and prostate cancer, whereas BRCA2 carriers, although less common, demonstrate increased risks of male breast and prostate cancers. Both mutations are rare in the general public (0.1%) but are more commonly identified in Jews of Ashkenazi descent (1% to 2.3%) (5). Genetic testing is available and should be considered if there is a high likelihood that results will be positive and will be used to influence decisions regarding the clinical management of the care of the patient and her family. Patients with three or more relatives with breast or ovarian cancer with one of the relatives being diagnosed before the age of 50, two first- or second-degree relatives with breast or ovarian cancer, any relative with male breast cancer, patients whose cancer has been diagnosed before the age of 50, and any patients with both breast and ovarian cancer in their family should undergo genetic counseling for BRCA testing. Ashkenazi Jewish patients should undergo genetic counseling if any first-degree relative, or two second-degree relatives on the same side have breast or ovarian cancer (6). Genetic testing is increasingly important given the evidence that prophylactic surgery may prevent new cancers from occurring, as well as prolong survival, in some cases. A prospective multicenter cohort study of 2,482 women with BRCA1 and BRCA2 mutations between 1974 and 2008 showed risk-reducing mastectomy was associated with a decreased risk of breast cancer. Risk-reducing salpingo-oophorectomy was associated with decreased risk of ovarian cancer, first diagnosis of breast cancer, all-cause mortality, breast cancer–specific mortality, and ovarian cancer–specific mortality (7).
There are marked geographic differences in the incidence of breast cancer that may be related to diet. A meta-analysis demonstrated an association between a healthy diet and lower risk of breast cancer (8). Although a definitive relationship between total alcohol consumption and increased risk of breast cancer has yet to be determined, high wine intake was associated with elevated risk (8,9).
Reproductive and Hormonal Factors

The risk of breast cancer increases with the length of a woman’s reproductive phase (10). Although early menarche was reported among breast cancer patients, early menopause appears to protect against the development of the disease, with artificial menopause from oophorectomy lowering the risk more than early natural menopause (11). There is no clear association between the risk of breast cancer and menstrual irregularity or the duration of menses. Although lactation does not affect the incidence of breast cancer, women who were never pregnant have a higher risk of breast cancer than those who are multiparous. Women who give birth to their first child later in life have a higher incidence of breast cancer than do younger primigravida women (12).

A historic well-controlled study from the Centers for Disease Control and Prevention showed that oral contraceptive use does not increase the risk of breast cancer, regardless of duration of use, family history, or coexistence of benign breast disease (13). A pooled analysis from 54 epidemiologic studies showed current users of oral contraceptives had a small but significant increased risk when compared with nonusers. Ten years after discontinuation, the risk of past users declined to that of the normal population (14).

It was reported that short-term estrogen treatment for menopausal symptoms did not increase the risk of breast cancer, but this belief was refuted by the results of the Women’s Health Initiative randomized trial. This prospective trial, involving 16,000 postmenopausal women randomly assigned to receive estrogen plus progesterone or placebo, revealed an association between hormone therapy use and the development of breast cancer. When invasive breast cancer developed, it was diagnosed at a more advanced stage compared with tumors that developed among placebo users. Based on interim analysis, the trial was stopped early and the investigators concluded that even relatively short-term use of combined estrogen–progesterone therapy increases the development of invasive breast cancer (15). The risk demonstrated by this study must be considered when postmenopausal hormone therapy is used to treat conditions such as hot flashes and osteoporosis.
Women with a history of breast cancer have a 50% risk of developing microscopic cancer and a 20% to 25% risk of developing clinically apparent cancer in the contralateral breast, which occurs at a rate of 1% to 2% per year (16). Lobular carcinoma has a higher incidence of bilaterality than does ductal carcinoma. A history of endometrial, ovarian, or colon cancer is associated with an increased risk of subsequent breast cancer, as is a history of radiation therapy for Hodgkin’s lymphoma, even if the patient is BRCA1 and BRCA2 negative.
Breast cancer commonly arises in the upper outer quadrant, where there is proportionally more breast tissue. Masses are often discovered by the patient and less frequently by the physician during routine breast examination. The increasing use of screening mammography has enhanced the ability to detect nonpalpable breast abnormalities. Metastatic breast cancer is found as an axillary mass without obvious malignancy in less the 1% of cases.

The standard screening modalities of mammography and physical examination are complementary. Approximately 10% to 50% of cancers detected mammographically are not palpable, whereas physical examination detects 10% to 20% of cancers not seen radiographically (17). The purpose of screening is to detect tumors when they are small (<1 cm) and have the highest potential for surgical cure. Most trials show a 20% to 30% reduction in breast cancer mortality for women age 50 and older who undergo annual screening mammography. Data on screening women younger than 40 years are more controversial. Results from the Gothenburg screening trial showed a 45% reduction in mortality for women screened between the ages of 40 and 49 (18). Because of these findings, it is recommended that all women undergo yearly screening mammography starting at age 40, along with clinical breast examination at least every 3 years (19). Monthly breast self-examination (BSE) is no longer recommended because there is little evidence to show that BSE is superior to heightened breast awareness such that any new symptoms related to the breast in daily activities would be reported promptly when noticed. BSE was not shown to improve survival. Women should be informed about the benefits and limitations of monthly BSE, mainly the risk of a false-positive result. Women who would still prefer to perform BSE should be instructed in the technique and occasionally have their technique reviewed. No other tests, including ultrasonography, computed tomography (CT) scans, sestamibi scans, positron emission tomography (PET) scans, or serum blood markers, have been shown to be effective screening modalities. Screening guidelines recommended by the American College of Radiology and the American Cancer Society are presented in Table 40.1. In 2010, the ACS recommended annual screening mammography and magnetic resonance imaging (MRI) starting at age 30 for women with a known BRCA mutation and other high-risk genetic syndromes, women who are untested with a first-degree relative with the BRCA mutation and women with an approximately 20% to 25% or greater lifetime risk of breast cancer, or women who have been treated with radiation for Hodgkin’s lymphoma (19). Although breast MRI may prove to be advantageous for other women with an elevated risk of breast cancer, there is currently insufficient evidence to make recommendations for women with lower than a 20% lifetime risk of breast cancer (19).

Table 40.1 Screening Recommendations

Bilateral mammograms
Beginning at age 40 yearly mammograms, which should continue as long as the patient is in good health.

Self-examination
Is an option for women starting in their 20s. Women should be counseled on the benefits and limitation of breast self-examination and should be told to report any changes in their breasts to their health professional right away.

Clinical breast examination
Age 20–40 examination by physician every 3 years, annually if positive history (May do annually if there is a positive family history)
Age ≥ 40 examination by physician every year

Breast magnetic resonance imaging (MRI)
High risk women (greater than 20% lifetime risk) should undergo MRI and mammography every year
Medium risk women (15%–20% lifetime risk) should talk to their health care professional about the benefits and limitations of adding MRI to their yearly mammographic screening.
Low risk women (less than 15% lifetime risk) are not recommended to undergo additional MRI screening.

Masses are easier to palpate in older women with fatty breasts than in younger women with dense, nodular breasts. An area of thickening amid normal nodularity may be the only clue to an underlying malignancy. Skin dimpling, nipple retraction, or skin erosion, while obvious, are later-stage disease signs. Algorithms for the evaluation of breast masses in premenopausal and postmenopausal women are presented in Chapter 21.

When a dominant breast mass is identified, the presence of a carcinoma must be considered, and biopsy should be performed to establish a tissue diagnosis. About 30% to 40% of lesions clinically believed to be malignant will be benign on histologic examination (20). Conversely, 25% of clinically benign-appearing lesions will be malignant when biopsied (21).
Biopsy Techniques

It is preferable for the patient to be involved in planning her therapy. In most instances, initial biopsy can be followed by definitive treatment at a later date. This approach allows the physician to discuss alternative forms of surgical therapy with the patient who has a malignancy. It gives the patient an opportunity to obtain a second opinion before undergoing definitive treatment.

Fine-Needle Aspiration Cytology

Fine-needle aspiration cytology (FNAC) is usually performed on palpable lesions or under ultrasound guidance using a 20- or 22-gauge needle. The technique has a high level of diagnostic accuracy, with low false-negative rates and rare, but persistent, false-positive results (20,22). In most reported series, false-negative rates range from 10% to 15%, and false-positive rates are generally less than 1%, whereas insufficient specimens account for about 15% of samples (23). If a mass appears malignant on physical examination, mammography, or both, FNAC cytology results can be used for definitive diagnosis, although in these circumstances a core biopsy is usually the biopsy of choice. Negative FNAC results do not exclude malignancy and should be evaluated by either a core needle or traditional excisional biopsy for suspicious lesions. In younger women, it is prudent to monitor a benign-appearing mass for one or two menstrual cycles. Confirmation of a clinically apparent fibroadenoma with FNAC can serve as the basis for observational follow-up without excision. FNAC may be used in cystic lesions to aspirate fluid, especially in benign-appearing cystic lesions. For benign cysts, cytologic examination is not necessary if the fluid is nonbloody and the cyst resolves after aspiration.

Core Needle Biopsy

Core needle biopsy (CNB) can be performed on both palpable and nonpalpable breast masses. Performing a core biopsy instead of FNAC on a palpable lesion has the advantage of obtaining more tissue for diagnostic purposes, including tests for estrogen and progesterone receptors and Her-2/neu, and has generally replaced FNAC unless aspiration of a cystic mass is being performed. Core biopsy of nonpalpable breast lesions usually is performed using mammographic or ultrasonographic guidance. MRI-detected lesions that cannot be seen with mammography or ultrasonography may be biopsied under MRI guidance. Mammographic units with computerized stereotactic modifications can be used to localize abnormalities and perform CNB without surgery. Under imaging guidance, a biopsy needle is inserted into the lesion and a core of tissue is removed for histologic examination. Devices with suction assistance often are used to increase the volume of tissue removed for evaluation. A titanium clip often is used to mark the biopsy site and serve as a guide should further excision be required. Ultrasonography may be used to perform core biopsy on a nonpalpable lesion. Because it is less invasive and less expensive than open mammographic localization biopsy, CNB is preferred for accessible
lesions. If a definitive diagnosis is not established, these procedures must be followed by open biopsy.

**Open Biopsy**

Open biopsy may be performed if the lesion cannot be successfully biopsied with a needle, or if FNAC or CNB has shown a lesion that may be associated with malignancy, such as atypical ductal hyperplasia (ADH) or lobular carcinoma in situ (LCIS). Excision must be performed if the results with needle biopsy are equivocal or discordant with the clinical findings. **An unequivocal histologic diagnosis of cancer should be obtained before treatment of breast cancer is undertaken.** Cytologic diagnosis may be relied on if the mass clinically or mammographically appears to be malignant.

**Open biopsy can be performed in the outpatient setting with local anesthesia** in the following manner (although this technique largely is replaced by core biopsy and usually is not necessary):

The patient is positioned and the location of the mass confirmed.
Local anesthesia is used to infiltrate the skin and subcutaneous tissue surrounding the palpable mass.
The skin is incised directly over the mass. Placement of this incision is critical. It should be situated in such a way that it can be excised with an ellipse of skin should the patient require a subsequent mastectomy, or placed cosmetically so that partial mastectomy can be performed successfully through it. Para-areolar incisions are appropriate only for lesions in proximity to the nipple–areolar complex.
The mass is gently grasped with Allis forceps or with a stay suture and moved into the operative field.
The mass should be excised completely whenever possible. Larger lesions that are difficult to totally excise can be incised for diagnostic purposes only. When an incisional biopsy is performed, a frozen section should be obtained to confirm that appropriate tissue for diagnosis is present. Such masses are preferably sampled with FNAC or CNB, with incisional biopsy rarely, if ever, indicated.
Once the mass is removed, hemostasis is achieved and the incision is closed. A cosmetically superior result will be achieved if the deep breast parenchyma is not reapproximated. The most superficial subcutaneous fat can be reapproximated with fine absorbable sutures, and the skin can be closed with a subcuticular suture and adhesive strips.

**Image-Guided Localization Biopsy**

Biopsy of nonpalpable lesions is a potentially difficult procedure that requires close cooperation between the surgeon and radiologist. Using ultrasonographic, mammographic, or MRI guidance, a needle or specialized wire is placed into the breast parenchyma at or near the site of the suspected abnormality. Some mammographers will inject a biologic dye into the breast.
parenchyma to assist localization. The surgeon reviews the films and localizes the abnormality with respect to the tip of the wire or needle. Alternatively, the surgeon will perform ultrasonography intraoperatively to directly localize the lesion. An incision is made directly over the abnormality, and a small portion of the breast tissue suspected of containing the abnormality is excised. For mammographically detected lesions, a specimen radiograph is obtained to ensure that the abnormality has been recovered. Often, the radiologist can place a needle in the specimen at the site of the abnormality to facilitate histologic evaluation and ensure that the pathologist examines the site of the abnormality. Image-guided biopsy should be performed only for lesions inaccessible to needle biopsy or those lesions that may be associated with malignancy such as ADH.
Pathology and Natural History

Breast cancer may arise in the intermediate-size ducts, terminal ducts, or lobules. In most cases, the diagnosis of lobular and intraductal carcinoma is based more on histologic appearance than site of origin. The cancer may be either in situ (ductal carcinoma in situ or lobular carcinoma in situ) or invasive (infiltrating ductal carcinoma, infiltrating lobular carcinoma). Morphologic subtypes of infiltrating ductal carcinoma include scirrhous, tubular, medullary, and mucinous carcinoma.

**True invasive ductal carcinoma accounts for 80% of all invasive tumors, with the final 20% split evenly between lobular carcinoma and special variants of infiltrating ductal carcinoma** (24). Mammographically, invasive ductal cancers are characterized by a stellate density or microcalcifications. Macroscopically, gritty, chalky streaks are present within the tumor that most likely represent a desmoplastic response. Invasion of the surrounding stroma and fat, with a fibrotic, desmoplastic reaction surrounding the invasive carcinoma, generally is present.

**Special types of infiltrating ductal carcinoma are uncommon and typically account for nearly 10% of all invasive cancers. Medullary carcinoma, which accounts for 5% to 8% of breast carcinomas,** arises from larger ducts within the breast and has a dense lymphocytic infiltrate. The tumor appears to be a slower growing and less-aggressive malignancy than other forms of carcinoma. Even when axillary disease is present, the prognosis with medullary carcinoma is better than that of other variants of invasive ductal carcinoma. **Mucinous (colloid) carcinoma accounts for 5% of all breast cancers.** Grossly, areas of the tumor may appear mucinous or gelatinous, whereas microscopically they are relatively acellular. Infiltrating comedo carcinoma accounts for less than 1% of all breast malignancies and is an invasive cancer characterized by foci of necrosis that exude a comedonecrosis-like substance when biopsied. Usually, comedocarcinomas are in situ malignancies. Papillary carcinoma is predominantly a noninvasive ductal carcinoma; when invasive components are present, it should be specified as invasive papillary carcinoma. **Tubular carcinoma, a well-differentiated breast cancer that accounts for 1% to 2% of all malignant breast neoplasms,** rarely metastasizes to axillary lymph nodes and tends to have a better prognosis than infiltrating ductal carcinoma. **Adenoid cystic carcinomas are extremely rare breast tumors that histologically are similar to those seen in the salivary glands.** They are well-differentiated cancers that are slow to metastasize.
Growth Patterns

The growth potential of breast cancer and the patient’s resistance to malignancy vary widely with the individual and the stage of disease. The doubling time of breast cancer ranges from several weeks for rapidly growing tumors to months or years for slowly growing lesions. If the doubling time of a breast tumor were constant and a tumor originated from one cell, a doubling time of 100 days would result in a 1-cm tumor in about 8 years (Fig. 40.1) (25). During the preclinical phase, tumor cells may be circulating throughout the body. Because of the long preclinical tumor growth phase and the tendency of infiltrating lesions to metastasize early, many clinicians view breast cancer as a systemic disease at the time of diagnosis. Although cancer cells may be released from the tumor before diagnosis, variations in the tumor’s ability to grow in other organs and the host’s response to tumor cells may inhibit dissemination of the disease. Many women with breast cancer can be treated successfully with surgery alone, and some patients have been cured even in the presence of palpable axillary disease. A pessimistic attitude that breast cancer is systemic and incurable at diagnosis is unwarranted.

Figure 40.1 Growth rate of breast cancer indicating long preclinical phase. (From Gullino PM. Natural history of breast cancer: progression from hyperplasia to neoplasia as predicted by angiogenesis. Cancer 1977;39:2699.)
A more realistic approach may be to view breast cancer as a two-component disease involving the breast and the body as a whole. Although the primary breast tumor and issues of local control must be managed, the possibility of systemic metastases with their life-threatening consequences should not be overlooked. Breast cancer can metastasize to any organ, and involvement of bone, lungs, or liver occurs in up to 85% of women who develop distant disease (26,27). In addition to these sites, invasive lobular carcinoma is known to disseminate to the abdominal viscera, uterus, ovaries, and peritoneal surfaces.
After the diagnosis of breast cancer is definitively established, the clinical stage of the disease should be determined. The Columbia Clinical Staging System was used historically but is replaced by the tumor-node-metastases (TNM) system of the American Joint Committee on Cancer (28,29). The TNM system allows both preoperative clinical staging and postoperative pathologic staging to be determined (Tables 40.2 and 40.3).

Preoperative Evaluation

The extent of the preoperative workup varies with the initial stage of the disease (30). For most patients with small tumors, clinically negative lymph nodes, and no evidence of metastasis (TNM stage I), the preoperative evaluation should consist of bilateral mammography, chest radiography, complete blood count, and screening blood chemistry tests. Bone, CT, and MRI scanning are unnecessary unless there are symptoms or abnormal blood chemistry levels to suggest the existence of bone or intra-abdominal involvement. For patients with clinical stage II, node-positive disease, a bone scan is recommended, but CT scan of the abdomen is not necessary unless symptoms or laboratory results suggest liver disease. Patients with clinical stage III or stage IV disease should undergo both bone and liver scanning. PET scanning is becoming a popular means of total body scanning for breast cancer, but there have been concerns that this modality may miss some bony metastasis. A study found that PET scan is highly concordant (81%) with bone scan in a study of 132 paired studies of breast cancer patients (31). Of 31 (19%) discordant pairs, 12 patients had pathology proven metastatic disease. Nine of these 12 patients had a positive PET scan but negative bone scan, supporting the use of PET scan in detecting osseous metastasis in breast cancer, although further studies are needed to ascertain whether this modality should supplant the use of bone scan in this setting.

Figure 40.2 Appearance of breast after radical mastectomy (A) versus modified mastectomy (B). (From Kruper L, Giuliano AE. Breast disease. In: Berek JS, Hacker NF. Berek & Hacker’s Gynecologic Oncology. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010:636.)
Radical Mastectomy

Traditionally, the treatment of breast cancer has been surgical, but the type of procedure has remained a controversial and highly emotional issue. During the 19th century, surgical treatment of breast cancer was haphazard, varying from local excision alone to total mastectomy. The radical mastectomy was based on the principle that breast carcinoma was a locally infiltrative process that spread in a stepwise fashion from breast, to nodes, to distant sites (32). Thus, radical mastectomy removes the entire breast, the underlying pectoral muscles, and the contiguous axillary lymph nodes in continuity (33) (Fig. 40.2A). A report of 51 years of experience with radical mastectomy, which included 1,036 patients with a follow-up of 47 years, is unequaled in evaluating any single method of treating breast cancer (34).

During the 20th century, extensions and modifications of the radical mastectomy were devised that involved removal of more local and regional tissue. At one time, supraclavicular lymph node dissections were considered a routine component of surgical treatment (35). Supraclavicular, mediastinal, and internal mammary lymph node dissections were performed (36).

An en bloc internal mammary lymph node dissection was added to the standard radical mastectomy in the 1960s (37). This technique became popular and is the operation commonly referred to as the extended radical mastectomy. Extended radical mastectomy did not enhance overall survival rates, because only 3% to 5% of patients with negative axillary nodes will have involvement of internal mammary nodes (38). Locally destructive surgery is not justified, based on current understanding of the biologic behavior of breast cancer. Radical mastectomy is no longer an indicated procedure, except in the most unusual circumstances, with extensive pectoralis involvement by direct tumor extension.
Modified Radical Mastectomy

In contrast to radical mastectomy, modified radical mastectomy preserves the pectoralis major muscle (39,40) (Fig. 40.2B). The breast is removed in a manner similar to that of radical mastectomy, but neither the axillary lymph node dissection nor the skin excision is as extensive. Consequently, there is no need for skin grafting. There are no differences in survival rates between radical and modified radical mastectomy, but the latter procedure has a better functional outcome and a superior cosmetic result (41). Modified radical mastectomy has replaced radical mastectomy in the United States and is an alternative to breast conserving surgery and axillary dissection for some patients.
Total Mastectomy

Total mastectomy involves removal of the entire breast, nipple, and areolar complex without resection of the underlying muscles or intentional excision of axillary lymph nodes. Low-lying lymph nodes in the upper outer portion of the breast and low axilla often are excised. Total mastectomy has local control rates comparable with those of radical or modified radical mastectomy but has a higher risk of axillary recurrence. In the past, regional recurrence would occur in at least 15% to 20% of patients treated with total mastectomy alone. With the addition of sentinel lymph node biopsy, which selects patients who are lymph node negative, local recurrence rates should be lowered in patients with total mastectomy and node negative disease compared to those in the past with unknown axillary status.
Skin-Sparing and Nipple-Sparing Mastectomy

More patients have early small cancers and others are undergoing prophylactic mastectomy for genetic mutations and for other high-risk lesions. Patients may elect to undergo a skin-sparing mastectomy (SSM) with nipple–areolar complex (NAC) removal that leaves a skin envelope to accommodate the breast reconstruction, as well as providing a nipple-sparing mastectomy (NSM) with preservation of the NAC. Both of these procedures are being studied for their potential utility and safety in various clinical situations. Retrospective series show that performing NSM does not impact survival, although a prospective randomized trial has not been performed (42).
McWhirter developed the combination of total mastectomy followed by radiation (43). Many advocated adjuvant radiation therapy used in combination with various operative procedures. Studies claiming improvements in overall survival usually are flawed by the use of historical controls and inaccurate preoperative staging. Classic trials, both prospective randomized and historical control studies, showed that adjuvant radiation therapy improves local control but not overall survival rates (44–47). In a prospective randomized trial performed by the National Surgical Adjuvant Breast Project (NSABP), the roles of postoperative radiation therapy and axillary treatment were examined. Patients were randomly assigned to either total mastectomy, radical mastectomy, or total mastectomy with radiation therapy. This trial showed no difference in survival among the three treatment arms, whereas radiation therapy and axillary treatment improved local and regional control. Twenty-five-year follow-up data continue to support these conclusions (48).

Three randomized control studies from the 1990s showed that postmastectomy radiation therapy reduced the risk of local–regional failure by 20% and produced an absolute survival benefit of 10% at 10 years among women with stage II to III breast cancer, regardless of menopausal status (49–51). Additional trials challenged the need for postmastectomy radiation among women with only one to three involved axillary nodes and T₁ or T₂ primary tumors. These studies showed adequate local–regional control rates with mastectomy and chemotherapy alone (52–54). In a large meta-analysis, an absolute risk reduction in local recurrence was found in women with radiation therapy after both breast conservation and mastectomy. One breast cancer death is avoided for every four local recurrences, reducing the 15-year mortality among patients with a greater than 10% risk of local recurrence (55).

Guidelines from the American Society of Clinical Oncology recommend postmastectomy radiation therapy for women with T₃ (>5 cm) primary tumors and four or more positive axillary lymph nodes (56).
Breast Conservation Therapy with or without Radiation Therapy

Radiation therapy alone, without excision of the tumor, is associated with a high local failure rate, as is local excision without radiation (57–60). Throughout the last quarter of the 20th century, a paradigm shift occurred in the surgical management of breast cancer. Data from the NSABP B-04 trial, for which 25-year follow-up exists, established the equivalency of radical versus total mastectomy with regard to overall survival. Shortly after initiation of the B-04 trial, a number of studies were designed to evaluate the efficacy of breast preservation among women with early-stage breast cancers. The Milan trial, a major prospective randomized trial that began accruing patients in 1973, compared treatment with either radical mastectomy or a combination of quadrantectomy, axillary lymph node dissection, and postoperative radiation therapy. In total, 701 clinically node-negative patients with noncentrally located, small tumors (<2 cm) (T1 N0 M0) were enrolled. After 25 years of follow-up, there continues to be no statistically significant difference between the two groups in either local control or overall survival rates (61).

Figure 40.3 Appearance of breast after lumpectomy, axillary dissection, and radiation therapy. (From Kruper L, Giuliano AE. Breast disease. In: Berek JS, Hacker NF. Berek & Hacker’s Gynecologic Oncology. 5th ed. Philadelphia, PA: Williams & Wilkins, 2010:638.)
At nearly the same time, in the NSABP B-06 trial, patients with early breast cancer (stage I or stage II, T1 or T2, and N0 or N1) were randomized to modified radical mastectomy, segmental mastectomy (lumpectomy) and axillary lymph node dissection, or segmental mastectomy, axillary lymph node dissection and postoperative radiation therapy. Unlike the quadrantectomy performed in the Milan study, segmental mastectomy consists of removing only the tumor and a small rim of normal surrounding tissue, yielding cosmetically superior results (Fig. 40.3). A total of 1,843 women were enrolled, with the lowest local recurrence rate seen among patients treated with segmental mastectomy and postoperative radiation therapy. The addition of radiation improved the local control rate, but no significant differences in overall survival or disease-free survival rates were detected among the three treatment arms; there was a trend, however, in favor of patients who had received radiation. This NSABP study established, now with 25-year follow-up, that the combination of segmental mastectomy (with negative surgical margins), axillary lymph node dissection, and postoperative radiation therapy is as effective as modified radical mastectomy for the management of patients with stages I and II breast cancer (62). A number of additional prospective randomized studies also demonstrated no decrease in overall survival among women being treated with breast preservation therapy (63–65).

Axillary lymph node status and the number of involved nodes are the most important prognostic indicators for patients with primary breast cancer (66). Axillary lymphadenectomy traditionally was used to detect and quantify the extent of nodal metastasis (67). Before the introduction of sentinel lymph node dissection in the 1990s, axillary lymph node dissection was performed routinely on all patients with early breast cancer. Although axillary dissection is associated with a very low risk of regional recurrence (1% to 3%), the rate of acute complications is as high as 30% (68). Similarly, the risk of chronic lymphedema ranges from 6% to as high 30% (69). Limiting the dissection to level I nodes or random sampling is associated with unacceptably high false-negative rates and should not be done (70). Only one-third of patients with a clinically negative axilla will have nodal metastasis after histopathologic examination of all harvested lymph nodes (71). This means that two-thirds of patients will be exposed to the morbidity of axillary lymph node dissection without proven benefit when performed routinely in the presence of invasive breast cancer.

In 1991 intraoperative lymphatic mapping and sentinel lymph node dissection were introduced to address these problems (72). The concept behind sentinel lymph node dissection is best described by the definition of a sentinel node. The sentinel node is the lymph node that has the greatest potential to harbor metastasis if axillary disease is present. Examination of the sentinel lymph node dissection can accurately predict the status of the entire nodal basin. Removing only one or two lymph nodes can accurately stage the axilla with minimal morbidity. Numerous investigators have demonstrated that, with proper training, sentinel lymph node dissection identification rates range from 90% to 99%, with false-negative rates of less than 5% found in most large studies (73). In
one study of 107 patients with $T_1$ and $T_2$ breast cancer who underwent sentinel lymph node dissection followed by axillary lymph node dissection, the sentinel node was successfully identified in 100 patients (93.5%) (73). There were no false-negative results, and the sentinel node accurately predicted axillary status in all 100 patients.

The technique of sentinel lymph node dissection is validated by a number of authors using a variety of techniques (74,75). The information obtained from sentinel lymph node dissection appears to be equivalent to that of axillary lymph node dissection. One prospective study demonstrated that in node-negative patients undergoing only sentinel lymph node dissection, the recurrence rate in the axilla was zero at a median follow-up of 39 months (76). Overall survival for patients who undergo sentinel lymph node dissection without axillary dissection appears to be excellent. In a randomized controlled trial, Veronesi et al. showed that the long-term breast cancer–related event-free survival among patients in the sentinel node biopsy arm (89.9%) was similar to that in the axillary lymph node dissection arm (88.8%), affirming not only that sentinel lymph node biopsy is as good as complete axillary dissection at staging the axilla, but that it is as safe as the once standard method of complete axillary dissection (77). Sentinel node biopsy alone without complete axillary lymph node dissection may have value in patients with micrometastatic and macrometastatic disease given low recurrence rates after sentinel lymph node biopsy. In a randomized controlled trial, in patients with hematoxylin and eosin (H&E) positive sentinel lymph nodes, there was no statistically significant difference in overall survival between patients randomized to complete axillary lymph node dissection and sentinel lymph node biopsy alone (78). The degree of accuracy in predicting axillary metastasis, combined with its very low morbidity rate, makes sentinel lymph node dissection the preferred procedure for staging the axilla in breast cancer.
Adjuvant Systemic Therapy

For many patients, local and regional control of breast cancer is achieved with a combination of surgery and radiation therapy. About 90% of patients will never experience an in-breast recurrence; these patients may develop metastatic disease. The goal of adjuvant systemic therapy is to eliminate occult metastases during the early postoperative period and thus reduce the risk of local and distant recurrence (79).

**Adjuvant systemic therapy will prolong survival in selected breast cancer patients.** In patients with favorable tumors and a low risk of recurrence and subsequent death, such as those with node-negative cancers smaller than 1 cm and favorable biology, this benefit is small and may not justify the risks of systemic therapy. **Adjuvant systemic therapy reduces the odds of death by 25% per year in both node-negative and node-positive patients** (80). Because this risk reduction is relatively constant, patients with favorable, node-negative disease have a much smaller absolute benefit compared with patients who have higher-risk, node-positive disease and/or patients with unfavorable biologic markers such as patients with triple negative disease or Her-2/neu positive disease. For patients with node-negative disease, the absolute benefit may be minimal versus 10% to 20% for those with nodal involvement.

Cytotoxic chemotherapy and hormonal therapy have inherent risks that must be considered when treatment decisions are made. There are many known acute side effects with standard regimens, and there is growing evidence that patients who undergo chemotherapy report more frequent chronic neurocognitive deficits than do untreated controls (81). The impact of these deficits remains undefined. Systemic therapy with tamoxifen is associated with an increased incidence of uterine cancer, vaginal dryness, and hot flashes, whereas aromatase inhibitors are linked to osteoporosis and musculoskeletal symptoms. Choosing those patients who should receive adjuvant therapy can be a difficult decision that often entails analyzing a variety of prognostic and predictive factors, identifying patients at risk for recurrence, and quantifying that risk. **Based on available data, adjuvant chemotherapy is recommended for women with greater than a 10% chance of relapse within 10 years.** The choice of therapy depends on an evaluation of specific risk factors. Two multigene assays such as the Oncotype DX and the Mammaprint have been introduced to help identify those estrogen receptor–positive, lymph node–negative patients who will benefit most from systemic chemotherapy. These tests, which calculate a recurrence risk score for each individual based on a 21-gene assay and 70-gene signature, respectively, allow the treating physician to determine the average rate of distant disease at 10 years and make treatment recommendations based on this risk (82).

**Prognostic Indicators**

Factors that determine each patient’s risk of recurrence include nodal involvement, tumor size, estrogen and progesterone receptor status, nuclear grade, histologic type, proliferative rate, and biologic markers such as Her-
These prognostic factors and their effects on recurrence are summarized in Table 40.4. Patients with high-risk prognostic factors are more likely to benefit from adjuvant cytotoxic or hormonal therapy and usually are offered such treatment.

Patients with lymph node metastasis have a higher risk of recurrence than patients with node-negative disease. The 10-year survival rate for women with palpable metastatic axillary lymph nodes who fail to receive systemic therapy is about 50% to 60%. The number of lymph nodes involved and the presence of extracapsular invasion are important indicators of poor prognosis.

Another prognostic indicator of relapse is primary tumor size. In an evaluation of 767 patients with node-negative disease who underwent radical or modified radical mastectomy without adjuvant chemotherapy, the relapse rate in patients with tumors larger than 1 cm or special tumor types larger than 3 cm (tubular, mucinous, or papillary) was 27% at 10 years, compared with 9% for tumors smaller than 1 cm (83).

Hormone receptor status is an important predictor not only of long-term prognosis but also of response to endocrine therapy. Several studies demonstrated that patients with positive estrogen and progesterone receptor status have improved overall survival (84,85). Receptor status should be known when determining the need for and choice of adjuvant therapy. Histologic grade appears to predict overall survival. Patients with well-differentiated tumors tend to have more favorable outcomes than those with poorly differentiated ones (Table 40.5). In a British study of 1,168 women, histologic grade, along with tumor size and lymph node status, was an independent predictor of overall survival at 10 years (86).

AJCC, American Joint Committee on Cancer.

Two multigene assays were rapidly developed and are commercially available including the 21-gene assay (Oncotype DX) and the 70-gene signature (Mammaprint). Oncotype DX was developed for identifying patients who have a high risk of recurrence distantly and for patients with node negative ER+ breast cancer. Large-scale phase III trials are under way in the United States and in Europe to test the clinical utility of these multigene assays, which will assist in determining the use of adjuvant systemic therapy.

The possible roles of specific tumor markers in predicting which patients will respond to chemotherapy regimens were investigated. The most thoroughly researched of these markers is HER-2/neu. In an NSABP study, patients with HER-2/neu overexpression who were not treated with anthracycline-based regimens fared worse (87). Another study showed that the addition of trastuzumab (Herceptin), an antibody directed against the HER-2/neu receptor, significantly increased the response rate to therapy over standard chemotherapy alone in the presence of metastatic disease (88). Reports from trials investigating the adjuvant use of trastuzumab for women with early-stage Her-2/neu breast cancers show significant improvements in disease-free survival for women receiving trastuzumab; trastuzumab is used as systemic adjuvant therapy for patients with Her-2/neu positive breast cancer, and the standard length of treatment is one full year (89–91).

Systemic Regimens

Based on the results of more than 100 prospective, randomized trials examining the role of adjuvant chemotherapy in breast cancer, a variety of systemic regimens emerged. Systemic therapy includes cytotoxic agents and hormonal agents, used alone or in combination. Following is a brief description of the more commonly used regimens. Initially, trials involved a single perioperative course of chemotherapy aimed at
eradicating circulating tumor cells. The Nissen-Meyer study from Norway showed that a single course of cyclophosphamide improved overall survival rates (92). Numerous trials demonstrated the benefit of adjuvant chemotherapy for certain subgroups of patients (93). In the initial NSABP adjuvant trial, a 2-year course of melphalan was superior to no treatment, and further trials demonstrated enhanced beneficial effect with the use of multiple drugs as well as with the combination of hormonal manipulation with chemotherapy (94,95).

Historically, the most frequently used adjuvant combination chemotherapy was CMF: cyclophosphamide (C), methotrexate (M), and 5-fluorouracil (5-FU). In the original study by Bonadonna et al., patients with positive axillary lymph nodes were randomized to receive either 12 monthly cycles of CMF or no therapy after radical mastectomy (96). A statistically significant benefit was found with CMF treatment for premenopausal patients, especially those with one to three positive nodes. A subsequent study showed six cycles of CMF to be as effective as 12 cycles (97). No significant effect was seen for postmenopausal women, which may result from the fact that these women were less likely to tolerate the full course of therapy (98). After 20 years of follow-up, this trial demonstrated a persistent survival advantage for premenopausal women receiving CMF adjuvant therapy (99). In a later study involving node-negative, estrogen receptor–negative breast cancer patients, after 12 years of follow-up, 71% of patients treated with adjuvant CMF remained disease free compared with 48% in the control group, regardless of menopausal status (100).

 Anthracyclines (A) were more commonly used in the adjuvant and metastatic treatment of breast cancer than any other agents. A large randomized NSABP study compared CMF with AC regimens in node-positive patients and found similar treatment outcomes among both groups. The AC regimen was preferred because of its shorter duration (four cycles for 3 months vs. six cycles for 6 months) and better tolerance (101).

Several landmark trials showed that taxanes such as paclitaxel and docetaxel in combination with anthracyclines have significant efficacy and are the new standard adjuvant therapy for node-positive breast cancer. The Cancer and Leukemia Group B was the first to show a 17% improvement in the rate of recurrence and 18% reduction in the rate of death with the addition of paclitaxel to cyclophosphamide (102). Given concerns over the cardiotoxicity of anthracyclines as well as the 0.21% risk of leukemia after the AC regimen at 5 years, a US oncology trial randomized stage I, II, and III patients to AC or docetaxel and cyclophosphamide (TC) every 3 weeks for four cycles and found that after 7 years' follow-up disease-free survival and overall survival statistically favored the TC group (103). This was the first trial to compare a taxane-based regimen to an anthracycline-based regimen. Concerns remain because multiple trials demonstrate that the duration of therapy is significant and the TC regimen used was a short-duration treatment of four cycles (104). Until results of an ongoing US oncology trial designed to assess whether an incremental benefit exists for adding an anthracycline to TC-based therapy for six cycles on a 3-week dosing schedule for Her-2/neu negative patients, oncologists will need to decide whether to add
anthracycline to taxane-based chemotherapy guided by their clinical judgment.

Neoadjuvant Systemic Therapy

The use of neoadjuvant chemotherapy traditionally was limited to those individuals with either inoperable locally advanced or inflammatory breast cancers. The goal of preoperative systemic therapy was to convert inoperable patients into resectable candidates on the basis of pathologic and clinical responses (105). Indications for neoadjuvant chemotherapy were broadened to include individuals presenting with large operable tumors and wanting to undergo breast preservation instead of mastectomy. Reports indicate that breast conservation therapy is possible and that low rates of in-breast or local–regional recurrences occur when neoadjuvant chemotherapy results in clinical and pathological tumor downstaging (106). In addition to large, operable tumors, neoadjuvant therapy continues to have a role in the treatment of inflammatory breast cancers and those presenting in a locally advanced state.

Hormonal Therapy

Hormonal manipulation with tamoxifen or an aromatase inhibitor, used alone or in combination with a cytotoxic regimen, is beneficial in select groups of women. Tamoxifen, an estrogen analogue, offers substantial benefits in both premenopausal and postmenopausal women. Taken at a dose of 20 mg per day for 5 years, tamoxifen reduces the annual risk of recurrence by about 50% and the annual risk of death by about 25%. These benefits occur in women with estrogen receptor–positive disease regardless of chemotherapy treatment (107).

Tamoxifen, when used in combination with cytotoxic chemotherapy, improves survival in women with positive axillary lymph nodes and tumor estrogen receptor expression (108). In patients with node-negative, estrogen receptor–positive disease, the addition of tamoxifen to chemotherapy improved disease-free survival rates after 5 years of follow-up (109). In NSABP study B-14, 2,644 patients with estrogen receptor–positive tumors and no axillary metastases were randomized to either tamoxifen (10 mg orally twice daily for 5 years) or a placebo control. After a 4-year median follow-up, the disease-free survival rate for the 1,318 patients treated with tamoxifen was 82% compared with 77% for the 1,326 patients treated with placebo (p = .00001), again regardless of menopausal status.

The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) performed a meta-analysis of adjuvant systemic therapy for breast cancer. They analyzed randomized trials involving adjuvant systemic hormonal, cytotoxic, or immune therapy administered to more than 75,000 women with stage I or II carcinoma. The investigators concluded that for postmenopausal women with estrogen receptor–positive tumors, tamoxifen daily for at least 2 years had a significant beneficial effect on disease-free survival rates, with these effects lasting up to
10 years. The incidence of both carcinoma in the contralateral breast and death rate from heart disease decreased.

In addition to tamoxifen, aromatase inhibitors have been approved for use in the adjuvant treatment of patients with estrogen receptor–positive cancers. Aromatase inhibitors act by inhibiting the aromatase enzyme, thus blocking the conversion of androgens into estrogens. These drugs should be used only in postmenopausal patients or premenopausal women who have undergone chemical ovarian suppression or oophorectomy. Although aromatase inhibitors cause fewer episodes of thrombotic events, hot flashes, and endometrial cancers, musculoskeletal symptoms and osteoporosis are more commonly encountered among aromatase inhibitor users than those taking tamoxifen. Results from the anastrozole (Arimidex), tamoxifen, Alone or in Combination (ATAC) trial showed overall lower recurrence rates, as well as fewer contralateral tumors, among women treated with anastrozole alone after 68 months of follow-up (110). A meta-analysis confirmed that aromatase inhibitor therapy alone conferred a 2.9% absolute decrease in recurrence; aromatase inhibitor therapy after 2 to 3 years of tamoxifen conferred a 3.1% reduction in recurrence, as well as a 0.7% decrease in mortality at 5-year follow-up, although additional long-term follow-up is needed (111). Based on these results, aromatase inhibitors are now often offered as a first-line treatment option for adjuvant therapy. Research suggests that conversion of patients from tamoxifen to an aromatase inhibitor, such as letrozole (Femara), after 2.5 or 5 years may improve survival, although concurrent use of the two agents offers no benefit (110,112).

General Recommendations

Adjuvant systemic therapy lowers the incidence of recurrence by 25% to 30%. It is important to understand that the proportional reduction in risk of relapse is relatively constant regardless of absolute risk (113). The EBCTCG meta-analysis showed that the risk reduction of recurrence and breast cancer–specific mortality from polychemotherapy occurs in all women, but the most benefit occurs in women under the age of 50 (Table 40.6). A meta-analysis from the EBCTCG assessing the effect of polychemotherapy and tamoxifen on estrogen receptor–poor breast cancer found that women under the age of 50 or between the ages of 50 and 69 had statistically significant decreases in 10-year risks of recurrence and mortality, with more benefit in women under the age of 50, confirming the results of the earlier study in patients with estrogen receptor–poor breast cancer (114). Tamoxifen did not add any benefit in patients with estrogen receptor–poor tumors. Adjuvant cytotoxic chemotherapy appears to affect the natural history of patients with either axillary node–negative or node–positive breast cancer. All high-risk patients with node-negative disease are considered candidates for adjuvant cytotoxic therapy.

Table 40.6 Effect of Systemic Therapy on Recurrence and Survival from Breast Cancer
In postmenopausal, estrogen receptor–positive women, chemotherapy is about one-half as effective as tamoxifen in the adjuvant setting (115). For most postmenopausal women with hormone-responsive disease (estrogen- and progesterone-responsive positivity), including node-positive patients, hormonal therapy alone may be adequate treatment. High-risk patients with hormone-resistant disease benefit from cytotoxic systemic therapy. Caution should be exercised when using chemotherapeutic agents. Patients in whom the risk of recurrence is low are likely to derive little overall benefit from the use of adjuvant systemic therapy, whereas those with a high risk of recurrence are likely to receive the greatest benefit. Comorbidities must always be considered on an individual basis.

The current recommendations for adjuvant systemic therapy in breast cancer are summarized as follows:

- Premenopausal women with lymph node involvement should be treated with adjuvant combination chemotherapy. Tamoxifen should be added for patients with estrogen receptor–positive tumors following cytotoxic therapy.
- Premenopausal women without evidence of lymph node involvement but with large (>1 cm) size, aneuploid, or estrogen receptor–negative tumors should be treated with combination chemotherapy. Tamoxifen should be given to patients with estrogen receptor–positive tumors.
- Postmenopausal patients with negative lymph nodes who are hormone receptor–positive should receive adjuvant aromatase inhibitor therapy as primary therapy. Those with positive lymph nodes should receive multidrug cytotoxic therapy, or a combination thereof if there are no medical contraindications.
- Postmenopausal women with lymph node metastases who are hormone receptor–negative may be treated with adjuvant chemotherapy.
- Adjuvant systemic therapy is not recommended for patients with favorable tumors smaller than 1 cm. Hormonal therapy may be considered if the patient’s tumor is estrogen receptor–positive.
- Trastuzumab is recommended as adjuvant treatment in addition to chemotherapy for patients with Her-2/neu positive breast cancer, especially those with positive nodes, young women, and women with large tumors.

Prognosis

The treatment of advanced, metastatic breast cancer is largely palliative. For most physicians, quality-of-life issues are paramount when choosing which type of therapy is offered. In patients with locally advanced disease in conjunction with distant metastasis, palliative radiotherapy may be advised to control pain or avoid pathologic fractures. This approach is best exemplified in the treatment of isolated bone metastases, chest wall recurrences, brain metastases, and spinal cord compression.

Systemic disease may be controlled by hormonal or cytotoxic therapy. Because the quality of life during an endocrine-induced remission is usually superior to one following cytotoxic chemotherapy, it is preferable to try endocrine manipulation first. As many as one-third of patients with disseminated disease respond favorably to either functional end-organ ablation (ovary, pituitary, adrenal glands) or administration of drugs that block hormonal function. For patients with estrogen receptor–positive tumors, this response rate may be as high as 60%. Because only 5% to 10% of women with estrogen receptor–negative cancers respond to endocrine treatment, they should not routinely receive hormonal therapy except in unusual cases, such as elderly women who are intolerant of cytotoxic therapy (116).

Cytotoxic chemotherapy should be considered for the treatment of metastatic breast cancer if organ involvement is potentially life-threatening (brain, lung, or liver), if hormonal treatment is unsuccessful, if the disease has progressed after an initial response to endocrine manipulation, or if the tumor is estrogen receptor–negative. The most useful single chemotherapeutic agent is an anthracycline such as doxorubicin, which has an estimated response rate of 40% to 50%. Combination therapy using multiple agents has response rates as high as 60% to 80% (117). Clinical trials, including those investigating the use of trastuzumab for Her-2/neu-positive women with metastases, are underway to examine a variety of combinations for stage IV disease. In Her-2/neu-positive women, the trastuzumab and vinorelbine or taxane (TRAVIOTA) study showed that both regimens were active as first-line treatments for metastatic breast cancer (118). The historically prominent side effects of debilitating nausea and vomiting are well controlled with central-acting antiemetics. The importance of controlling these potentially devastating symptoms cannot be overemphasized.

Bisphosphonates have played an increasing role in the treatment of breast cancer that has metastasized to bone. Zoledronic acid (Zometa) was found to be superior to pamidronate (Aredia) in patients with breast cancer, with a relative risk reduction of skeletal-related events, defined as pathological fracture, spinal cord compression, radiation therapy, or surgery to bone, by an additional 16% (119). A review that compared all oral and intravenous bisphosphonates that were approved for breast cancer treatment in 2005 demonstrated a 41% risk reduction in skeletal related events with zoledronic acid versus placebo, compared with a 14% to 23% risk reduction for ibandronate (Boniva), clodronate, and pamidronate (120). Bisphosphonates may be important in preventing bone loss during hormone-based therapies for breast cancer.
Bisphosphonates garnered interest as a possible adjuvant treatment for breast cancer, with early trials showing a decrease in breast cancer recurrence. Further investigations in randomized, controlled trials, including a trial by the Southwest Oncology Group, are comparing stages I through III breast cancer patients randomized to three different bisphosphonates prescribed after adjuvant systemic antitumor treatment.
Special Breast Cancers

Paget’s Disease

In the 1870s, Sir James Paget described a nipple lesion similar to eczema and recognized that this nipple change was associated with an underlying breast malignancy (121). The erosion results from invasion of the nipple and surrounding areola by characteristic large cells with irregular nuclei, now called Paget cells. Although the origin of these cells is much debated by pathologists, they are probably extensions of an underlying carcinoma into the major ducts of the nipple–areolar complex. There may be no visible changes associated with the initial invasion of the nipple. Often, the patient’s presenting symptom will be nipple discharge, which is actually a combination of serum and blood from the involved ducts. The patient may have a delay in the diagnosis because the presenting symptoms are overlooked. The diagnosis is established by incisional or punch biopsy of the area of the skin changes.

The overall prognosis for patients with this rare form of breast cancer depends on the stage of the underlying malignancy. When an intraductal carcinoma alone is identified, the prognosis remains favorable, whereas patients with infiltrating ductal carcinoma metastatic to the regional lymph nodes have worse outcomes. Traditional treatment was total mastectomy and lymph node dissection, although breast conservation therapy with resection of the tumor and nipple–areolar complex, followed by whole breast radiation, is being performed in appropriately identified patients (122).
Inflammatory Carcinoma

Patients presenting with inflammatory carcinoma initially appear to have acute inflammation of the breast with corresponding redness and edema. Additional clinical findings are variable and range from complete absence of a dominant mass to the presence of either satellite skin nodules or a large palpable abnormality.

Inflammatory cancer, rather than infiltrating ductal carcinoma, should be diagnosed when more than one-third of the breast is involved with erythema and edema and when biopsy of the involved area, including the skin, demonstrates metastatic cancer in the subdermal lymphatics. Most of these tumors are poorly differentiated. Mammographically, the breast shows skin thickening with an infiltrative process and may or may not show a mass or calcifications.

Except for biopsy of the lesion to establish the diagnosis, surgery is not part of the initial management of inflammatory carcinoma. Mastectomy usually fails locally within 2 years of the initial diagnosis and does not improve overall or disease-free survival rates. Better results are achieved with a combination of chemotherapy and radiation therapy. Mastectomy may be indicated for patients who remain free of distant metastatic disease after initial chemotherapy and radiation (123).
In Situ Carcinomas

Both lobular and ductal carcinoma may be confined by the basement membrane of the ducts. These carcinomas do not invade the surrounding tissue and, theoretically, lack the ability to spread.

Lobular Carcinoma In Situ

Lobular carcinoma in situ should not be considered a true malignancy but rather a risk factor for the subsequent development of invasive ductal or lobular carcinoma in either breast (124). A more appropriate nomenclature for lobular carcinoma in situ may be lobular neoplasia. Most women with lobular carcinoma in situ are premenopausal and have neither clinical nor mammographic signs of an abnormality. The lesion typically is not a discrete mass, but rather a multifocal entity within one or both breasts incidentally discovered by the pathologist during the evaluation of a completely unrelated issue. Lobular carcinoma in situ usually is managed with an excisional biopsy followed by careful surveillance with clinical breast examinations and mammography. Occasionally, a patient may request either bilateral prophylactic mastectomy or tamoxifen for chemoprevention. Women with lobular carcinoma in situ have a 1% per year and up to a 30% lifetime risk of developing an invasive cancer.

An increasingly diagnosed subtype of LCIS that has more of a pleomorphic and florid appearance appears to act in a more aggressive manner similar to ductal carcinoma in situ (DCIS). In this instance, the lesions should be managed as DCIS with wide segmental mastectomy and radiation treatment (125).
Ductal Carcinoma In Situ

DCIS is more common in postmenopausal women. It may manifest as a palpable mass but usually is detected mammographically as a cluster of branched or Y-shaped pleomorphic microcalcifications. By definition, intraductal disease does not invade beyond the basement membrane. **Unlike patients with LCIS, 30% to 50% of patients with DCIS will develop an invasive ductal cancer within the same breast if treated by excisional biopsy alone** (126).

Although modified radical mastectomy was previously the standard treatment for intraductal carcinoma, more conservative surgery, with or without radiation therapy, yielded good results. In NSABP trial B17, 818 patients were randomly assigned to excision alone or excision followed by radiation therapy. The mean extent of DCIS lesions was 13 mm, and 88% were larger than 20 mm. All lesions were completely resected with negative margins. After a median follow-up of 43 months, the actuarial 5-year local recurrence rate was 10.4% without radiation versus 7.5% with radiation (p = .055) for noninvasive cancers, and 10.5% without radiation versus 2.9% with radiation (p > .001) for invasive cancers. Of 83 recurrences, only 9 (11%) were not in the index quadrant. A reanalysis with a mean follow-up of 90 months confirmed these results (127). These data suggest that segmental mastectomy offers excellent local control.

**Axillary metastases occur in fewer than 5% of patients diagnosed with DCIS, making routine axillary dissection unnecessary.** When axillary disease is identified, further evaluation of the breast or surgical specimen or both is warranted because nodal metastases indicate that an invasive ductal component was missed. Sentinel node biopsy may be offered to certain individuals with DCIS, especially if the lesion is high grade, contains comedonecrosis, or was diagnosed on core biopsy and has clinical or radiographic features suggesting invasive disease. About 5% of patients whose initial biopsy results show intraductal carcinoma will have infiltrating ductal carcinoma when treated with mastectomy, whereas core biopsy may underestimate the invasiveness of the disease in up to 20% of patients. The incidence of contralateral breast cancer in women with intraductal carcinoma is the same as in those with invasive ductal carcinoma (5% to 8%) (128).
Breast Cancer in Pregnancy

Breast cancer complicates 1 in 3,000 pregnancies (129,130). It is the second most common malignancy seen in association with pregnancy, surpassed only by cervical cancer. Initial studies suggested a significantly worse prognosis for patients first diagnosed during pregnancy, but data indicate that the hormonal changes associated with pregnancy seem to have little, if any, influence on prognosis. When pregnant patients are matched stage for stage with nonpregnant patients, survival rates seem equivalent (131). Patients typically present with a painless mass. Up to 60% will have concurrent lymph node involvement. The evaluation includes imaging with ultrasonography and mammography, which, although controversial, expose the fetus to less than 0.02 cGy of radiation when used with proper abdominal shielding (132). If biopsy is warranted, the procedure can be performed safely and should not be delayed until after delivery. Needle biopsy is safe and easily accomplished in the office setting.

The treatment of breast cancer in pregnant women must be highly individualized. Considerations include the patient’s age and desire to continue the pregnancy. The overall prognosis should be considered, especially when axillary lymph nodes are involved, because adjuvant chemotherapy can be teratogenic or lethal to the fetus during the first trimester, but may be given later in the pregnancy. It is believed that interruption of pregnancy does not alter the prognosis for patients with potentially curable breast cancer.

Following are generalized recommendations for treatment of pregnant women with breast cancer:

**Traditionally, cancers diagnosed during the first or second trimester of pregnancy were treated with modified radical mastectomy.** Sentinel node biopsy remains a controversial procedure in pregnancy; the use of blue dye is contraindicated as it is classified as a pregnancy category C drug, and there are serious concerns about the risk of fetal irradiation with the use of radiocolloid despite some literature supporting its safety (133). Most centers do not offer breast conservation therapy based on the theory that radiation therapy should not be given to the gravid patient. In a patient diagnosed before the third trimester, waiting until after delivery may result in an unacceptable delay in the initiation of therapy and should not be encouraged. Adjuvant chemotherapy can be given after the first trimester, although many oncologists prefer not to give it to pregnant women outside of clinical trials. A classic study reported the risk of fetal malformations to be 20% during the first trimester, a rate that dropped to 1.5% during the second and third trimesters (134). Tamoxifen, however, is a class D drug and should not be given to pregnant or lactating patients with breast cancer.

**Localized tumors found during the third trimester of pregnancy can be managed with breast conservation therapy, with radiation delayed until after delivery, or with modified radical mastectomy.** Tumors should be excised early in the third trimester using local anesthesia. If delivery is imminent, standard therapy can be performed immediately postpartum. In the patient with a viable fetus, it may be
preferable to induce early labor to avoid delaying definitive cancer therapy.

**If the breast cancer is diagnosed during lactation, lactation should be suppressed and the cancer should be treated definitively.**

**Advanced, incurable cancer should be treated with palliative therapy.** Decisions regarding continuation of the pregnancy should be based on the therapy necessary and the desires of the mother.

Counseling regarding future childbearing is important for women who have had carcinoma of the breast. It was assumed that subsequent pregnancies would be detrimental because of the high levels of circulating estrogens, but **there is no clear difference in survival for women who become pregnant after the diagnosis of breast cancer.**

One study evaluated the effect of subsequent pregnancy on overall survival after the diagnosis of early-stage breast cancer. Approximately 40% of the women in the study had node-positive disease. The 5- and 10-year survival rates were better in women who became pregnant than in matched pair controls who did not. This study suggests that subsequent pregnancy does not adversely affect the prognosis of early-stage breast cancer (135). A subsequent investigation demonstrated no increase in the relative risk of death for patients who gave birth more than 10 months after their initial diagnosis of cancer (136). Theoretically, it may be that only women with estrogen receptor–positive or progesterone-positive tumors would be affected deleteriously by subsequent pregnancy, but this possibility has not been studied. Because recurrences are most frequent within the first 2 to 3 years after diagnosis, patients with receptor-positive tumors and advanced-stage disease probably should wait until after that time before becoming pregnant again.
